Library of Congress Cataloging-in-Publication Data

Names: Flanagan, Dawn P., editor. | McDonough, Erin M., editor.
Title: Contemporary intellectual assessment : theories, tests, and issues / edited by Dawn P. Flanagan, Erin M. McDonough ; foreword by Alan S. Kaufman.
Description: Fourth Edition. | Fourth edition. | New York : The Guilford Press, 2018. | Revised edition of Contemporary intellectual assessment, c2012. | Includes bibliographical references and index.
Identifiers: LCCN 2017055258 | ISBN 9781462535781 (hardback : alk. paper)
Subjects: LCSH: Intelligence tests. | Intelligence tests—History. | BISAC: PSYCHOLOGY / Assessment, Testing & Measurement. | EDUCATION / Testing & Measurement. | MEDICAL / Psychiatry / Child & Adolescent. | PSYCHOLOGY / Psychotherapy / Child & Adolescent. | EDUCATION / Educational Psychology.
Classification: LCC BF431 .C66 2018 | DDC 153.9/3—dc23
LC record available at *https://lccn.loc.gov/2017055258*

About the Editors

Dawn P. Flanagan, PhD, is Professor of Psychology at St. John's University in Queens, New York, and Affiliate Clinical Professor at Yale Child Study Center, Yale University School of Medicine. She serves as an expert witness, learning disability consultant, and test/measurement consultant and trainer for organizations nationally and internationally. Dr. Flanagan is a Fellow of the American Psychological Association (APA) and a Diplomate of the American Board of Psychological Specialties. She received the inaugural Contributions to Practice Award from Division 16 (School Psychology) of the APA. Dr. Flanagan has published extensively on cognitive assessment, specific learning disabilities, and psychometric theories of the structure of cognitive abilities. She is also an author of the Cross-Battery Assessment Software System (X-BASS).

Erin M. McDonough, PhD, is Clinical Assistant Professor in the School Psychology Program of the Graduate School of Applied and Professional Psychology at Rutgers, The State University of New Jersey, and serves as Director of the Rutgers School Psychology Internship Consortium. Dr. McDonough is also the founder and Director of Psychological Diagnostic Evaluations of New York, where she sees clients and supervises psychologists and interns. Dr. McDonough publishes on issues related to psychological assessment of students with learning disabilities, and lectures and conducts workshops in this area at the state, regional, and national levels.

Foreword

Alan S. Kaufman

Dawn Flanagan and her colleagues have been on the cutting edge of assessment with *Contemporary Intellectual Assessment: Theories, Tests, and Issues* since the first edition was published in 1997. This first edition set the tone with a trend-setting array of amazing chapters by a "who's who" of authors, including John Horn and John Carroll, providing in-depth coverage of theory and practice. The book introduced Cattell–Horn–Carroll (CHC) theory to a generation of psychologists, integrated theory with practice against a backdrop of the history of assessment and test interpretation, and became so popular that it helped *define* the cutting edge of assessment.

Psychologists could barely wait for the second edition of *Contemporary Intellectual Assessment* to be published in 2005, given the ongoing dramatic changes in the field of assessment. Between 2001 and 2004, cognitive tests received major "facelifts" with the advent of two new Wechsler scales (the Wechsler Preschool and Primary Scale of Intelligence—Third Edition [WPPSI-III] and the Wechsler Intelligence Scale for Children—Fourth Edition [WISC-IV]), as well as an array of theory-based tests (the Woodcock–Johnson III [WJ III], the Kaufman Assessment Battery for Children [KABC-II], and the Stanford–Binet Intelligence Scales, Fifth Edition [SB5]). The field needed to have the state of the art redefined. Theory had never before so influenced practice; the psychometric-based CHC theory and Luria-based neuropsychological theories moved from the ivory tower to testing rooms; and the second edition of *Contemporary Intellectual Assessment* helped practitioners ease into the transition.

The exceptional third edition, published in 2012, tried to unify a field that had been fractured by the Individuals with Disabilities Education Act (IDEA) and response to intervention (RTI). And this new fourth edition, edited by Dawn Flanagan and Erin McDonough, captures the essence of where the field of assessment has ventured and where it is today. But I must admit that the field is *not* where I thought it would be now, and it is not where test publishers (at least Pearson, the publisher of the Wechsler and Kaufman batteries) thought it would be. A half-dozen years ago, really closer to a dozen years ago, we thought that the assessment of intelligence and achievement would follow the rest of the world into the digital age. We thought that somewhere in basements, groups of 19-year-old nerds were applying the latest technology to assemble the next generation of IQ tests that would take the field by storm. We (my wife, Nadeen, and I) and Pearson were deep into the development of the KABC—Digital (KABC-D), hoping to beat the high-tech teens to the punch. The WISC-V, to the best of my knowledge, included *three* forms of the test, at least for a short while during its development: two that were published (clinical test kit and Q-interactive versions) and one that I believe was left on the cutting room floor (an all-digital version). We were advised by different professionals at Pearson that "paper-and-pencil" tests like the KABC-II had a shelf life of 5–7 years; that almost all examiners would switch to Pearson's Q-interactive administration in that time; and that the future was digital. Hence the push for the KABC-D and the all-digital WISC-V.

Well, it didn't happen. "Paper-and-pencil" tests have continued to thrive (how I hate that term when applied to clinical test kit versions of tests such as the Cognitive Assessment System—Second Edition [CAS2] or WISC-V!). The exodus from clinical versions to Q-interactive versions did not occur—at least, not as rapidly as anticipated—and it has met resistance from many school systems. It still may be the wave of the future, but it does not define the cutting edge of the present. The KABC-D, embraced by a vibrant, dynamic, innovative, intervention-oriented test development process for half a decade, is now "on hold." An all-digital version of the WISC-V has not yet been published (although the Wechsler Adult Intelligence Scale [WAIS 5] of the future may include such a version). Traditional clinical tests, like the amazing array of cognitive batteries published in 2014—the CAS2, WJ IV, and WISC-V—continue to dominate our field and are seemingly setting the tone for the future.

How did we get it so wrong? For one thing, we underestimated scientist-practitioners—most notably the school psychologists and neuropsychologists who had been leading the field into the future on the foundation of a sophisticated amalgamation of refined theory, state-of-the-art methodology, and empirically based educational interventions. They were neither ready nor willing to reduce the role of the examiner as clinician and keen observer, even if the burdens of administration, scoring, and timing of test items could easily be passed on to a machine. They have also been unwilling to give up concrete test materials, which afford the opportunity for firsthand observations of a child's or adult's problem-solving strategies (even though images on a computer screen can undoubtedly yield reliable and valid scores, just as group-administered IQ tests have done for a century). And they worry about confidentiality—an ethical concern that looms even larger now than before, in light of the impact of possible hacking on even the most seemingly secure areas.

These are all reasonable and thoughtful concerns. The field of assessment may ultimately yield to the pressures of digital technology, but not yet, and probably not soon. Computer-based administration and scoring such as Q-interactive methods will undoubtedly grow in popularity, but I no longer believe that the 19-year-olds will take over our field with digital technology, the way that Binet once ousted Galton or Wechsler once surpassed everyone.

The ultimate, perhaps inevitable, shift from clinical test kit to digital assessment will only happen when a computerized test is published that addresses the scientist-practitioner's important concerns and is clearly seen as a better alternative—one that takes full advantage of digital capabilities without squelching the role of the clinician.

This fourth edition of *Contemporary Intellectual Assessment*, once again, is on the cutting edge of the field of assessment. Since the third edition was published in 2012, the field has continued to shift. The advances are more subtle than in previous decades, but nonetheless tests have become more integrated, more complex, and more focused on both neuropsychological and educational interventions. The fourth edition has kept pace with these changes, which have included the following:

- *An integration of psychometric (CHC) and neuropsychological processing traditions.* This integration is evident in chapters by Joel Schneider and Kevin McGrew (Chapter 3) and by Daniel Miller and Denise Maricle (Chapter 33). This interface is taken a step further by Richard Woodcock and colleagues (Chapter 32), who present a "functional" classification system for CHC abilities—a system they propose as being more informative and useful for practitioners in school psychology, neuropsychology, and special education. And this interweaving of psychometric and neuropsychological processing approaches pervades the entire volume. Examples include the discussions of assessing special populations—gifted children, children with various disabilities, and English language learners (Part IV of the book).

- *An expansion—not a reduction—of the number of viable theories available to inform diagnosis and interventions.* All editions of *Contemporary Intellectual Assessment* have rigorously covered important theories of intelligence, even those that have *not* been translated to clinical tests of intelligence—most notably Robert Sternberg's triarchic theory of successful intelligence (Chapter 5) and Howard Gardner's multiple-intelligences theory (Chen & Gardner, Chapter 4). The fourth edition has expanded the theory section to include two innovative approaches—Richard Haier and Rex Jung's parieto-frontal integrative theory (PFIT) (Chapter 7) and Phillip Ackerman's intelligence-as-process, personality, interests, and intelligence-as-knowledge (PPIK) framework for adult intellectual development (Chapter 8). The PPIK theory, which is primarily focused on Raymond Cattell's ideas, also incorporates neurological concepts advocated by D. O. Hebb (always my favorite learning theorist); this new chapter ensures an increased focus on *adult* development and intelligence. Both the PFIT and PPIK theories highlight the rapidly growing influence of neuropsychology on the current and future assessment scene.

- *Enhanced psychometric and theoretical sophistication evident in assessment research that has accompanied the development and interpretation of all major cognitive, achievement, and neuropsychological tests.* Part III of this newest *Contemporary Intellectual Assessment* has separate chapters on the latest editions of all the major cognitive batteries—all of the Wechslers (including the WISC-V Integrated), as well as the Reynolds Intellectual Assessment Scales, Second Edition (RIAS-2), Universal Nonverbal Intelligence Test—Second Edition (UNIT2), CAS2, NEPSY-II, WJ IV, KABC-II Normative Update, and Differential Ability Scales–II (DAS-II). Major achievement batteries are included as well; see especially Chapter 29 by Jaclyn Morrison, Jennie Singer, and Susan Raiford, which juxtaposes the Kaufman Test of Educational Achievement, Third Edition (KTEA-3) with the WISC-V and WISC-V Integrated to link assessment results to interventions. Contemporary psychometric sophistication peaks in Chapter 31, as Timothy Keith and Matthew Reynolds address a heated and controversial debate in the literature regarding the efficacy of bifactor models versus hierarchical confirmatory factor analysis (CFA) models as the best explanation of the structure of intelligence.

- *A more in-depth neuropsychological understanding of reading disabilities and specific learning disabilities (SLD).* State-of-the-art approaches dominate the chapters by Marlene Sotelo-Dynega on the use of neuropsychological assessment in the identification of reading disorders (Chapter 34); by David Kilpatrick on the role of orthographic processing in reading (Chapter 35); by Dawn Flanagan and colleagues on the use of patterns of strengths and weaknesses (PSW) in the identification of SLD (Chapter 22); and by Erin McDonough and colleagues on the diagnosis of SLD via DSM-5 (Chapter 37).

- *Greater emphasis on the translation of theory, clinical insights, and test scores into hands-on educational interventions.* This focus on the direct translation of test results to the classroom permeates nearly all chapters in the book, but is especially salient in Part V, as luminaries in the field such as Dawn Flanagan, Vincent Alfonso, Samuel Ortiz, Nancy Mather, Barbara Wendling, Catherine Fiorello, and Susan Raiford share their insights and innovations.

The publication of the fourth edition of *Contemporary Intellectual Assessment* marks a half-century since I entered the field of assessment. In 1967, I took a course in the clinical psychology department at Columbia University that covered the Wechsler tests (WISC and WAIS), the 1960 Stanford–Binet, the Rorschach, and the Thematic Apperception Test (TAT). I was taught that IQ tests were personality tests, and that we shouldn't pay too much attention to the numbers. It was OK to deviate from standardized administration, because, after all, we are clinicians. Most subtests were interpreted from a neo-Freudian perspective, in which a low score on Information was more likely to denote repression than a lack of knowledge. Similarly, high Comprehension coupled with low Information signified a hysteric reaction; missing a few easy Comprehension items was likely to reflect schizophrenia or psychotic depression; higher Digits Backward than Digits Forward meant obstinacy or negativism; and relatively high Picture Completion suggested a paranoid trend. There was no statistical significance to worry about. How high meant "high"? How low was "low"? It just didn't matter. A scaled score of 11 on Digit Symbol (now Coding) coupled with an 8 or 9 on Digit Span was usually enough for a clinician to infer that the person was controlling strong and pressing anxiety by excessive activity.

I asked my lab instructor many questions: Why was a child or adult not told to give a second reason on WISC or WAIS Comprehension, when the scoring system gave 2 points only if two different ideas were expressed? Why were we told to keep the stopwatch hidden from view, and why were clients not told that they should work quickly when they could earn as many as 3 bonus points for quick perfect performance on a single nonverbal item? What was the validity evidence for interpreting specific verbal responses to Vocabulary and Comprehension items as evidence of social incompetence, psychopathology, dependence, or grandiosity? She laughed at my ignorance and impertinence and embarrassed me in front of the other lab students.

That was 1967. In 1968, I selected psychometrics as my main area of study, and Robert L. Thorndike agreed to be my chair. That same year, I started working at The Psychological Corporation, where my boss was Alexander Wesman (who coined the term *intelligent testing* in a 1968 *American Psychologist* article). By 1970, I had begun my 4-year apprenticeship with David Wechsler. Revising the WISC and developing the WISC-R became my life; learning everything I could from my brilliant mentor became my passion; applying that knowledge became my life's work. I was given the chance to fix the flaws in Wechsler's scales, to the extent that the Master was accepting of change. Later in the 1970s, Nadeen and I were developing the K-ABC and training brilliant doctoral students at the University of Georgia who would change the face of cognitive, behavioral, and neuropsychological assessment—Bruce Bracken, Jack Cummings, Patti Harrison, Randy Kamphaus, Steve McCallum, Jack Naglieri, and Cecil Reynolds. I realized that I had totally freed myself from the shackles of my early training: the notion that IQ tests were no more and no less than measures of personality.

In the 1970s, I joined other psychologists, most notably Joe Matarazzo and Jerry Sattler, in writing books that attempted to bridge the gap between psychometrics and school/clinical psychology. When Nadeen and I published the K-ABC in 1983 (with the spectacular help of the Georgia doctoral students mentioned above), we started the movement toward theory-based tests and the integration of psychometric and neuropsychological processing traditions. But that was just a small beginning. The 1980s saw new approaches to theory-based assessment, highlighted by the Horn-inspired WJ-R in 1989. Dawn Flanagan and her colleagues, many of them coauthors of chapters in this volume, used those benchmarks as merely the starting point of what was to come—namely, the explosion of sophisticated theoretical, clinical, and psychometric constructs, and the interdisciplinary expansion of the fields of test construction and clinical assessment (in the present volume, see Kamphaus et al., Chapter 2, for the history of intelligence test interpretation).

And here we are a half-century later, standing on the cutting edge of our field as we ingest the innovative ideas of brilliant professionals who have come together to write the 39 chapters that constitute the 2018 edition of *Contemporary Intellectual Assessment.* Not a weak link in the bunch, not a wasted word or graphic. Not a single chapter devoted to computerized assessment.

Preface

The history of intelligence testing has been well documented, from the early period of mental measurement to present-day conceptions of the structure of intelligence and valid assessment methods. The foundations of psychometric theory and practice were established in the late 1800s and set the stage for the ensuing measurement of human cognitive abilities. The technology of intelligence testing was apparent in the early 1900s, when Binet and Simon developed a test that adequately distinguished children with intellectual disabilities from children with normal intellectual capabilities, and was well entrenched when the Wechsler–Bellevue was published in the late 1930s. In subsequent decades, significant refinements and advances in intelligence-testing technology have been made, and the concept of individual differences has remained a constant focus of scientific inquiry.

Although several definitions and theories have been offered in recent decades, the nature of intelligence, cognition, and competence continues to be elusive. Perhaps the most popular definition was that offered by Wechsler in 1958. According to Wechsler, *intelligence* is "the aggregate or global capacity of the individual to act purposefully, to think rationally and to deal effectively with his environment" (p. 7). It is on this conception of intelligence that the original Wechsler tests were built. Because the Wechsler batteries were the dominant intelligence tests in the field of psychology for decades and were found to measure global intelligence validly, they assumed "number one" status and remain in that position today. As such, Wechsler's definition of intelligence continues to guide and influence the present-day practice of intelligence testing.

In light of theoretical and empirical advances, however, it is clear that earlier editions of the Wechsler tests were not based on the most dependable or current evidence of science, and that overreliance on these instruments served to widen the gap between intelligence testing and cognitive science. From the 1980s through the 2000s, new intelligence tests have been developed to be more consistent with contemporary research and theoretical models of the structure of cognitive abilities, and the Wechsler scales (most notably the Wechsler Intelligence Scale for Children—Fifth Edition [WISC-V]) are now keeping pace with advances in theory and practice. In addition, changes in services, programs, legislation, and policy in psychology and education have had many implications for practical uses of cognitive assessments and for the client populations with whom they are applied. More recently, technological advances including tablet-based test administration have increased the ease and convenience of cognitive assessment. Since the publication of the first edition of *Contemporary Intellectual Assessment: Theories, Tests, and Issues* in 1997, there has been tremendous growth in research about cognitive constructs, and this research—for example, recent research in neuropsychology and executive functions—has in turn influenced contemporary purposes of cognitive assessment in psychology and education. These include the development and delivery of multi-tiered services for children experiencing learning problems, as well as increasing uses of cognitive and neuropsychological assessment for people who have specific learning disabilities, autism spectrum disorder, attention-deficit/hyperactivity disorder, and other challenges.

The information presented in this text on modern intelligence theory and assessment technology suggests that clinicians should be familiar with the many approaches to assessing intelligence that are now available. For the field of intellectual assessment to continue to advance, clinicians should use instruments that operationalize empirically supported theories of intelligence and should employ assessment techniques that are designed to measure the broad array of cognitive abilities represented in current theory and research. It is only through a broader measurement of intelligence—grounded in well-validated theories of the nature of human cognitive abilities—that professionals can gain a better understanding of the relationship between intelligence and important outcome criteria (e.g., school achievement, occupational success). They can also continue to narrow the gap between the professional practice of intelligence and cognitive ability testing on the one hand, and theoretical, empirical, and practical advances in psychology and education on the other.

PURPOSE AND OBJECTIVES

The purpose of the fourth edition of this book is to provide a comprehensive conceptual and practical overview of current theories of intelligence, individual measures of cognitive ability, and uses of intellectual assessments. This text summarizes the latest research in the field of intellectual assessment and includes comprehensive treatment of critical issues that should be considered when the use of intelligence tests is warranted. The three primary objectives of this book are as follows: (1) to present in-depth descriptions of prominent theories of intelligence, tests of cognitive abilities, and neuropsychological instruments, and issues related to the use of these tests; (2) to provide important information about the validity of contemporary intelligence, cognitive, and neuropsychological tests and their use in diagnosis and intervention planning; and (3) to demonstrate the utility of a well-validated theoretical and research foundation for developing cognitive tests and interpretive approaches, and for guiding research and practice. The ultimate goal of this book is to provide professionals with the knowledge necessary to use the latest cognitive instruments effectively.

Practitioners, university faculty, researchers, undergraduate and graduate students, and other professionals in psychology and education will find this book interesting and useful. It would be appropriate as a primary text in any graduate (or advanced undergraduate) course or seminar on cognitive psychology, clinical or psychoeducational assessment, or measurement and psychometric theory.

ORGANIZATION AND THEMES

This book consists of 39 chapters, organized into six parts.

Part I, "The Origins of Intellectual Assessment," traces the historical roots of test conceptualization, development, and interpretation up to the present day. The updated chapters provide readers with an understanding of how current practices evolved, as well as a basis for improving contemporary approaches to test interpretation. Chapters provide a necessary foundation for understanding and elucidating the contemporary and emerging theories, tests, and issues in the field of intellectual assessment that are presented in subsequent sections of this volume.

Part II, "Contemporary Theoretical Perspectives," updates several models presented in the previous editions of this text (e.g., Cattell–Horn–Carroll [CHC] theory; planning, attention, simultaneous, and successive [PASS] theory; the triarchic theory of successful intelligence) and presents two alternative theoretical conceptualizations of human intelligence: the parieto-frontal integration theory (PFIT) and the intelligence-as-process, personality, interests, and intelligence-as-knowledge (PPIK) framework for adult intellectual development. These theories are described in terms of (1) how they reflect recent advances in psychometrics, neuropsychology, and cognitive psychology, as well as neuroimaging; (2) what empirical evidence supports them; and (3) how they have been operationalized and applied. A comprehensive description of each theory is provided, focusing specifically on its historical origins, as well as the rationale and impetus for its development and modification. The theories represent viable foundations from which to develop and interpret cognitive measures—measures that may lead to greater insights into the nature, structure, and neurobiological substrates of cognitive functioning.

Part III, "Contemporary Intelligence, Cognitive, and Neuropsychological Batteries and Associated Achievement Tests," includes comprehensive chapters on the most widely used and most current individual intelligence batteries and their utility in understanding the cognitive capabilities of individuals from early school age through adulthood. This new edition of *Contemporary Intellectual Assessment: Theories, Tests, and Issues* updates information found in the third edition: It provides current research about the WISC-V and the other most recent revisions of the Wechsler intellectual, memory, and achievement scales; the Kaufman Assessment Battery for Children—Second Edition, and Normative Update and the Kaufman Test of Educational Achievement, Third Edition; the Woodcock–Johnson IV Tests of Cognitive Abilities, Oral Language, and Achievement; the Differential Ability Scales—Second Edition; the Universal Nonverbal Intelligence Test—Second Edition; the Cognitive Assessment System—Second Edition; and the Reynolds Intellectual Assessment Scales, Second Edition. In general, the authors provide descriptions of their assessment instruments and discuss the instruments' theoretical and research underpinnings, organization and format, and psychometric characteristics. The authors also summarize the latest research and practical uses and provide recommendations for interpreting the abilities measured by their instruments.

Part IV, "Relevance of Tests of Intelligence, Cognitive Abilities, and Neuropsychological Processes in Understanding Individual Differences," includes chapters about the use of cognitive tests to assess individuals for giftedness, intellectual disability, specific learning disabilities, and traumatic brain injury, as well as individuals from culturally and linguistically diverse populations.

Part V, "Linking Assessment Data to Intervention," includes chapters about using test data to inform interventions aimed at ameliorating the manifestations of cognitive weaknesses.

Part VI, "Contemporary and Emerging Issues in Intellectual, Cognitive, and Neuropsychological Assessment," includes updated chapters related to the validity of intelligence batteries and presents an updated practical and simplified nomenclature for CHC abilities. In addition, this section's chapters discuss the relationship between cognitive assessment and reading disorders, as well as the role of cognitive testing in the assessment of executive functions and specific learning disorder as defined in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5). The integration of neuropsychological assessment into school-based practice is discussed in two chapters. Suggestions and recommendations regarding the appropriate use of intelligence, cognitive ability, and neuropsychological tests, as well as future research directions, are provided throughout this section of the book.

DAWN P. FLANAGAN
ERIN M. MCDONOUGH

Acknowledgments

We are deeply grateful for the extraordinary contributions of our chapter authors. It has been a rewarding experience to work with such a dedicated group of people, many of whom are nationally and internationally recognized authorities in their respective areas. We thank Katherine Palma and Alexa Pate for their editorial assistance in the preparation of this book. Their careful attention to detail improved the quality of this work. We thank Natalie Graham for her support of another edition of this book, Marie Sprayberry for her outstanding copy-editing skills, and Laura Specht Patchkofsky for her skillful management of the production process. The staff at The Guilford Press are gratefully acknowledged for their expertise and their pleasant and cooperative working style. The professionalism and expertise of our contributors and the staff at Guilford made this project a most enjoyable and productive endeavor.

PART I

The Origins of Intellectual Assessment

CHAPTER 1

A History of Intelligence Assessment

The Unfinished Tapestry

John D. Wasserman

> When our intelligence scales have become more accurate and the laws governing IQ changes have been more definitively established it will then be possible to say that there is nothing about an individual as important as his IQ, except possibly his morals; that the greatest educational problem is to determine the kind of education best suited to each IQ level; that the first concern of a nation should be the average IQ of its citizens, and the eugenic and dysgenic influences which are capable of raising or lowering that level; that the great test problem of democracy is how to adjust itself to the large IQ differences which can be demonstrated to exist among the members of any race or nationality group.
>
> —LEWIS M. TERMAN (1922b)

This bold statement by the author of the first Stanford–Binet intelligence scale captures much of both the promise and the controversy that have historically surrounded, and that *still* surround, the assessment of intelligence. Intelligence tests and their applications have been associated with some of the very best and very worst human behaviors. On the one hand, intelligence assessment can provide a meaningful basis for understanding the strengths and weaknesses of misunderstood children, adolescents, or adults—thereby providing data that can be used to design and implement interventions to help people reach their potential more effectively. On the other hand, intelligence assessment can be used to segregate and label people—treating their future as a fixed outcome, an unchangeable fate. The history of forced sterilizations of individuals with intellectual disabilities in the United States and many other countries is a tragic example of how intelligence tests may be misused, exceeded only by the systematic extermination of intellectually disabled individuals in Nazi Germany (e.g., Friedlander, 1995). The topic of intelligence and its assessment deservedly elicits many strong feelings.

Intelligence is arguably the most researched topic in the history of psychology, and the concept of *general intelligence* has been described as "one of the most central phenomena in all of behavioral science, with broad explanatory powers" (Jensen, 1998, p. xii). Still, social, legal, and political forces have in some instances excluded intelligence test results from important types of educational and personnel decision-making processes. Tangible advances in assessment practices have been slow and episodic. Following Alfred Binet's initial successes, the beginning of the 20th century saw an accelerated pace of small- and large-scale applied intelligence testing, but many anticipated educational and occupational benefits were never realized. Buros (1977) considered 1927 as the "banner year" in which "the testing movement reached maturity" (p. 9). The middle of the century saw only incremental gains in testing, such as electronic scoring, analysis, and reporting of test results, but with comparatively "little progress" (Buros, 1977,

p. 10) and more than a little "stagnation" (Carroll, 1978, p. 93). A landmark quantitative review of factor-analytic investigations near the end of the 20th century (i.e., Carroll, 1993) stimulated a new school of thinking about intelligence assessment, but the story remains unfinished. In the United States, federal educational reforms and civil rights legislation have had pronounced effects upon the use of intelligence tests in education. It is possible to see the history of intelligence assessment as an unfinished tapestry depicting the rich saga of a developing discipline, with recurrent characters interwoven through different narratives, as well as more than a few loose and unresolved thematic threads.

In this chapter, the origins of intelligence assessment are recounted, with an emphasis on milestone events and seminal individuals. Thematic strands present from the early days are traced, including some that were resolved and some that remain unresolved. An effort has been made whenever possible to provide samples of primary source material. Finally, although we all tend to view history through the lens of our own experiences, it is helpful to appreciate the sociocultural context, institutional traditions, and professional *Zeitgeist* associated with historical events, as well as the experiences and personal motivations that may have driven the ideas and behaviors of historical figures.

PSEUDOSCIENTIFIC ANTECEDENTS: PHRENOLOGY IN THE 19TH CENTURY

The first science purporting to be a "true science of mind" that could measure mental qualities and functions was *cranioscopy,* introduced at the beginning of the 19th century by Franz Joseph Gall, and later renamed *phrenology* by Gall's associate, Johann Gaspar Spurzheim. Gall (1758–1828) was a Viennese physician and neuroanatomist, and Spurzheim (1776–1832) was a physician and colleague who would ultimately be responsible for the widespread dissemination of phrenology. But it would be a Scotsman, George Combe (1788–1858)—who developed and published a two-volume system of phrenology in 1824, as well as launching a phrenology journal with his brother—who would prove most instrumental in the popularization of phrenology. Combe's system appears in Figure 1.1. He also wrote the immensely successful book *The Constitution of Man,* which advanced the idea that all the laws of nature were in harmony with one another, and that people could best fulfill God's will and obtain the greatest happiness by discovering these laws and obeying them. The book went through eight editions and sold approximately 350,000 copies between 1828 and 1900.

The basic tenets of phrenology can be summarized easily. In a letter to a Viennese official, Gall (1798/1857) asserted that the brain was the organ of the mind, that the mind could be reduced to a number of faculties, that the faculties were innate, that the faculties were located in distinct and particular organs of the brain, that the surface of the skull was determined by the external form of the brain, and that phrenologists could judge the development of individual faculties merely by examining the form of the skull. A well-developed faculty was thought to have a large cerebral organ that corresponded to a cranial protuberance. Gall originally described and localized 27 distinct faculties; Spurzheim (1815) increased the list to 32 faculties; Combe (1853) further expanded the list to 35; and others expanded the list to 43 (e.g., Payne, 1920).

Gall and Spurzheim traveled through Europe promoting phrenology, which Gall advocated as a science and Spurzheim as a way to reform education, religion, and penology. It quickly became popular in the United Kingdom, and Spurzheim came to the United States in 1832 to promote phrenology to a scientific community that was already quite familiar with it. By the time Combe conducted his 1839 American phrenology lecture tour, audiences averaged over 500 across each of the 16 lectures (Walsh, 1976). A satirical depiction of a phrenological examination from about the same time appears in Figure 1.2.

Gall and Spurzheim are today credited with recognizing the significance of gray matter as the source of nerve fibers; most importantly, they are credited with introducing the neuroscientific concept of functional localization in the cerebral cortex (Simpson, 2005). Dallenbach (1915) provides evidence that they should be credited with the terms *mental functions* and *faculties*. British philosopher and critic G. H. Lewes (1867) went a step further, asserting that Gall laid the groundwork for psychology as a science rather than philosophy: "Gall rescued the problem of mental functions from Metaphysics and made it one of Biology" (p. 407). Even so, there is a long history of disparaging efforts to localize mental functions in specific regions in the brain by calling them a new "phrenology" (e.g., Franz, 1912; Fuster, 2008, p. 346).

PHILOSOPHICAL AND SCIENTIFIC ANTECEDENTS

The most prominent British philosopher of his era, Herbert Spencer (1820–1903) sought to synthesize universal natural laws (especially *evolution*) across the disciplines of biology, psychology, sociology, and ethics. Spencer coined the phrase "survival of the fittest" (p. 444) in *The Principles of Biology* (1864) after reading Charles Darwin (1859), although he was reluctant to accept Darwin's evolutionary mechanism of natural selection. In *The Principles of Psychology* (1855), Spencer described how the behavior of the individual organism adapts through interaction with the environment, and defined *intelligence* as a "continuous adjustment" of "inner to outer relations" (p. 486). Spencer's ideas persist in a number of ways to this day. Intelligence, as we shall see, is still widely considered to represent a capacity associated with adaptation to one's environment. In a critical review of Spencer's synthesis, John Dewey (1904) was struck by the luck that Spencer and Darwin published almost simultaneously, thereby making their very different concepts of evolution indistinguishable to the public.

Beyond Spencer's philosophical influence, the foundation for psychology as a science, as well as for the scholarly study of intelligence, was laid by naturalist Charles Darwin (1809–1882), who is most remembered for his theory of evolution by natural selection. In his writings, Darwin frequently referred to adaptive behavior in animals and humans as "intelligent"; more importantly, he argued that the same forces that act on animal evolution also apply to human mental abilities: "There is no fundamental difference between man and the higher mammals in their mental faculties" (Darwin, 1871, p. 35). In *The Descent of Man*, Darwin (1871) went even further in applying his evolutionary theory to human mental characteristics—probably after reading the work of his half-cousin Francis Galton, the Victorian polymath, whose drive for scientific measurement of human capabilities would start the race to develop measures of intelligence in motion.

It is difficult to overstate the impact of Darwin's theory of evolution on psychology. By considering human behavior in an evolutionary context, Darwin treated the study of psychology as no less a science than biology and other natural sciences. His influence was substantial and may be seen, for example, in Joseph Jastrow's (1901) American Psychological Association (APA) presidential address to start the 20th century. Jastrow described psychology as both a laboratory science and an applied science, setting the study of intelligence in a somewhat Spencerian evolutionary context:

> Intelligence must first be realized as an advantage-gaining factor in the evolutionary struggle; that struggle is not merely, and indeed in all the stages that here come into consideration, not mainly a conflict of tooth and nail, a contest of strength of claw and fleetness of foot, but a war of wits, an encounter of skill and cunning, a measure of strategy and foresight. (p. 9)

Francis Galton and the Anthropometric Laboratory

If you lived in London in the mid-1880s or 1890s, you could pay three- or fourpence for you or your children to undergo a variety of physical measurements and tests, with the option to register results for future reference and follow-up. The measurements were available from Francis Galton's Anthropometric Laboratory, first located at the International Health Exhibition (see Figure 1.3), then at the University of Cambridge, the South Kensington Museum, and finally at the Clarendon Museum at Oxford. *Anthropometry* referred to the "measurement of man," and Galton's laboratory was, according to Diamond (1977), "a device to tease the public into providing the data he needed for his research" (p. 52). As a lifelong advocate for objective scientific measurement, Galton (1822–1911; see Figure 1.4) was a pioneer in the use of test batteries and questionnaires for data collection, the concept of control groups in research, and statistical methods (as developer of the techniques of regression and correlation).

Galton introduced his system of anthropometric measurements in *Inquiries into Human Faculty and Its Development* (1883), where he wrote, "It is needless for me to speak here about the differences in intellectual power between different men and different races, or about the convertibility of genius as shown by different members of the same gifted family achieving eminence in varied ways" (pp. 82–83). He conceptualized his measurements as constituting indicators of physical efficiency to complement performance on formal academic written literary examinations, which he thought were the best available measures of intelligence (e.g., Galton, 1884, 1891).

FIGURE 1.3. Francis Galton's first Anthropometric Laboratory was featured at the International Health Exhibition held in London in 1884–1885. Nearly 10,000 people paid threepence each to be examined and receive a copy of their measurements. From Pearson (1924, Plate L). Reprinted by permission of Cambridge University Press.

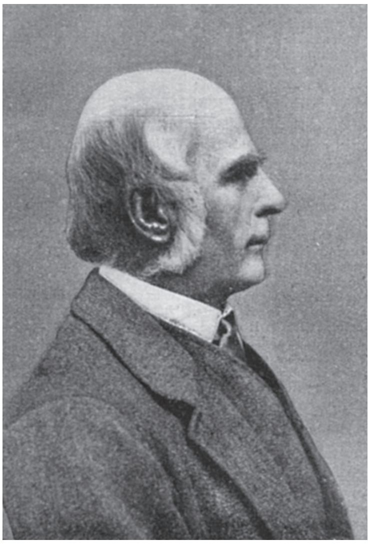

FIGURE 1.4. Francis Galton in 1888 at the age of 66, when the Anthropometric Laboratory remained active. From the copperplate prepared for *Biometrika.* In the public domain.

The examination took less than 1 hour. Although the makeup of the battery changed slightly over time, each session began with the completion of a card recording age, birthplace, marital status (married, unmarried, or widowed), residence (urban, suburban, or country), and occupation. The examinee's name, birth date, and initials were collected in the laboratory's later years, with the full name indexed in a separate list. The examiner then recorded the color of the examinee's eyes and hair, followed by tests and measurements of sensory acuity, stature, strength, and lung capacity:

- Eyesight keenness, color sense, and judgment in estimating length and squareness
- Hearing keenness and highest audible note
- Height standing, without shoes
- Height sitting, from seat of chair
- Span of arms (between opposite fingertips, with arms fully extended)
- Weight, in usual indoor clothing
- Breathing capacity (volume of air exhaled after a deep breath)
- Strength of pull (as an archer draws a bow)
- Strength of grasp (squeeze with the strongest hand)
- Swiftness of blow with fist (against a flat bar with pad at one end)

Specialized instruments (some invented by Galton) were employed, such as the spirometer, which required exhaling into a tube to measure the number of cubic inches of water displaced in a tank. Galton (1890b) interpreted breathing (lung) capacity as an indicator of energy level:

> The possession of a considerable amount of breathing capacity and of muscular strength is an important element of success in an active life, and the rank that a youth holds among his fellows in these respects is a valuable guide to the selection of the occupation for which he is naturally fitted, whether it should be an active or a sedentary one. (p. 238)

Galton constructed normative distributions for each measurement, including mean values and *percentile ranks* (i.e., the percentage of cases falling below the obtained score) in specified age ranges, differentiated by gender. Some measures, like breathing capacity and strength of grip, were assessed in relation to stature. It was possible to look at a normative chart and instantly know your approximate percentile rank. After collecting data on nearly 10,000 examinees at the International Health Exhibition, Galton's laboratory at South Kensington collected data on an additional 3,678 examinees (Galton, 1892), so adult norms were based on fairly large samples.

Galton never directly asserted that his tests measured *intelligence.* Instead, he observed that sensory measures are relevant in determining the breadth of experience upon which intelligence can operate:

> The only information that reaches us concerning outward events appears to pass through the avenue of our senses; and the more perceptive our senses are of difference, the larger is the field upon which our judgment and intelligence can act. (1907, p. 19)

In 1890, Galton acknowledged that only research could reveal the most important areas of human functioning to measure, through careful examination of test results and correlations with external criteria:

> One of the most important objects of measurement is hardly if at all alluded to here and should be emphasized. It is to obtain a general knowledge of the capacities of a man by sinking shafts, as it were, at a few critical points. In order to ascertain the best points for the purpose, the sets of measures should be compared with an independent estimate of the man's powers. We thus may learn which of the measures are the most instructive. (1890a, p. 380)

The uncertainty, of course, was where to sink the "shafts"—or, in other words, which abilities to measure.

With the methods initiated by Galton, favorable perspectives about the scientifically based mental measurement of individual differences began to crystallize in the 1890s, and many independent research efforts were launched in the United States and Europe. Charles E. Spearman (1904, pp. 206–219) counted over 30 international investigators studying mental tests, and this was probably an underestimate. The quest for mental tests is generally agreed to have started in Great Britain with Galton's initiatives, but Spearman's discovery of a *general intellectual factor,* described in a later section, would almost immediately begin to guide theory development. The earliest U.S. efforts in mental testing came through large-scale studies from James McKeen Cattell (Cattell & Farrand, 1896) at Columbia University; Franz Boas, then at Clark University (see Bolton, 1892); J. Allen Gilbert (1894) at Yale University; and Joseph Jastrow (1893) at the University of Wisconsin–Madison. In France, Alfred Binet and his colleagues (principally Victor Henri and then Théodore Simon) were the pioneers. Germany's early contributors included Hermann Ebbinghaus and Emil Kraepelin, especially his student Axel Oehrn (1896).

It is debatable whether efforts to develop a working intelligence test ever became a scientific race, like the competitive quest to identify the molecular structure of deoxyribonucleic acid (DNA) or the pursuit of space travel technology to become the first nation to land a person on the moon. Certainly, there was constant comparison between test development efforts in different nations. For example, Sharp (1899) reviewed the competing perspectives of "M. Binet and the French psychologists," "Prof. Kraepelin and the German psychologists," and the American psychologists (p. 334), pitting the assertions of each research group against one another. In journals like *L'Année Psychologique,* Binet and his colleagues could be found reviewing work by all competing laboratories, even commenting on Sharp's paper. After Spearman (1904) described his statistical method of quantifying "general" intelligence, competition between research groups may have become even more pronounced because a more focused end goal had been specified (i.e., a test of "general" intelligence per se, rather than random tests of associated mental processes). As shown in Figure 1.5, the practice of intelligence assessment in the earliest years of the 20th century essentially consisted

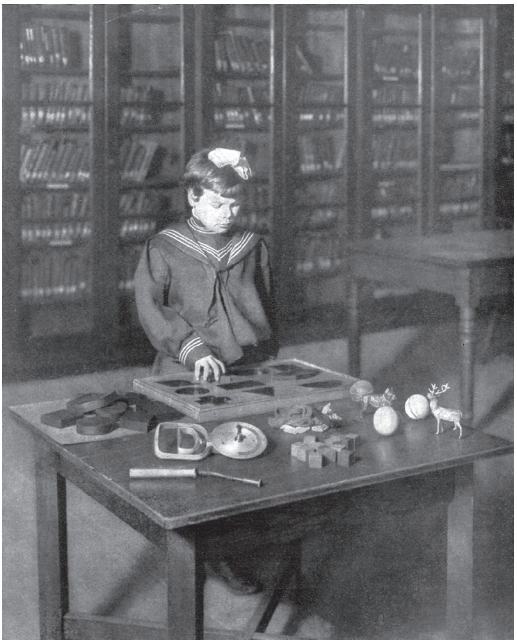

FIGURE 1.5. A photograph depicting the array of tasks used to measure intelligence at Lightner Witmer's Psychological Clinic at the University of Pennsylvania in about 1908. On the table are a Galton whistle for testing the upper limit of sound perception; a dynamometer for testing hand strength; colored yarns and blocks for testing counting skills and color perception; toys to test common knowledge, play, instinctive reactions, and coordination; and the formboard for identifying nonverbal problem solving and detecting feeble-mindedness. From Carter (1909, p. 166). In the public domain.

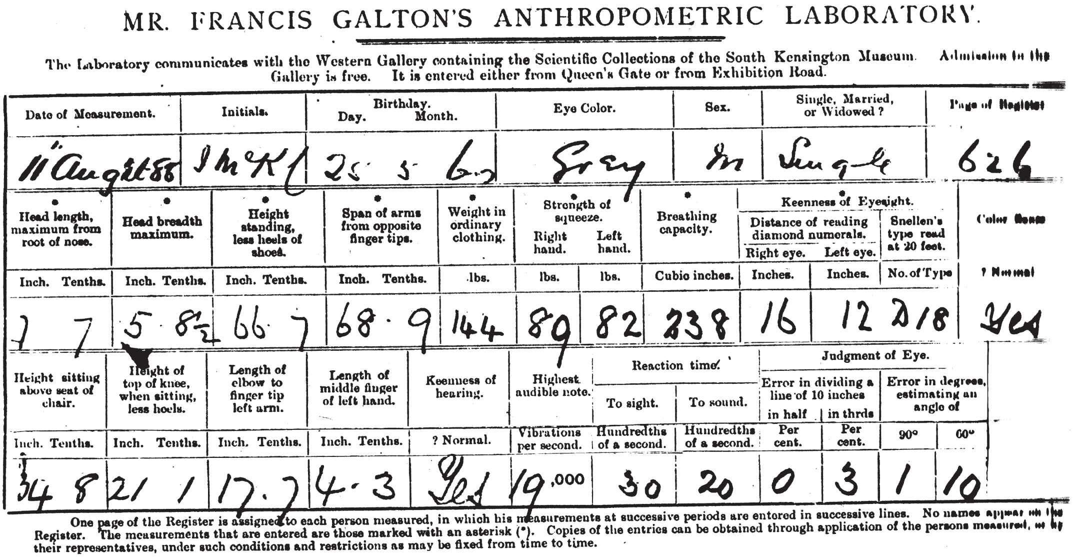
of an array of sensory and motor measures, with a formboard to measure higher mental processes.

James McKeen Cattell and the End of Anthropometrics

If there were royalty in the field of psychology, James McKeen Cattell (1860–1944) might qualify. He was the son of a professor at (and later the president of) Lafayette College in Easton, Pennsylvania, where he graduated as valedictorian in 1880. After studying for 2 years in Germany, he won a fellowship at Johns Hopkins University, where he began researching the timing of various mental processes in G. Stanley Hall's "physiologico-psychological laboratory" (Sokal, 1981, p. 64). He left to study with Wilhelm Wundt, the father of experimental psychology, at the University of Leipzig, in Germany, where he worked from 1883 to 1886 before receiving his doctorate. His article "The Time It Takes to See and Name Objects" (Cattell, 1886) summarized two of his studies on basic reading processes, which are now considered to be the first research studies to support a whole-word, sight-reading approach to reading instruction (Venezky, 2002, p. 6). Rejecting Wundt's reliance on experimenter introspection, Cattell conducted reaction time experiments with some of his own instruments, growing interested in the measurement of individual differences. According to his biographer, Michael M. Sokal, Cattell "refocused psychological research away from experimenters' self-observation of their mental activity and toward subjects' behavior in a laboratory setting precisely defined by experimenters" (Sokal, 2006, p. 25). In just a few years, Cattell would become the leading American experimental psychologist of his time.

In 1887, Cattell took a position at the University of Cambridge, where he came to know and work closely with Francis Galton. Cattell's data card from his personal anthropometric measurements appears in Figure 1.6. Cattell helped Galton set up the Anthropometric Laboratory at South Kensington. Cattell would remain devoted to Galton for the rest of his life, acknowledging in his late 60s that Galton was "the greatest man whom I have known" (Cattell, 1930, p. 116). For 2 years, Cattell split his time between work in Galton's laboratory, lecturing and establishing a laboratory at Cambridge University, and lecturing also at Bryn Mawr College and the University of Pennsylvania in the United States. In 1888, Cattell became a professor of psychology at the University of Pennsylvania (the first such professorship established anywhere, he claimed). In 1891, Cattell relocated to Columbia University, where he became the administrative head—beginning Columbia's experimental psychology laboratory and mentoring doctoral students like Edward L. Thorndike, Robert S. Woodworth, and Harry L. Hollingworth, who would themselves become faculty and leading figures in psychology. Over 40 students would take their doctorates with Cattell, seven of them becoming presidents of the APA. Cattell himself served as president of the APA in 1895.

With respect to intelligence testing, Cattell is a seminal historical figure due to his tireless advocacy for psychology as a science, his own test development efforts, and his advocacy for psychometrics and testing, as well as his emphasis on statistical analyses of individual differences, all of



MR. FRANCIS GALTON'S ANTHROPOMETRIC LABORATORY.

The Laboratory communicates with the Western Gallery containing the Scientific Collections of the South Kensington Museum. Admission to the Gallery is free. It is entered either from Queen's Gate or from Exhibition Road.

One page of the Register is assigned to each person measured, in which his measurements at successive periods are entered in successive lines. No names appear on the Register. The measurements that are entered are those marked with an asterisk (*). Copies of the entries can be obtained through application of the persons measured, or by their representatives, under such conditions and restrictions as may be fixed from time to time.

FIGURE 1.6. Measurement data card recorded in 1888 at Galton's Anthropometric Laboratory for J. McKeen Cattell, who was deeply influenced by Francis Galton. Papers of James McKeen Cattell, 1835–1948, Library of Congress, Washington, D.C. In the public domain.

which established a fertile environment for test development at Columbia University and in American psychology in general. In the British journal *Mind,* Cattell (1890) used the term *mental tests* for the first time:

> Psychology cannot attain the certainty and exactness of the physical sciences, unless it rests on a foundation of experiment and measurement. A step in this direction could be made by applying a series of mental tests and measurements to a large number of individuals. The results would be of considerable scientific value in discovering the constancy of mental processes, their interdependence, and their variation under different circumstances. Individuals, besides, would find their tests interesting, and perhaps, useful in regard to training, mode of life or indication of disease. (p. 373)

Cattell made his principal research initiative at Columbia an investigation to determine whether a battery of Galtonian anthropometric tests and sensory, motor, and higher cognitive tasks could measure intelligence. Beginning in 1894, the Cattell–Columbia Tests (as Cattell referred to them in 1924) were given to freshmen at Columbia's School of Arts and School of Mines. With student consent, the tests were to be repeated at the end of the sophomore and senior years. In the course of an hour, 26 measurements were made in the laboratory, and 44 observations were recorded. Later, each student sent in answers to 50 questions with regard to background, health, physical condition, habits (including coffee, smoking, alcohol use, and exercise), and interests. Cattell also had access to student academic records and athletic accomplishments.

Tests and measurements conducted in the laboratory included some of Galton's sensory measures; some of Cattell's reaction time measures; and some newer measures, including letter cancellation, rapid color naming, memory for digits, logical memory, self-reported retrieval of mental images, and a word association test. The battery was something of a hybrid of anthropometric, lower-order, and higher-order measures. Cattell had always relied on the experimental approach as producing descriptive results that would speak for themselves; he did not offer a priori hypotheses or even articulate his concept of intelligence. Cattell's commitment to quantitative measurement and statistical analysis of experimental results was unshakeable, and as late as 1924, Cattell, pictured in Figure 1.7, still expressed a belief that his test battery might correlate with long-term student accomplishments. He would not have the chance to find out, as two studies would put a conclusive end

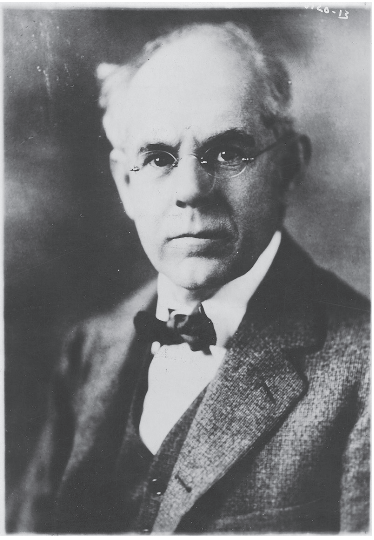

FIGURE 1.7. James McKeen Cattell at the age of 63 in December 1923. Long after the failure of his anthropometric testing program and after his 1917 dismissal from Columbia University, Cattell founded The Psychological Corporation and continued to edit several scientific journals. From the chapter author's personal collection.

to Cattell's approach to intelligence testing and his experimental research efforts.

First, a dissertation completed by Stella Sharp (1899) in Edward B. Titchener's laboratory at Cornell University sought to examine the variability of complex mental processes and the relations between complex mental processes, with the intention of demonstrating the practicality of testing complex processes rather than the simpler mental processes endorsed by Cattell and Galton. She assessed seven advanced philosophy students at the university with the test battery formulated by Binet and Henri (1895), including measures of memory, mental images, imagination, attention, observation/comprehension, suggestibility, and aesthetic tastes. Her results listed the scores of individual participants and described these results in terms of rank order and variability. Sharp concluded:

> We concur with Mm. Binet and Henri in believing that individual psychical differences should be sought for in the complex rather than in the elementary processes of mind, and that the test method is the most workable one that has yet been proposed for investigating these processes. (p. 390)

She further concluded that the Binet–Henri measures required modification but were practical and yielded considerable variation in scores. She offered only qualitative observations about relations between tests of different mental processes, however. Although she did not collect data on other assessment approaches, she was critical of the anthropometric tests as unproven and lacking an explanatory theory.

The second blow to Cattell's testing program, and its *coup de grâce*, came from a Columbia University psychology graduate student, Clark Wissler (1901). Wissler examined the correlations between the Cattell–Columbia Tests and student grades for 300 undergraduates at Columbia and Barnard Colleges. He reported that while isolated correlations were large (e.g., height and weight, $r = .66$; Latin and Greek grades, $r = .75$), the laboratory mental tests had negligible correlations with each other and with college class grades. The failure to correlate with academic grades was considered fatal to Cattell's testing program because academic performance had long been considered an independent criterion measure of intelligence. In the words of Cattell's biographer, Wissler's analysis would definitively "discredit anthropometric testing" (Sokal, 2006, p. 29).

It remains to note that over a century after Galton's and Cattell's testing programs were discredited, the relations of elementary cognitive processes (reaction time and sensory discrimination) to mental abilities and intelligence are now being revisited. Jensen (2006) has effectively summarized the literature relating reaction time to intelligence, while Deary and his colleagues (Deary, 1994; Deary, Bell, Bell, Campbell, & Fazal, 2004) have documented findings with sensory discrimination and intelligence. There is uniform agreement as to the serious methodological flaws in the Sharp and Wissler studies, including small sample size, restriction of range, and unreliability of measures (e.g., Buckhalt, 1991; Deary, 1994; Jensen, 2006).

THE ORIGINS OF CONTEMPORARY INTELLIGENCE TESTING

I have described the pseudoscience of phrenology and the visionary science of Galton, who inspired the search for effective ways to measure intelligence and who pioneered many statistical methods that would be critical for norm-referenced assessment. I have also recounted the tale of the psychologist that Galton so profoundly influenced, J. McKeen Cattell, who threw down a gauntlet of sorts when proposing that *mental tests* should constitute part of establishing psychology as a science that can measure individual differences. The unfortunate fate of Cattell's test battery has been told. Even after his assessment work was discredited, however, Cattell remained a highly connected institutional scientist and a pioneer in the development of scientific psychology in American universities.

Ironically, the problem of developing a working intelligence test would be solved by an outsider, a man with few friends, who worked without pay and who had no institutional connections of any benefit. He did have his own journal, however, where he reviewed the work of his contemporaries. His name was Alfred Binet.

Alfred Binet: The Innovative Outsider

Alfred Binet (1857–1911) is generally acknowledged as the father of intelligence tests, having developed the first working measure of intelligence (see Figure 1.8). Binet's remarkable history has been most definitively documented by biographer Theta Wolf (1973). He was educated as a lawyer, but chose not to practice; some historical accounts also report that Binet studied medicine until his father, a physician, traumatized him by showing him a cadaver. As an only child of a wealthy family, he could afford to pursue a career with little remuneration, and he developed a consuming interest in the study of psychology. He was a voracious reader across several languages who educated himself as a psychologist, spending considerable time studying in the Bibliothèque Nationale [French National Library]. He wrote his first article at age 23 and completed a doctorate in the natural sciences at age 37. According to long-time colleague Théodore Simon, for most of Binet's career "psychology was his sole occupation" (quoted by Wolf, 1973, p. 9).

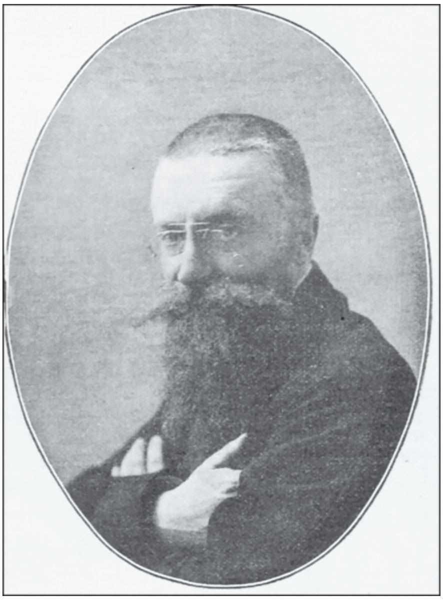

FIGURE 1.8. Alfred Binet in 1910. Reprinted courtesy of the Professor Serge Nicolas Private Collection.

Although he is remembered for his intelligence test (from which he does not appear to have profited financially), Alfred Binet was a remarkably productive and versatile researcher, authoring nearly 300 works during his career; he is now credited with pioneering experimental investigations in areas of abnormal, cognitive, developmental, educational, forensic, personality, and social psychology (e.g., Siegler, 1992; Wolf, 1973). Regrettably, most of his work has never been translated into English, although nearly all of it has been brought back into print in the last two decades. Personally, he has been described as a loner, "a reserved man with few friends" (Tuddenham, 1974, p. 1071), and as a domineering individual who antagonized many of his coworkers (cf. Henri Piéron, according to an interview with Wolf, 1961, p. 246). In 1901, Binet wrote a friend, "I educated myself all alone, without any teachers; I have arrived at my present scientific situation by the sole force of my fists; *no one,* you understand, no one, has ever helped me" (quoted by Wolf, 1973, p. 23). Lacking patronage, he was denied academic positions in France (Nicolas & Ferrand, 2002), and his efforts for educational reform and mental measurement in the military were resisted by a rigid French establishment (e.g., Carson, 2007; Zazzo, 1993). Several scholars have sought to explain why so much of his work was forgotten after his death (e.g., Fancher, 1998; Schneider, 1992; Siegler, 1992; Wolf, 1973), and the answer seems to lie in his disconnection from the professional and academic community in France: He did not present at conferences, he did not leave students to continue his work, and he preferred to work alone or with a collaborator. Only at the 2005 centennial of the first Binet–Simon scale did he begin to garner national recognition in his native France for his remarkable contributions.

From 1890 through his death, Binet published more than 200 articles, many in the journal *L'Année Psychologique,* which he cofounded and edited. In 1891, he became an unpaid staff member at the Laboratory of Physiological Psychology at the Sorbonne. Three years later, he became director of the laboratory, a position he held until his death. Between 1894 and 1898, Binet and Victor Henri sought new methods that would "substitute for vague notions of man in general, of the archetypal man, precise observations of individuals considered in all the complexity and variety of their aptitudes" (Binet & Henri, 1894, p. 167; translated and cited by Carson, 2007, p. 132). In 1899, Binet was approached by a young intern physician and *aliéniste* (psychiatrist), Théodore Simon, who had access to clinical populations (Wolf, 1961). Simon completed his doctoral thesis under Binet's supervision, and their subsequent collaborations included Binet's most important work in intelligence assessment.

The creative work that culminated in the intelligence scales began in 1890, when Binet published three papers describing experimental studies with his two young daughters, Madeleine and Alice (given the pseudonyms Marguerite and Armande), whom he had carefully observed and tested with a variety of cognitive and personality tasks. In describing their attentional styles, he wrote that Madeleine was "silent, cool, concentrated, while Alice was a laugher, gay, thoughtless, giddy, and turbulent" (translated by Wolf, 1966, p. 234). Madeleine had greater "stability" and had better voluntary control of her attention; she could more effectively focus on assigned work and memorize neutral, uninteresting material; and she tended to respond with shorter and more constant reaction times. Alice presented more "variability"; she was more imaginative and emotional; and material to be learned had to be of interest to her, or she would have difficulty. She could not memorize long literary passages verbatim as her sister could, but she could accurately remember a series of ideas provided just once (see Wolf, 1973, p. 132). Binet continued to test his daughters through midadolescence with a battery of cognitive and personality tests, including measures of attention, language, reasoning, and memory (many repeated multiple times in alternative forms over several years), always accompanied by careful qualitative observation and interview inquiries. He reported the results in 1903 in *L'étude Expérimentale de l'Intelligence [The Experimental Study of Intelligence]*.

Comparison of his children's performances with each other and with those of adults led Binet to conclude that complex, multidimensional tasks were more sensitive to developmental changes than narrow, unidimensional tasks. He further concluded that a mental developmental progression from childhood through adulthood should be reflected in task performance:

> In case one should succeed in measuring intelligence—that is to say, reasoning, judgment, memory, the ability to make abstractions—which appears not absolutely impossible to me, the figure that would represent the average intellectual development of an adult would present an entirely different relation to that of the figure representing the intellectual development of a child. (1890, p. 74; translated by Wolf, 1966, p. 235)

In 1895, Binet and Henri outlined the project for the development of an intelligence test, specifying 10 discrete mental faculties that would be measured: memory, imagery, imagination, attention, comprehension, suggestibility, aesthetic sentiment, moral sentiment, muscular strength/willpower, and motor ability/hand–eye coordination. Higher-order, complex processes were considered to show greater variability among individuals and to constitute better measures of intelligence than simpler sensory and motor processes:

> The higher and more complex a process is, the more it varies in individuals; sensations vary from one individual to another, but less so than memory; memory of sensations varies less than memories of ideas, etc. The result is, that if one wishes to study the differences existing between two individuals, it is necessary to begin with the most intellectual and complex processes, and it is only secondarily necessary to consider the simple and elementary processes. (Binet & Henri, 1895, p. 417; translated by Sharp, 1899, p. 335)

In a passage that made direct reference to the work of Galton and Cattell, Binet and Henri (1895) rebutted the claim that greater experimental precision was possible in the measurement of simpler mental processes:

> If one looks at the series of experiments made—the *mental tests* as the English say—one is astonished by the considerable place reserved to the sensations and the simple processes, and by the little attention lent to the superior processes. . . . The objection will be made that the elementary processes can be determined with much more precision than the superior processes. This is certain, but people differ in these elementary ones much more feebly than in the complex ones; there is no need, therefore, for as precise a method for determining the latter as for the former. . . . Anyway, it is only by applying one's self to this point that one can approach the study of

> individual differences. (pp. 426, 429; translated by Siegler, 1992, p. 181)

The formal mandate that led to the development of the intelligence test came in October 1904, when Joseph Chaumié, the Minister of Public Instruction, established a commission chaired by Léon Bourgeois and charged it with studying how France's 1882 mandatory public education laws could be applied to abnormal [*anormaux*] children, including students who were blind, deaf-mute, and backward [*arriérés*] (Carson, 2007; Wolf, 1969). The ministry was persuaded to take this initiative by public pressure, including a resolution from the 1903 Third National Congress of Public and Private Welfare held at Bordeaux, where critics noted France's failure to comply with its own special education laws. A resolution from an educational advocacy group, La Société Libre pour l'Étude Psychologique de l'Enfant [Free Society for the Psychological Study of the Child], was also a reason for creation of the Bourgeois Commission. Binet was a leader of La Société Libre and an author of the resolution, and he became a member of the commission, which began its work by circulating questionnaires to teachers and principals throughout France. The commission met on numerous occasions in 1904 and 1905, issuing its report in 1906.

Binet saw in the commission's mandate an opportunity to complete his efforts toward a norm-referenced standard for diagnosis and educational decision making. Building on the earlier work with Henri (who had departed), Binet and Simon developed and tested a series of cognitive tests. Their collaborations worked in tandem: One of them would talk with and question the examinee, while the other wrote the replies and noted salient behaviors. The assessments had "the air of a game" for children, with encouragement being constantly provided (1905/1916a, p. 141). The work culminated in the 1905 publication of the Binet–Simon Intelligence Scale (Binet & Simon, 1905/1916c), consisting of 30 items that could be given in about 20 minutes; it was normed on some 50 children from ages 3 through 11 years; and one of its chief advances may have been to combine a wide range of cognitive tasks to obtain a global estimate of intelligence (e.g., DuBois, 1970). Binet and Simon (1905/1916c) sequenced tasks in a cognitive-developmental order from easy to hard and from simpler to more complex, while sampling a wide range of tasks tapping various abilities. In general, they sought tasks that tapped the higher-order ability of *judgment*—especially procedures that had demonstrated the capacity to differentiate groups on the basis of intelligence. For example, individuals considered *idiots* generally could not move beyond the sixth of the 30 tasks; individuals considered *imbeciles* rarely went beyond the 15th task (Binet & Simon, 1905/1916a).

The Bourgeois Commission issued its report early in 1906, based primarily on a subcommittee report drafted by Binet. Recommendations were that the *anormaux* be educated through *classes spéciales* annexed to ordinary primary schools and, in certain situations, through separate institutions. A five-part classification of exceptional students was proposed, identifying students who were blind, deaf, medically abnormal, intellectually backward, and emotionally unstable. The commission recommended that students who did not benefit from education, teaching, or discipline should receive a "medico-pedagogical examination" before being removed from primary schools, and that such children, if educable, should be placed in special classes. The examination was to be overseen by an examination committee consisting of an inspector of primary schools, a physician, and a director of the separate special school. The commission did not offer any specific content for the examination, recommending that the Minister of Public Instruction appoint a competent person to draw up a scientific guide for the school examination committee (Carson, 2007). Undoubtedly Binet hoped to draw up the scientific guide, and Binet and Simon's book *Les Enfants Anormaux* (1907/1914) was probably intended to serve as the guide; it even contained a preface by Léon Bourgeois, the head of the commission.

Unfortunately, Binet's efforts were almost completely rebuffed by the French establishment. When the French legislature enacted the law of April 15, 1909, on the education of the *anormaux*, it stated that the commission determining eligibility for special education should be composed of a physician, school inspector, and director or teacher at an *école perfectionnement*. It highlighted the medical examination and made no mention of any role for psychologists or use of special methods (i.e., intelligence tests) for assessing students (Carson, 2007). Binet's efforts had little visible impact on practice in his native France.

In the 1908 revision, the Binet–Simon Scale took its definitive revolutionary form, the "graded scale of intelligence" [*L'échelle métrique de l' intelligence*], which was easier to use and interpret (Binet & Simon, 1908/1916b). It featured 56 tests arranged by difficulty so that tests were placed at levels, or grades, corresponding to approximately a 75% pass rate for children of a given age, based on normative performances of about 200 children between the ages of 3 and 15. The 1908 scale permitted a student's mental level [*niveau mental*] to be estimated through what later became interpreted in the United States as a mental age level. The mental level was determined by the highest age at which a child passed four or five tests (the basal year), with an additional year credited for each of the five tests passed beyond the basal. By the completion of the 1911 edition (Binet, 1911/1916), the scale was extended from age 3 through adulthood, with 11 levels and five items administered at each level. Table 1.1 lists content from the final 1911 scale. The Binet–Simon Scale never yielded an intelligence quotient (IQ), but Binet endorsed the convention of identifying intellectual disability [*arriérés*] for a mental level delay of "two years when the child is under [age] nine, and three years when he is past his ninth birthday" (Binet & Simon, 1907/1914, p. 42). Long after Binet's death, Simon indicated that the use of a summary IQ score was a betrayal [*trahison*] of the scale's objective (cited by Wolf, 1973, p. 203).

In the spring of 1908, Henry H. Goddard, director of the psychological research laboratory at the New Jersey Training School for Feeble-Minded Girls and Boys (later known as the Vineland Training School), traveled to Europe. He visited doctors and teachers working in 19 different institutions and 93 special classes. Ironically, he did not even look up Binet in Paris, having been told by Pierre Janet that "Binet's Lab. is largely a myth . . . Not much being done—says Janet," according to his journal (cited by Zenderland, 1998, pp. 92–93). In Brussels, he met Ovide Decroly, a Belgian teacher, physician, and psychologist, engaged in a tryout of the 1905 Binet–Simon Scale. Decroly provided him with a copy of the test, and upon his return home, Goddard began to use the test on the children at the training school. In the words of Goddard's biographer Leila Zenderland (1998), Goddard immediately understood the significance of the Binet–Simon Scale:

> Two years of frustrating institutional experience had prepared him to see what Janet, Cattell, and even [G. Stanley] Hall, the most prescient of contemporary psychological entrepreneurs, had missed. Contained within Binet's articles, Goddard quickly realized, was an entirely new psychological approach toward diagnosing and classifying feeble minds. (p. 93)

In a short time, Goddard would become the United States' leading advocate for Binet's approach to assessment and diagnosing intellectually disabled individuals. He described his evaluation of the ease, simplicity, and the utility of the 1908 scale as "a surprise and a gratification" (1916, p. 5), and he promoted the test widely. The Binet–Simon Scale was both praised and criticized widely in professional journals; for example, several consecutive issues of the *Journal of Educational Psychology* in April, May, and June 1916 were dedicated to "Mentality Tests: A Symposium," a wide-ranging exchange of experiences with the Binet–Simon Scale (and other tests) by 16 leading psychologists. Goddard arranged for Elizabeth S. Kite, his laboratory's field worker and contributor to the famous Kallikak study, to complete the definitive translations into English of Binet and Simon's writings on their intelligence scale. By 1916, the Vineland laboratory had distributed 22,000 copies of a pamphlet describing administration of the Binet–Simon Scale and 88,000 record forms, as well as publishing a two-volume translation of the Binet–Simon articles (Goddard, 1916). By 1939, there were some 77 available adaptations and translations of the Binet–Simon Scale (Hildreth, 1939), including the most used psychological test of all, the Stanford–Binet. According to Théodore Simon, Binet gave Lewis M. Terman at Stanford University the rights to publish an American revision of the Binet–Simon Scale "for a token of one dollar" (cited by Wolf, 1973, p. 35). Terman's work would change the landscape for mental testing in the United States.

The Binet–Simon Intelligence Scale represented a major paradigm shift for the young field of psychology. It tapped intelligence through assessment of complex mental abilities, as opposed to the narrow sensory and motor measures dominating the Galton–Cattell batteries. It was standardized, with explicit procedures for administration and objective scoring guidelines. It was norm-referenced, permitting an individual's performance to be compared with that of his or her age peers. It was reliable, yielding consistent scores from one occasion to another. It was developmentally sensitive, recognizing that mental abilities in children develop in a meaningful progression and that the abilities of children differ substantially from that of adults. It was efficient and engaging, administered in an adaptive format in which content changed frequently. It offered clinical assessment, aimed at diagnosing intellectual disabilities, identifying cognitively advanced students, and describing

TABLE 1.1. Contents of the Binet–Simon (Binet, 1911/1916) Intelligence Scale [*L'Échelle Métrique de l' Intelligence*]

Three years

Show eyes, nose, mouth
Name objects in a picture
Repeat 2 figures
Repeat a sentence of 6 syllables
Give last name

Four years

Give sex
Name key, knife, penny
Repeat 3 figures
Compare 2 lines

Five years

Compare 2 boxes of different weights
Copy a square
Repeat a sentence of 10 syllables
Count 4 sous
Put together two pieces in a "game of patience"

Six years

Distinguish morning and evening
Define by use
Copy diamond
Count 13 pennies
Compare 2 pictures esthetically

Seven years

Right hand, left ear
Describe a picture
Execute 3 commissions
Count 3 single and 3 double sous
Name 4 colors

Eight years

Compare 2 objects from memory
Count from 20 to 0
Indicate omission in pictures
Give the date
Repeat 5 digits

Nine years

Give change out of 20 sous
Definitions superior to use
Recognize the value of 9 pieces of money
Name the months
Comprehend easy questions

Ten years

Place 5 weights in order
Copy a design from memory
Criticize absurd statements
Comprehend difficult questions
Place 3 words in 2 sentences

Twelve years

Resist the suggestion of lines
Place 3 words in 1 sentence
Give more than 60 words in 3 minutes
Define 3 abstract words
Comprehend a disarranged sentence

Fifteen years

Repeat 7 figures
Find 3 rhymes
Repeat a sentence of 26 syllables
Interpret a picture
Solve a problem composed of several facts

Adults

Comprehend a cut in a folded paper
Reversed triangle
Answer the question about the President
Distinguish abstract words
Give the sense of the quotation from Hervieu

Note. The final 1911 Binet–Simon Scale extended from 3 years into adulthood. In this edition, an individual's mental level [*niveau mental*] was estimated by identifying the highest age at which all the tests were passed (the basal year), to which is added one-fifth of a year for every test passed. The Binet–Simon Scale never yielded an intelligence quotient (IQ), but Binet endorsed the convention of identifying intellectual disability for a mental-level delay of 2 years when a child is under age 9, and 3 years past his or her 9th birthday. From Binet (1911/1916). In the public domain.

the characteristics of both "normal" and "abnormal" individuals. Finally and most importantly, it seemed to work fairly well, providing an empirical foundation for the nascent study of intelligence and cognitive abilities.

Lewis M. Terman: Defender of the Discipline

> I hate the impudence of a claim that in fifty minutes you can judge and classify a human being's predestined fitness in life. I hate the pretentiousness of that claim. I hate the abuse of scientific method which it involves. I hate the sense of superiority which it creates, and the sense of inferiority which it imposes.
>
> —WALTER LIPPMANN (1923)

When journalist Walter Lippmann launched the first high-profile public attack on intelligence testing in a series of articles in *The New Republic* (Lippmann, 1922a, 1922b, 1922c, 1922d, 1922e, 1922f, 1923), it was Lewis M. Terman (1922a) who responded and defended the new discipline. He was the natural choice—developer of the Stanford University revision of the Binet–Simon Intelligence Scale (later called the Stanford–Binet Intelligence Scale); member of the National Research Council team that created the Army mental tests in 1917 and 1918; coauthor of the National Intelligence Tests and Terman Group Test of Mental Ability, released in 1920; principal investigator on the longitudinal Genetic Studies of Genius, initiated in 1921–1922; and coauthor of the Stanford Achievement Test, which would be released in 1923. For decades, Terman would be the living American most strongly associated with intelligence testing and its value for educational decision making.

The 12th of 14 children from a rural Indiana farming family, Lewis M. Terman (1877–1956) was a brilliant, hard-working, and determined student from an early age; he accelerated from first grade to third grade and memorized most of his textbooks. Graduating early from eighth grade (the conclusion of education in typical Midwest farming communities of that era), he began teacher's college at the age of 15, attending when he could and taking breaks to earn enough money to return. Terman pursued training in education, as teaching was the "only avenue of escape for the youth who aspired to anything beyond farm life" (1932, p. 300); eventually he would teach for one year in a one-room schoolhouse. By the age of 21, he had earned three baccalaureate degrees from Central Normal College in Danville, Indiana, and he became a principal of a small high school. He then pursued a master's degree in psychology at Indiana University, followed by a doctorate at Clark University. In 1905, recurrent tubercular hemorrhages in his lungs (eventually the cause of his death) forced Terman to relocate his family to Southern California, where he worked again as a high school principal and then as a professor of pedagogy at Los Angeles State Normal School (later UCLA) before accepting a position in 1909 at Stanford University, where he remained for the duration of his career. Figure 1.9 shows Terman at about the time he started his career at Stanford University.

Terman is described by two biographers, Henry L. Minton (1988) and May V. Seagoe (1975), as having been a highly gifted man and voracious learner, who was tirelessly persistent, intense, and sensitive. As a rigorous and careful researcher, he became a pioneer in mental testing by creating the best of many adaptations of the Binet–Simon Scale. He also harbored a progressive vision of large-scale testing to identify the individual differences and needs of schoolchildren, as well as to identify intellectually gifted children (Chapman, 1988). Like Cattell, Terman had been seen by a

FIGURE 1.9. Lewis M. Terman in 1910, the year he arrived at Stanford University. Terman was the leading advocate for intelligence testing in the first half of the 20th century. Reprinted by courtesy of the Department of Special Collections and University Archives, Stanford University Libraries.

phrenologist as a child; he was deeply impressed by the experience and remembered that the phrenologist "predicted great things of me" (Terman, 1932, p. 303). Having spent 6 months each year during his adolescence toiling at farmwork from 5:00 A.M. through about 7:00 or 8:00 P.M., Terman considered his intellectual abilities to have been inherited; he remembered his lengthy stints at farmwork as periods without mental stimulation, contributing to his conviction that environment was substantially less important than heredity in explaining intelligence.

Terman's master's thesis on leadership, his doctoral dissertation on genius, and his longitudinal study of gifted children beginning in 1921–1922 all contributed to his status as founder of the "gifted child" movement. Terman's thesis, published as a journal article in 1904, used experimental methodology (from Binet's suggestibility studies), teacher ratings, and questionnaires to examine leadership in male and female schoolchildren from grades 2 through 8. It is a qualitatively rich study that identifies different types of leaders and subtly links leadership with perceived intelligence. Terman's dissertation, completed in 1905 and published as a journal article in 1906, was entitled "Genius and Stupidity: A Study of Some of the Intellectual Processes of Seven 'Bright' and Seven 'Stupid' Boys." For his dissertation, Terman administered a variety of higher-order mental tests to seven boys identified by teachers as the "brightest" and seven boys identified as the "dullest," based on a holistic review (i.e., not merely based on classwork) of willing boys. All of the boys were 10–13 years of age. Terman tested the boys for about 20–40 hours in each of eight areas: creative imagination, logical processes, mathematical ability, mastery of language, interpretation of fables, ease of learning to play chess, powers of memory, and motor abilities. Some tests were culled from the literature, including measures from Binet and Henri, Ebbinghaus, and others; other tests were tasks developed by Terman that would reappear in the Stanford–Binet. Terman found that the bright boys were superior to the dull boys in all but the motor tests, with creative imagination tests showing modest differences between bright and dull boys. Most tests administered tended to agree with one another—a finding that Terman interpreted as supporting the presence of Spearman's general factor. Bright children preferred to read, while dull children preferred to play games; there was little difference between the two groups in terms of persistence.

In 1910, Terman began his revision of the Binet–Simon Scale, a technical *tour de force* that would be published in 1916. Terman began initial studies by administering the 1908 Binet–Simon Scale to some 400 schoolchildren, as well as examining all available published studies of age-level placement for the Binet tests. It soon became evident that some tests were misplaced, with tests at the lower age levels too easy and those at the upper age levels too hard. He also wanted to add tests to reach six at each age level, eventually augmenting the Binet–Simon with 36 new tasks and clarifying administration and scoring criteria. Terman, his students, and his colleagues tested some 700 additional children in pilot studies. Some of Terman's new tasks were noteworthy, including a 100-word vocabulary test yielding full credit for correct definitions, half credit for partially correct definitions, and no credit for incorrect responses; and (arguably) the first executive function measure, the Ball and Field Test of Practical Judgment (see Littman, 2004, for an account of its origins). Terman and Childs (1912a, 1912b, 1912c, 1912d) published a "tentative revision and extension" of the Binet–Simon Scale, but further revision was necessary, given the 1911 extension of the Binet–Simon Scale through adulthood. As Seagoe (1975) reports, Terman's "unfamiliarity with statistics" and dislike of the "drudgery of computation" (p. 47) caused him to rely heavily on Arthur S. Otis, and for later editions on Truman L. Kelley and Quinn McNemar, for statistical analyses and data management. Dahlstrom (1985) noted the critical contribution of Otis's statistical knowledge and skills to the 1916 Stanford–Binet. Otis would later make important contributions to the development of the Army mental tests.

Terman's final standardization sample for the 1916 Stanford–Binet included 905 participants between the ages of 5 and 14 years, all within 2 months of a birthday and drawn from public schools in California and Nevada. No foreign-born or minority children were included. Special population studies included 200 "defective" and "superior" children. The adult sample consisted of 150 adolescent delinquents, 150 unemployed men, 50 high school students, and 30 businessmen across California and Oregon. The overall sample was predominantly white, urban, and middle-class, with an average adult mental age of 15–17 years. The final 1916 Stanford–Binet consisted of 90 items—six at each age level from ages 3 to 10; eight items at age 12; six items at age 14; and six items at each of two adult levels (average adult, superior adult). Sixteen alternative tests were available for tests that were inappropriate or otherwise spoiled. Of the final 90 items, 60% were drawn from the Binet–Simon and 40% from Terman and other sources. Terman adapted William Stern's (1914) "mental quotient" to generate the IQ (mental age divided by chronological age, with the product multiplied by 100 to remove decimals). Although Terman was critical of Spearman's work, he explicitly stated that the Stanford–Binet measured general intelligence, in effect making the single IQ score a functional estimate of Spearman's *g* and treating intelligence as a unitary construct:

> The scale does not pretend to measure the entire mentality of the subject, but only *general intelligence*. There is no pretence of testing the emotions or the will beyond the extent to which these naturally display themselves in the tests of intelligence. (1916, p. 48; original emphasis)

Terman retained Binet's adaptive testing format, which permitted flexibility in determining at which level to start the test, and different item types were intermixed to make the testing experience a fast-moving experience with tasks changing frequently.

Terman's Stanford–Binet was a resounding success, becoming the most frequently used psychological test (and intelligence test) in the United States for decades (Louttit & Browne, 1947). The Stanford–Binet would be renormed and expanded to create two parallel forms (Form L for Lewis, and Form M for coauthor Maud A. Merrill) spanning the ages 2 years through Superior Adult III in a remarkable 1937 revision (Terman & Merrill, 1937). The best items from the two forms would be retained in a single form for two updates (Terman & Merrill, 1960, 1973). From sales of test record forms, R. L. Thorndike (1975) estimated that the Stanford–Binet was administered to an average of about 150,000 persons a year from 1916 to 1937, to about 500,000 persons a year from 1937 to 1960, and to about 800,000 a year from 1960 to 1972. The fourth edition would make radical changes, including conversion to a point scale format and assessment of discrete factors of ability according to extended Gf-Gc theory (Thorndike, Hagen, & Sattler, 1986), but the fifth edition would endeavor to restore some of the features that distinguished the Stanford–Binet from its start (Roid, 2003).

Terman was also responsible, more than any other psychologist, for the rapid growth of intelligence and achievement tests in schools. The "Oakland experiment" of 1917–1918 was one of the first systematic attempts to use intelligence/ability tests as a basis for grouping students—a movement that is well documented in Chapman's *Schools as Sorters* (1988). Beginning in 1917, one of Terman's students, Virgil E. Dickson, became director of research for the Oakland Public Schools and organized the testing of 6,500 schoolchildren with the Stanford–Binet, the Otis Absolute Point Scale, and other tests in all of Oakland's 45 elementary schools. From his findings, Dickson concluded that many students fail because their ability levels make mastery of the ordinary curriculum impossible; furthermore, he asserted, the "mentally superior" are in need of accelerated curricula. Dickson called for segregation of students into special classes based on their ability levels. Figure 1.10 depicts the introduction of intelligence tests in the schools. Receiving enthusiastic endorsements from administrators and teachers, Dickson (1919) concluded:

> Standard tests, both psychological and pedagogical—group and individual—should be of great assistance in classification of pupils according to ability and capacity to do the work. They should inspire better teaching and better educational guidance through a more intimate knowledge of the individual child. (p. 225)

In 1923, Dickson published *Mental Tests and the Classroom Teacher,* the first in a series of "measurement and adjustment" books to be edited by Terman and published through the World Book Company. In 5 years, Terman would oversee nine additional titles, each focusing on problems of student testing and "adjustments to meet the problems of instruction and school administration arising out of individual differences" (see Chapman, 1988, p. 104, for a description of Terman's blueprint for the series).

Large-Scale Assessments and the Army Mental Tests

In retrospect, it was a remarkable accomplishment: In the span of only 18 months during World War I, a small team of psychologists developed, tried out, and then directed the administration of the first intelligence measures designed for large-scale adult testing. By the time the Armistice was signed in November 1918, an estimated 1,726,966 Army enlisted men and officers had been tested with the new group tests. More than 83,500 en-

FIGURE 1.10. After the success of the "Oakland experiment" of 1917–1918, Terman and other psychologists advocated successfully for the use of intelligence tests to group students according to their ability levels. Educators recognized the value of measuring "individual differences" but were wary of the proliferating tests (e.g., Hines, 1922). From Heaton (1922). In the public domain.

listed men were also given individual examinations. Although the military was not particularly appreciative of the testing program, psychologists used the perceived success of the Army mental tests to sell the general public on the value of mental testing; large-scale assessment thus found its way into American education system, where it remains prominent today. Accounts of World War I Army mental testing are available in official narratives from the psychologist directing the process (e.g., Yerkes, 1919, 1921; Yoakum & Yerkes, 1920), as well as a number of independent scholars (e.g., Camfield, 1969; Carson, 1993; Kevles, 1968; Napoli, 1981; Samelson, 1977; Sokal, 1987; Spring, 1972; von Mayrhauser, 1986, 1987, 1989). I draw on these sources and others for the following history.

The story of the Army mental tests begins with the United States' lack of preparation for the war. World War I, which started in 1914, was fought mainly in Europe between the Allied Powers (the Russian and British Empires, France, and later Italy and the United States) and the Central Powers (the Austro-Hungarian, German, and Ottoman Empires and Bulgaria). An isolationist United States, under the leadership of President Woodrow Wilson, sought neutrality in what was perceived as a European conflict, leaving the U.S. military unprepared to enter the war. As of April 1917, the strength of the U.S. Army was below 200,000 men, the smallest number since the Civil War (e.g., Yockelson, 1998).

Wilson finally asked Congress for a declaration of war against Germany on April 2, 1917 (Wilson, 1917). Congress declared war 4 days later. President Wilson signed the Selective Service Act into law on May 18, 1917; within a few months, 10 million men had registered for the draft, with almost 2.8 million men actually being drafted by the U.S. Army (Baker, 1918). Under General John J. Pershing, troops of the American Expeditionary Forces (AEF) began arriving in Europe in June 1917.

The draft, however, had no established procedures to identify and exclude men who were unfit for service. There was also no way to identify large numbers of potential officers, since the existing officers had been selected and trained through the U.S. Military Academy at West Point and fell far short of needs. Secretary of War Newton Baker (1918, p. 15) wrote that "one of the most serious problems confronting the War Department in April 1917, was the procurement of sufficient officers to fill the requirements of the divisions that were to be formed for overseas duty." Moreover, there was no systematic way to assign men to specialized military jobs similar to those they had held in civilian life (e.g., assigning a practicing accountant to military requisitions tracking or record keeping). The massive draft provided an opportunity for the young scientific discipline of psychology to demonstrate the value of its still-new technologies—the intelligence test and personnel selection procedures—to efficiently screen large numbers of enlisted men.

Yerkes and the Army Mental Tests

The involvement of psychologists in the war effort formally began on April 6, 1917, at the annual meeting of Edward B. Titchener's Society of Experimental Psychologists at Harvard University. When war was officially declared by the U.S. Congress on that day, Robert M. Yerkes, the president of the APA, asked the assembled psychologists how they could assist the government in time of war. A committee was proposed under Yerkes's chairmanship, "to gather information concerning the possible relations of psychology to military problems" (Yerkes, 1921, p. 7). Almost 2 weeks later, on April 21, the executive council of the APA met in the Hotel Walton in Philadelphia. In preparation, Yerkes had been busy behind the scenes, touring Canadian hospitals, interviewing military doctors, and soliciting support from APA council members and members of the National Research Council. According to historian Richard T. von Mayrhauser (1987), Yerkes would use the military crisis to assert "near-dictatorial power within the profession" of psychology (p. 135).

The meeting at the Hotel Walton was misguided from the start because it involved a discussion among academic psychologists about what the military needed, rather than a request to the military as to how psychology might serve military needs. Moreover, a heavy-handed Yerkes sought to impose his narrow vision of mental testing on psychology, while suppressing input from another council member, Walter Dill Scott, who had more applied experience in personnel selection than anyone else at the meeting. With simultaneous authorization from the APA council and the National Research Council Psychology Committee, Yerkes appointed a dozen war-related psychology committees and chairs, dealing with areas such as aviation, recreation, propaganda, vision, acoustics, shellshock, emotional stability, and deception. Yerkes appointed himself chair of the "Committee on the Psychological Examining of Recruits," which was charged with preparation and standardization of testing methods and the demonstration of their effectiveness. Yerkes's initial testing plan—10-minute individual mental testing of at least 20% of "exceptional or unsatisfactory" recruits (von Mayrhauser, 1987, p. 141) by psychologists working under the supervision of military physicians—was in part a recapitulation of his own experiences working half-time directing research in the Psychopathic Department at Boston State Hospital under the supervision of Harvard psychiatrist Elmer Ernest Southard. At the same hospital, Yerkes had developed his own point scale adaptation of the Binet–Simon (Yerkes, Bridges, & Hardwick, 1915), which he probably hoped would be prominent in any testing program.

APA council member Walter V. Bingham later described his (and colleague Walter Dill Scott's) revulsion at events in Yerkes's meeting: "Meeting of the council in the smoke-filled room of a Philadelphia hotel. Midnight. Scott's utter disgust with the shortsighted self-interest revealed. His insurrection not previously told" (cited by von Mayrhauser, 1987, p. 139). Elsewhere in Bingham's papers appears the following disclosure:

> As the meeting proceeded it became clear to Scott and Bingham that Yerkes and the others were interested primarily in going into the army in order to acquire new psychological knowledge. They seemed to be more concerned with what the army could do for them than with what they could do for the army. Angrily, Scott and Bingham walked out in a huff. (cited by von Mayrhauser, 1987, p. 139)

With this divisive start, Yerkes alienated Scott, who had experience and skills he sorely needed. There was much at stake, as George Ellery Hale, famed astronomer and organizer of the National Research Council, warned Yerkes in May 1917:

> In the case of psychology, it is obvious that the first thing to do is to prove conclusively that the psychologists can perform service of unquestioned value to the government. . . . It is of fundamental importance that no tests be adopted which are not absolutely conclusive because if they were, the science of psychology would suffer an injury from which it would not recover for many years. (G. E. Hale to R. M. Yerkes, 1917; cited by Camfield, 1992, p. 107)

Yerkes's Committee and Arthur Otis

The Committee on the Psychological Examining of Recruits, made up of Robert M. Yerkes, Walter V. Bingham, Henry H. Goddard, Thomas H.

Haines, Lewis M. Terman, F. Lyman Wells, and Guy M. Whipple, met at the Vineland Training School in New Jersey from May 28 to June 9 to develop the Army mental tests. After reaching agreement that the tests had the goals of eliminating "unfit" recruits and identifying those with "exceptionally superior ability" (who might become officers), discussion turned to the merits of brief individually administered tests versus group-administered tests. Deciding that efforts should be made to test all recruits, the committee concluded that brief individual tests were problematic in terms of reliability and uniformity of method and interpretation, opting instead for group administration (Yerkes, 1921, p. 299). At this point, Lewis Terman presented the group-administered tests developed by his Stanford graduate student Arthur S. Otis. According to Yerkes (1921, p. 299), 4 of the 10 tests in the original Army scale for group testing were accepted with little change from the Otis scale, and certain other tests were shaped in part by the content and format of the Otis series.

Committee members identified a dozen criteria to use for selection of additional tests: suitability for group use; interest and appeal; economy of administration time; score range and variability; scoring objectivity; scoring ease and rapidity; minimal writing requirements; resistance to coaching; resistance to malingering; resistance to cheating; independence from educational influences; and convergent validity with independent measures of intelligence. Each test was to consist of 10–40 items, with a time limit not to exceed 3 minutes. Moreover, oral directions needed to be simple, and written instructions easy to read. All tests needed to be accompanied by two or three completed sample items to ensure that examinees understood task requirements.

Psychologists around the country were recruited to write additional items to create 10 parallel equivalent forms of the Army mental tests. The tests underwent a series of pilot studies with 400 examinees drawn from different settings. After revisions were made, a larger trial with the 10 forms was conducted on 4,000 recruits in Army and Navy settings during July and August 1917. The final test occurred in the fall of 1917, when 80,000 men in four national Army cantonments were tested, along with 7,000 college, high school, and elementary school students to check the Army results. All processing of record forms and statistical analyses were conducted by a small group working out of Columbia University, directed by Edward L. Thorndike with assistance from Arthur Otis and Louis L. Thurstone. Thorndike and his statistical analysis group endorsed the psychometric properties of the group tests, although clearly not all forms were equivalent, and some had to be dropped in the end.

Examination Beta was developed after Alpha, when it became evident that a different approach was needed for valid assessment of recruits who were either illiterate or limited in their English proficiency. It included ideas from Otis, Terman, and others and was tested at several training camps and at the Vineland Training School. After some 15 tests were reduced to 8 tests, the Beta was completed in April 1918. It was designed to correlate well with Examination Alpha, to differentiate average from very low levels of ability, and to be easily understood and administered, yielding few zero scores.

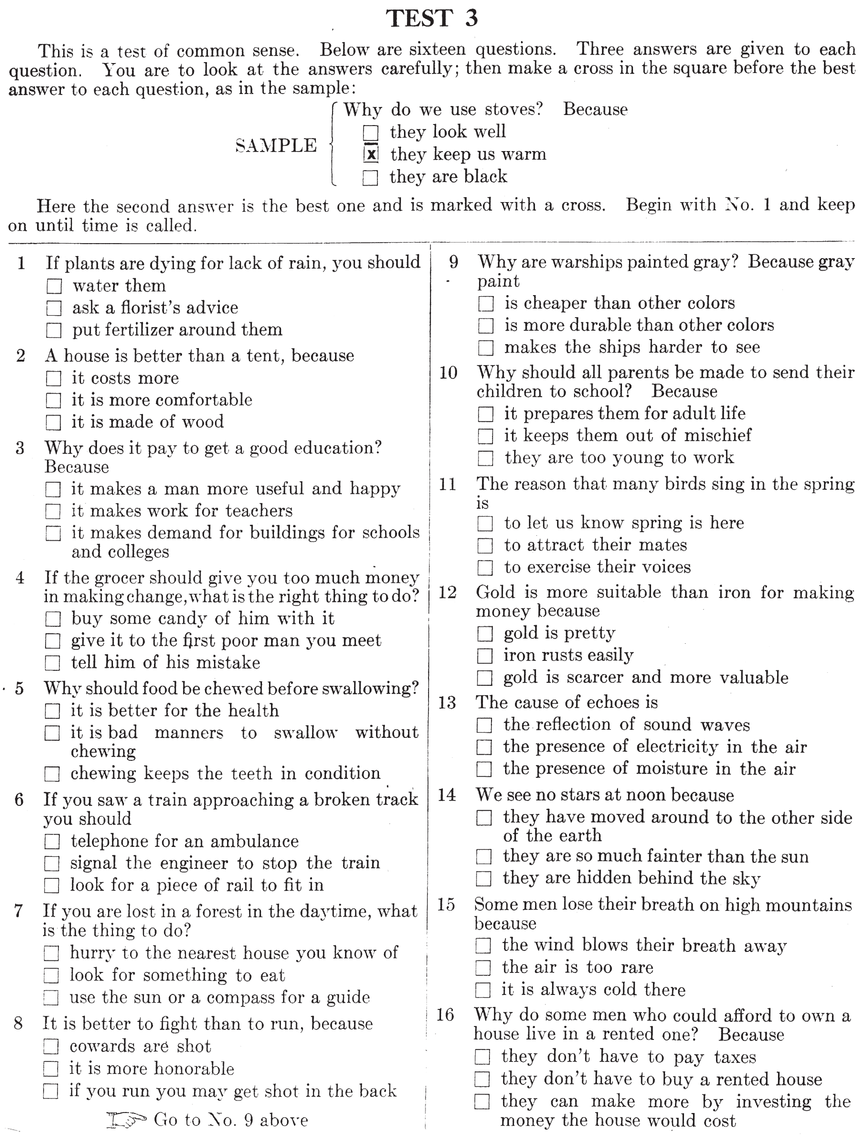
In December 1917, the Surgeon General recommended to the Secretary of War the continuance and extension of psychological examining to the entire Army. In January 1918, the Secretary of War authorized creation of a division of psychology in the Sanitary Corps out of the Surgeon General's office and expansion of the psychological examining program. A school for military psychology was organized with the Medical Officers Training Camp in Fort Oglethorpe, Georgia. While the school was active in 1918, approximately 100 officers of the Sanitary Corps and 300 enlisted men were given special training in military psychology. By the end of the war, psychological examining occurred at 35 army training camps and several army hospitals (Yerkes, 1919, 1920).

Examinations Alpha and Beta

The Army Alpha was intended for fluent and literate English-language speakers. Alpha was typically administered to men who could read newspapers and write letters home in English, with at least a fourth-grade education and five years of residency in the United States (Yerkes, 1921, p. 76). The Army Beta was a largely nonverbal scale intended for examinees with inadequate English-language proficiency or illiteracy (Yoakum & Yerkes, 1920). Beta was also given to low scorers on the Alpha. Men who had difficulty reading or writing in English were to be given both Alpha *and* Beta. E. G. Boring (1961) described the informal process of separating recruits into those suitable for Alpha or Beta: "You went down the line saying 'You read

American newspaper? No read American newspaper?'—separating them in that crude manner into those who could read English and take the Alpha examination and those who must rely for instructions on the pantomime of the Beta examination" (p. 30).

Examination Alpha consisted of eight tests, required approximately 40–50 minutes to administer, and could be given to groups as large as 500. A sample test from Alpha appears in Figure 1.11. Examinees were provided with the test form and a pencil. Responses were scored with stencils based on examinee responses (which usually involved writing numbers, underlining, crossing out, or checking a selected answer). After illiterate and non-English-speaking examinees were removed, and all recruits were seated with pencils and test forms, the examiner said:



TEST 3

This is a test of common sense. Below are sixteen questions. Three answers are given to each question. You are to look at the answers carefully; then make a cross in the square before the best answer to each question, as in the sample:

SAMPLE
Why do we use stoves? Because
☐ they look well
☒ they keep us warm
☐ they are black

Here the second answer is the best one and is marked with a cross. Begin with No. 1 and keep on until time is called.

1 If plants are dying for lack of rain, you should
☐ water them
☐ ask a florist's advice
☐ put fertilizer around them

2 A house is better than a tent, because
☐ it costs more
☐ it is more comfortable
☐ it is made of wood

3 Why does it pay to get a good education? Because
☐ it makes a man more useful and happy
☐ it makes work for teachers
☐ it makes demand for buildings for schools and colleges

4 If the grocer should give you too much money in making change, what is the right thing to do?
☐ buy some candy of him with it
☐ give it to the first poor man you meet
☐ tell him of his mistake

5 Why should food be chewed before swallowing?
☐ it is better for the health
☐ it is bad manners to swallow without chewing
☐ chewing keeps the teeth in condition

6 If you saw a train approaching a broken track you should
☐ telephone for an ambulance
☐ signal the engineer to stop the train
☐ look for a piece of rail to fit in

7 If you are lost in a forest in the daytime, what is the thing to do?
☐ hurry to the nearest house you know of
☐ look for something to eat
☐ use the sun or a compass for a guide

8 It is better to fight than to run, because
☐ cowards are shot
☐ it is more honorable
☐ if you run you may get shot in the back

☞ Go to No. 9 above

9 Why are warships painted gray? Because gray paint
☐ is cheaper than other colors
☐ is more durable than other colors
☐ makes the ships harder to see

10 Why should all parents be made to send their children to school? Because
☐ it prepares them for adult life
☐ it keeps them out of mischief
☐ they are too young to work

11 The reason that many birds sing in the spring is
☐ to let us know spring is here
☐ to attract their mates
☐ to exercise their voices

12 Gold is more suitable than iron for making money because
☐ gold is pretty
☐ iron rusts easily
☐ gold is scarcer and more valuable

13 The cause of echoes is
☐ the reflection of sound waves
☐ the presence of electricity in the air
☐ the presence of moisture in the air

14 We see no stars at noon because
☐ they have moved around to the other side of the earth
☐ they are so much fainter than the sun
☐ they are hidden behind the sky

15 Some men lose their breath on high mountains because
☐ the wind blows their breath away
☐ the air is too rare
☐ it is always cold there

16 Why do some men who could afford to own a house live in a rented one? Because
☐ they don't have to pay taxes
☐ they don't have to buy a rented house
☐ they can make more by investing the money the house would cost

FIGURE 1.11. The Army Examination Alpha Practical Judgment Test. Soldiers were allowed 1½ minutes for this test. From Yerkes (1921). In the public domain.

Attention! The purpose of this examination is to see how well you can remember, think, and carry out what you are told to do. We are not looking for crazy people. The aim is to help find out what you are best fitted to do in the Army. The grade you make in this examination will be put on your qualification card and will also go to your company commander. Some of the things you are told to do will be very easy. Some you may find hard. You are not expected to make a perfect grade, but do the very best you can. (Yoakum & Yerkes, 1920, p. 53; emphasis added)

Beta was typically administered with task performance modeled through pantomimed demonstrations and some brief verbal directions (e.g., "Fix it!" while pointing to the incomplete pictures

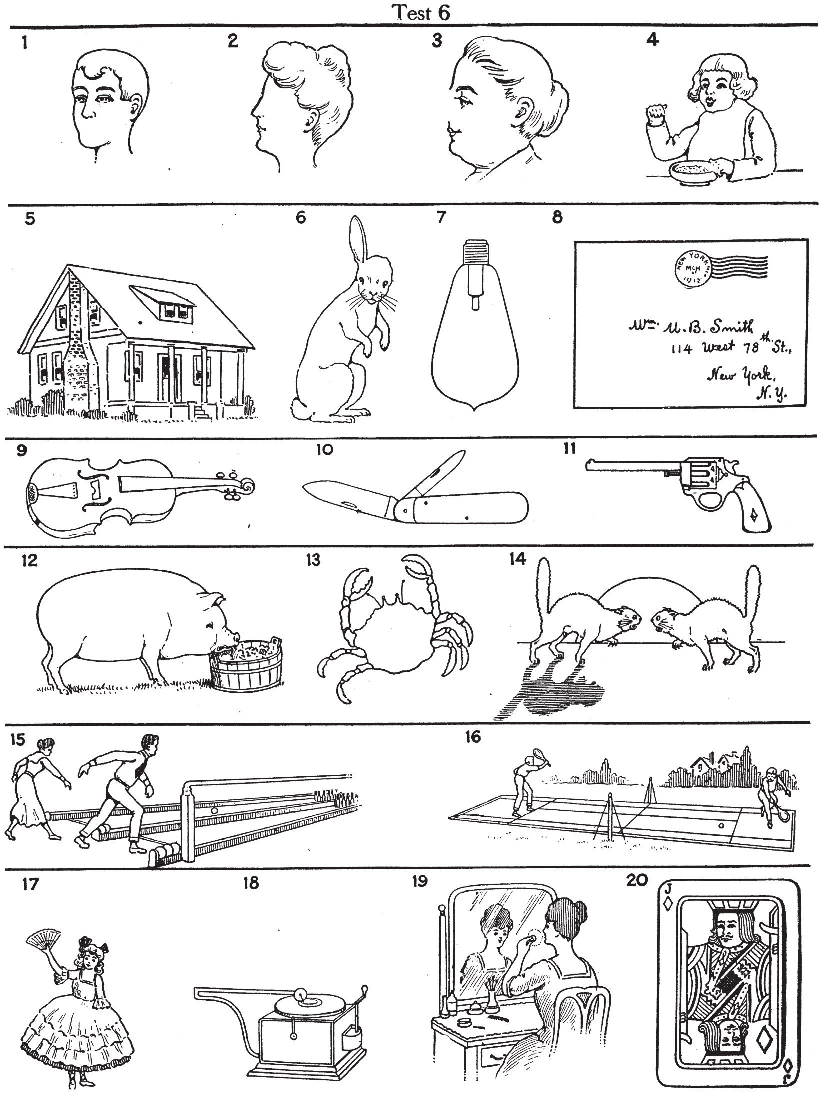


FIGURE 1.12. The Army Examination Beta Picture Completion Test. Instructions: "This is Test 6 here. Look. A lot of pictures . . . Now watch." Examiner points to separate sample at front of room and says to Demonstrator, "Fix it." After pausing, the Demonstrator draws in the missing part. Examiner says, "That's right." The demonstration is repeated with another sample item. Then Examiner points to remaining drawings and says, "Fix them all." Demonstrator completes the remaining problems. When the samples are finished, Examiner says to all examinees, "All right. Go ahead. Hurry up!" At the end of 3 minutes, Examiner says, "Stop!" From Yerkes (1921). In the public domain.

on Pictorial Completion; Yoakum & Yerkes, 1920, p. 87). A sample test from Beta appears in Figure 1.12. Administered to groups as large as 60, it was typically completed in about 50–60 minutes and required a blackboard with chalk, eraser, curtain, and chart (on a roller to show 27 feet of pictorial instructions in panels). The examiner gave brief instructions, while a demonstrator pantomimed how to complete tasks correctly on the blackboard panels corresponding to the test response form. There were seven final tests in Beta.

Reports of intelligence ratings derived from test scores were typically made within 24 hours and entered on service records and qualification cards that were delivered to commanding officers and personnel officers. Individual examinations with the Yerkes–Bridges Point Scale, the Stanford–Binet Intelligence Scale, or the Army Performance Scale were usually reserved as checks on questionable or problematic group examination results. The test scores yielded grade ratings from A to E, with the following descriptions drawn from Yoakum and Yerkes (1920):

- *A (Very Superior).* An A grade was earned by only 4–5% of drafted men. These men were considered to have high officer characteristics when they were also endowed with leadership and other necessary qualities. They were shown to have the ability to make a superior record in college or university.
- *B (Superior).* A B grade was obtained by 8–10% of examinees. This group typically contained many commissioned officers, as well as a large number of noncommissioned officers. A man with B-level intelligence was capable of making an average record in college.
- C+ *(High Average).* The C+ group included 15–18% of all soldiers and contained a large number of recruits with noncommissioned officer potential and occasionally commissioned officer potential, when leadership and power to command were rated as being high.
- C *(Average).* The C group included about 25% of soldiers who made excellent privates, with a certain amount of noncommissioned officer potential.
- C– *(Low Average).* The C– group included about 20% of soldiers; these men usually made good privates and were satisfactory in routine work, although they were below average in intelligence.
- *D (Inferior).* Men in the D group were likely to be fair soldiers, but they were usually slow in learning and rarely went above the rank of private. They were considered short on initiative and required more than the usual amount of supervision.
- *D– and E (Very Inferior).* The last group was divided into two classes: D–, consisting of men who were very inferior in intelligence but who were considered fit for regular service, and E, consisting of men whose mental inferiority justified a recommendation for development battalion, special service organization, rejection, or discharge. The majority of men receiving these two grades had a mental age below 10 years. Those in the D– group were thought only rarely able to go beyond the third or fourth grade in primary school, however long they attended.

To his chagrin, Yerkes's division of psychology was appointed to the Sanitary Corps instead of the Medical Corps (where he had hoped psychologists would be classified), but he was still a member of the Surgeon General's staff. Yerkes encountered near-continual resistance to the testing program from the military establishment, and the Army mental examiners often had inadequate testing facilities or faced a deeply entrenched military establishment that did not see the value in intelligence tests. In response to queries about testing from Army officers, Yerkes gave the psychological examiners standard responses to provide as needed—specifying the potential value of the Alpha and Beta in military decision making, but also emphasizing that test scores alone should not constitute the sole basis for making military service decisions:

> The rating a man earns furnishes a fairly reliable index of his ability to learn, to think quickly and accurately, to analyze a situation, to maintain a state of mental alertness, and to comprehend and follow instructions. The score is little influenced by schooling. Some of the highest records have been made by men who had not completed the eighth grade. . . . The mental tests are not intended to replace other methods of judging a man's value to the service. It would be a mistake to assume that they tell us infallibly what kind of soldier a man will make. They merely help to do this by measuring one important element in a soldier's equipment, namely, intelligence. They do not measure loyalty, bravery, power to command, or the emotional traits that make a man "carry on." (Yoakum & Yerkes, 1920, pp. 22–24)

According to Yerkes (1918a, 1918b), the Army testing program was tasked with four military objectives: (1) aiding in the identification and elimination of "mentally defective" men who were unfit for service; (2) identifying men of exceptional intelligence for special responsibilities or possible officer training; (3) balancing military units in terms of intelligence; and (4) assisting personnel officers in the camps with the classification of men. The tests appear to have functioned well in identifying recruits of very high intelligence and very low intelligence, although research findings showed a disproportionate number of minority, foreign-born, and illiterate recruits as having very low intelligence, in spite of efforts to correct for the language and literacy demands of the Alpha with the Beta (Yerkes, 1921). There is little evidence that the Alpha and Beta were effectively used to balance the intellectual composition of military units. Although Army battalions ideally should be comparable and interchangeable in terms of effectiveness, individual battalion commanders no doubt wanted the best available recruits and held onto the recruit who received A and B grades. Yoakum and Yerkes (1920) described the challenge:

> In making assignments from the Depot Brigade to permanent organizations it is important to give each unit its proportion of superior, average, and inferior men. If this is left to chance there will inevitably be "weak links" in the army chain. Exception to this rule should be made in favor of certain arms of the service which require more than the ordinary number of mentally superior men; for example, Signal Corps, Machine Gun, Field Artillery and Engineers. These organizations ordinarily have about twice the usual proportion of "A" and "B" men and very much less than the usual proportion of "D" and "D–" men. (p. 25)

With respect to the final objective, of assisting with personnel decisions, the Army mental tests provided a single piece of information—intelligence level—that was of considerable value. It would be Walter Dill Scott's Army Committee on Classification of Personnel that provided a context for the Army mental test scores in making military personnel decisions.

Scott's System of Personnel Selection

Walter Dill Scott (1869–1955) was a pioneering industrial psychologist, applying principles of experimental methodology to practical business problems (Ferguson, 1962, 1963a; Lynch, 1968; Strong, 1955). An interest in identifying and selecting successful salesmen led Scott (1916) to develop a multimethod quantitative personnel selection approach consisting of historical information from former employers (i.e., a model letter soliciting information and ratings, which was included in a *personal history record*); performance on tests of intellectual ability devised by Scott; performance on tests of technical ability (written calculation and clerical transcription) scored for accuracy, speed, and legibility; and multiple ratings based on a series of "interviews" with trained raters (in which the examinee was to introduce himself and try to sell merchandise to a series of interviewers posing as merchants). In 1916, Walter V. Bingham, the head of the division of applied psychology at Carnegie Institute of Technology, offered Scott the opportunity to direct the newly formed Bureau of Salesmanship Research and to become the first professor of applied psychology in the United States (Ferguson, 1964a). In a remarkable partnership between the Carnegie Bureau and 30 large national businesses, Scott had the opportunity to test his personnel selection methods with the hiring of 30,000 new salesmen each year, and comparison of personnel decisions against actual sales performances. It was a highly successful arrangement, possibly unprecedented in the history of psychology, and Scott's work was well regarded by the business community.

The history of Scott's personnel selection system in the military may be found in several resources, including official accounts from the Army (Committee on Classification of Personnel in the Army, 1919a, 1919b) and contemporary accounts from von Mayrhauser (1987, 1989); the most in-depth accounts are available from Ferguson (1963b, 1963c, 1964b, 1964c). When war was declared in 1917, Scott realized that his existing methods could readily be applied to personnel selection in the military. At the Hotel Walton meeting on April 21, Scott objected to Yerkes's positions on the war as an opportunity to advance the prominence of psychology. Scott and Bingham were the only psychologists at the meeting with experience in personnel selection, and they knew that Scott's system already had demonstrated effectiveness. In Scott's system, the mental test results had value, but Scott and Bingham were certain that interview ratings would be more important in the selection of officers. Moreover, Scott did not want to subordinate psychologists to psychiatrists, but instead thought they should report to a high official such as the Secretary of War. Offended by Yerkes's self-serving agenda, Scott and Bingham walked out.

Scott decided to launch his own initiative, independent of Yerkes. Scott revised his existing salesman rating scale, completing A Rating Scale for Selecting Captains by May 4, 1917. He shared with it several psychologists and asked Edward L. Thorndike to write a letter of support to Frederick P. Keppel, who had been a dean at Columbia and was now Third Assistant Secretary of War. Keppel invited Scott to Washington, D.C., where Scott presented his scale, did some testing with it, made some improvements, and overcame institutional resistance (including having his scale ripped "to tatters" by officers in Plattsburg who had been invited to suggest improvements [Committee on Classification of Personnel in the Army, 1919a, p. 50]). When he finally met directly with Secretary of War Newton D. Baker, Scott suggested that a group of psychologists and experienced employment managers be appointed to advise the Army on personnel selection, volunteering to assemble such a group. On August 5, 1917, Scott received approval of a plan to include scientific staff, a group of civilian experts for research and planning, and a board of military representatives to bring problems to the Committee on Classification of Personnel in the Army and help implement its recommendations. Within 6 weeks, the committee created and implemented a classification and assignment system for the Army where none had existed before. It was the largest program of personnel selection ever attempted up to that time. Scott was the committee's director, Bingham was its executive secretary, and they answered directly to the Adjutant General of the Army. They began with a single office that grew to 11 rooms in the War Building (then the central hub of military decision making, housing the offices of the Secretary of War, Chief of Staff, and Adjutant General).

Scott's personnel system for the army included a Soldier's (or Officer's) Qualification Card, grades on the Army mental tests and proficiency on specialized trade tests, and the Officers' Rating Scale in various forms for noncommissioned and commissioned officers. The Qualification Card relied on interviews to obtain occupational history, education, leadership experience, and military history. Test scores on the Army mental tests ranged from A through E and were provided by Yerkes's examiners. For recruits claiming experience in specific trades of value to the military, Scott's committee oversaw development of special trade tests that measured specific proficiencies, generating a range of scores from "Expert" through "Novice." Finally, the Officers' Rating Scale became the main tool used for the selection and promotion of officers, with all officers receiving quarterly ratings by the end of the war. This scale involved ratings in five areas: physical qualities, intelligence, leadership, personal qualities, and general value to the service.

If the Army mental tests were intended to measure general intelligence, the trade tests measured specific ability and knowledge related to the performance of several hundred specific occupations needed by the military. Vocational training was impractical, and men were frequently found to have misrepresented their civilian jobs and skills on the Soldier's Qualification Card. In order to identify personnel requirements for specific jobs, occupational titles were compiled and detailed personnel specifications were prepared by Scott's team. With the criteria of covering all trades rapidly and objectively by examiners who did not have to be knowledgeable about each individual trade, a series of oral, picture, and/or performance trade tests were administered and scored so that the number of questions correctly answered predicted status as a novice, apprentice, journeyman, or expert. There were 84 trade tests for jobs as varied as butchers, electricians, pipefitters, and most other specialties needed by the military. For example, the trade test officer issued driver's licenses for all drivers of touring cars, motorcycles, and trucks (Committee on Classification of Personnel in the Army, 1919a, p. 135). Examples of trade tests appear in the committee's personnel manual (1919b), and after the war compilations of trade tests were published in Chapman (1921) and Toops (1921).

From the military's perspective, it is clear that Scott's personnel selection procedures were much more valued than Yerkes's testing program. At the end of the war, Yerkes's Division of Military Psychology was summarily and completely shut down. Scott's Committee on Classification of Personnel in the Army was transferred to the General Staff and merged with the newly created Central Personnel Branch, in effect institutionalizing Scott's personnel selection procedures within the Army (Yerkes, 1919). The War Department awarded Scott the Distinguished Service Medal when he left the service in 1919, and asked *him* to convey its appreciation to Major Yerkes. Scott became the highest-ranking psychologist in the Army, having been commissioned as a colonel in the Adjutant General's Department in November 1918.

Undoubtedly, multiple factors explained the military's different responses to Scott and to Yerkes. Scott adapted his system to military needs, while Yerkes sought to impose academic know-how on an unreceptive army. Scott partnered with military personnel, while Yerkes's examiners were seen as unwelcome, externally imposed "pests" and "mental meddlers" by camp commanders (cited by Kevles, 1968, p. 574). No less than three independent investigations were launched by Army personnel suspicious of Yerkes and his men (Zeidner & Drucker, 1988, p. 11). Scott worked initially in an advisory capacity, while Yerkes continually sought authority. Scott had considerable personal skills in persuasion and salesmanship (Strong, 1955), whereas Yerkes was a strong planner but a poor manager (Dewsbury, 1996). Scott's system had substantial and understandable face validity for military performance, while Yerke's Examinations Alpha and Beta did not have obvious relevance for soldiering. From the perspective of the history of intelligence testing, however, a broader argument should be considered: Yerkes's committee created the tests and his examiners generated scores, but Scott's committee provided a systematic context (including recruits' history and specific skills) within which the test scores made sense and could be used to make practical decisions by teams of military personnel not schooled in psychology.

World War II Assessment Procedures

In World War II, the plan developed by Scott was streamlined and implemented again, this time with Walter V. Bingham in charge of the personnel system and mental tests (Bingham, 1942, 1944). Bingham served as chair of the Committee on Classification of Military Personnel, the committee having been appointed in 1940 by the National Research Council at the request of the Adjutant General, months before passage of the Selective Service and Training Act (Bingham, 1944). In contrast to the unwelcoming reception Yerkes had received in World War I, Bingham and the infrastructure he established were valued by the Army (Zeidner & Drucker, 1988). The Army Alpha was replaced by the Army General Classification Test, a shorter version of the Alpha; initial versions were administered in spiral omnibus form in about 40 minutes, and there were four parallel forms (Bittner, 1947; Staff, Personnel Research Section, 1945). Conceptualized as a test of "general learning ability," it consisted of vocabulary items (intended to tap verbal comprehension), arithmetic problems (thought to tap quantitative reasoning), and block-counting problems (intended to measure spatial thinking), all endeavoring to deemphasize speed somewhat. Grades of A to E were replaced with five levels of learning readiness, I to V. Terms like *mental age* and *IQ* were largely eliminated from group tests.

As in World War I, specialized Non-Language Tests were developed and standardized to test illiterate and non-English-speaking recruits (Sisson, 1948). In 1944, the Wechsler Mental Ability Scale, also known as the Army Wechsler, was replaced by the Army Individual Test, which included three verbal subtests (Story Memory, Similarities–Differences, and Digit Span) and three nonverbal subtests (Shoulder Patches, Trail Making, and Cube Assembly) (Staff, Personnel Research Section, 1944). Rapaport (1945) praised the Army Individual Test, noting that it was "admirably well-constructed" (p. 107) as a measure of general mental ability, but he also raised cautions about its diagnostic limitations. Numerous specialized trade tests and aptitude tests (e.g., mechanical aptitude, clerical aptitude) were developed as well. Most importantly, the Personnel Research Section of the Adjutant General's Office that Bingham established quickly earned the military's trust, leading to the creation of the Army Research Institute (which still exists). One of Bingham's charges was to put the "brakes on projects . . . of great scientific interest" if they did not help the Army "toward early victory" (Zeidner & Drucker, 1988, p. 24). It was a lesson in military priorities that Yerkes, whose agenda included advancing psychology as a science, may not have learned in World War I.

David Wechsler: The Practical Clinician

The practice of contemporary applied intelligence assessment in the second half of the 20th century may arguably be said to have been most strongly and directly influenced by the measurement instruments developed by David Wechsler (1896–1981). Beginning in the 1960s, the Wechsler intelligence scales supplanted the Stanford–Binet as the leading intelligence tests (Lubin, Wallis, & Paine, 1971). Surveys of psychological test usage decades after his death show that Wechsler's intelligence tests continue to dominate intelligence assessment among school psychologists, clinical psychologists, and neuropsychologists (Camara, Nathan, & Puente, 2000; Wilson & Reschly, 1996). Early in the 21st century, the Wechsler scales for adults, children, and preschoolers are still taught at much higher frequencies than any other intelligence tests in North American clinical and school psychology training programs (Cody & Prieto, 2000; Ready & Veague, 2014).

In many ways, David Wechsler was an unexpected success—coming to the United States as a child amid a flood of Eastern European immigrants, losing both parents by the age of 10, compiling a relatively ordinary academic record in high school and college (while graduating early), registering as a conscientious objector to the 1917 World War I draft (a risky decision at the time, when "slackers" were universally condemned), and not having become a naturalized citizen by the time of the war. Even so, these risk factors may have been somewhat ameliorated by the guidance of an accomplished older brother (pioneering neurologist Israel S. Wechsler), who became his caretaker and role model; by the opportunity to provide military service as an Army mental test examiner, thereby quickly learning about assessment and making key professional contacts; and by receiving his graduate education and professional psychology training at an opportune time and place in the development of what eventually would become "clinical" psychology.

Wechsler's Early Life and Education

David Wechsler was the youngest of three boys and four girls born in Romania to Moses Wechsler, a merchant, and Leah (Pascal) Wechsler, a shopkeeper (see, e.g., Matarazzo, 1972). At the time the Wechsler family emigrated in 1902, poor harvests in 1899 and 1900 had produced famine and an economic downturn in Romania, worsening the scapegoating of Jews and resulting in severe applications of existing anti-Jewish decrees (e.g., Kissman, 1948). The family's new life on the Lower East Side of New York City was marked by tragedy. Within 5 years of their arrival, both Moses and Leah Wechsler passed away from malignancies ("Deaths reported Aug. 23," 1903; Wechsler, 1903; Wexler, 1906). The effects of these losses upon the family, particularly David as the youngest, are likely to have been profound. By 1910, David's older brother Israel S. Wechsler, then a physician in general practice, appears to have taken over as the head of the family.

Wechsler was educated in the public schools on the Lower East Side (see Wechsler, 1925, p. 181). After high school graduation, Wechsler attended the College of the City of New York (now known as City College) from 1913 to 1916, graduating with an AB degree at the age of 20 ("206 get degrees at City College," 1916). Following his graduation, Wechsler enrolled in graduate studies in psychology at Columbia University, where he would complete his master's degree in 1917 and his doctorate in 1925. His decision to continue his education beyond college had family precedent; Israel had graduated from New York University and Bellevue Medical College in 1907 at the age of 21. Israel would take a position in neurology at Mount Sinai Hospital in 1916 and begin teaching neurology at the outpatient clinic of the Columbia University College of Physicians and Surgeons in 1917 (Stein, 2004; see also "Israel Wechsler, Neurologist, Dies," 1962). Israel initially intended to become a psychiatrist and was self-taught in psychoanalysis, but personally identified as a neurologist because, as he later explained, "If the brain is the organ of thought and disturbance of its functions expresses itself in disorders which are called neuroses and psychoses, it seemed reasonable and necessary to know neurology" (Wechsler, 1957, pp. 1113–1114). Israel Wechsler was involved in the early-20th-century struggles between psychiatry and neurology, when each medical discipline was vying for control of the care of those with mental illness. David instead pursued psychology, but he would follow his brother's lead in becoming a practicing clinician, a hospital-based academic, and the author of professional textbooks.

Columbia was one of the few major universities that provided graduate experimental psychology training with a willingness to address applied problems, termed *experimental abnormal psychology* by Woodworth (1942, p. 11)—an educational orientation that would eventually evolve into clinical psychology (Routh, 2000). The Columbia graduate psychology department in this era was made up primarily of commuter students "who emerged from the subway for their classes and research and departed immediately into the subway afterwards" (Thorne, 1976, p. 164). Columbia University was the academic home of faculty J. McKeen Cattell (until his dismissal in October 1917), Robert S. Woodworth, and Edward L. Thorndike, three of the most influential psychologists of the early 20th century. "Cattell, Woodworth, and Thorndike were the trio at Columbia," said F. L. Wells, who had worked as an assistant to Cattell and Woodworth, adding, "Cattell might inspire awe, Thorndike admiration, and Woodworth affection. Affection toward Cattell and Thorndike was not possible" (quoted in Burnham, 2003, p. 34).

For his master's thesis, completed (and published as a journal article) in 1917, Wechsler (1917a) patched together a clinical memory battery from existing published and unpublished tests, closely following the memory framework suggested by Whipple (1915). Wechsler spent 2½ months conducting in-depth assessment of six patients with Korsakoff psychosis at the Manhattan State Hospital on Ward's Island. He saw each patient as many as 20 times, and he also had the opportunity to observe psychiatric assessment on the wards. Wechsler's master's thesis represented his first known attempt to build a test battery. He established a pattern he was later to follow with intelligence tests, memory tests, and a failed personality test: that of appropriating practical and clinically useful procedures from other authors, making slight improvements and modifications, and synthesizing them into a battery of his own.

World War I Service

After the U.S. Congress declared war on Germany in April 1917, Wechsler (1917b) completed his required registration for the draft, listing himself as a "Consciencious [*sic*] Objector" and as an alien who was a citizen of Romania, who was disabled by "Near Sightness [*sic*]" and "Physical Unfitness." Wechsler's draft registration thus used multiple methods to avoid being drafted—claiming status as a conscientious objector, claiming exemption from military service by reason of alien (noncitizen) status, and claiming physical deficiencies that would disqualify him for military service. We do not know what motivated David Wechsler to try to avoid military service at age 21, but the public press treated conscientious objectors with contempt, and some were arrested and imprisoned. Even Army mental examiners considered conscientious objector status to be a form of psychopathology (May 1920). Wechsler's status as a noncitizen native of Romania, some 15 years after his arrival in the United States, also put him at risk. As an alien, he could not be drafted, but he could be deported. The U.S. Congress tried to close this draft loophole in response to the perceived "alien slacker" problem, but treaty obligations circumvented final passage ("Alien Slackers May Not Escape Service," 1917; "Pass Alien Slacker Bill," 1918). Within military training camps, however, some officers considered all aliens who had not become naturalized citizens as suspect.

Becoming an Army mental test examiner represented a way by which Wechsler could avoid seeing combat, and it was probably through back-channel communications from his professor Robert S. Woodworth to Robert M. Yerkes that Wechsler was identified as a prospective tester. In May 1918, Yerkes requested in writing that Wechsler and 13 others who had "qualifications for psychological service" be sent authorization for military induction and be assigned for course instruction in military psychology at Camp Greenleaf, Chickamauga Park, Georgia. Shown in Figure 1.13 at the time of his military service, Wechsler reported to the School for Military Psychology, where he was taught the Army Alpha, Army Beta, Stanford–Binet, Yerkes Point Scale, and other tests. Trainees also received instruction in military practices, including military law, field service, honors and courtesies, equipment, and gas attack defense instructions and drills. E. G. Boring, who reported to Camp Greenleaf as a captain in February 1918, described what may have also been Wechsler's experience:

> We lived in barracks, piled out for reveillé, stood inspection, drilled and were drilled, studied testing procedures, and were ordered to many irrelevant lectures. As soon as I discovered that everyone else resembled me in never accomplishing the impossible, my neuroses left me, and I had a grand time, with new health created by new exercise and many good friendships formed with colleagues under these intimate conditions of living. (1961, p. 30)

FIGURE 1.13. David Wechsler at the age of 23, from his 1918 passport application. Wechsler used a program designed to educate World War I veterans in Europe to pursue educational opportunities in France and London, including time with Charles E. Spearman and Karl Pearson. From Wechsler (1918b). National Archives and Records Administration, Washington, D.C. In the public domain.

In May 1918, Congress enacted legislation that allowed aliens serving in the U.S. armed forces to file a petition for naturalization without having made a declaration of intent or proving 5 years' residence (e.g., Scott, 1918). Under this new law, Wechsler became a naturalized citizen in June 1918, with Captain John E. Anderson and Lt. Carl A. Murchison, two psychologists who would have noteworthy careers, serving as his witnesses (Wechsler, 1918b). Wechsler completed his training at Camp Greenleaf in July, was promoted to the rank of corporal, and was assigned to Camp Logan in Houston, Texas, in early August 1918. There he would give individual psychological assessments to recruits who had failed the Alpha and/or the Beta, largely because of limited English proficiency or illiteracy. Conditions at Camp Logan were poor, with inadequate space and support, but the Army examiners administered over 300 individual assessments (Yerkes, 1921, p. 80).

It was during his time as an Army examiner that many of Wechsler's core ideas about assessment were born, especially his idea to construct an intelligence scale combining verbal and nonverbal tests, paralleling the Army Alpha and Army Beta/performance exams (Wechsler, 1981). Most of the assessment procedures appropriated by Wechsler for his intelligence scales appear in Yerkes (1921). Matarazzo (1981) relates that Wechsler realized the value of individual assessment when group tests yielded misleading results, as many of his examinees functioned adequately in civilian life in spite of their low group test scores. Wechsler also reportedly learned the value of nonverbal assessment and the limitations of the Stanford–Binet with adults. He even (Wechsler, 1932) described an approach to profile analysis of Army Alpha subtests—a clear antecedent to the intraindividual (ipsative) profile analyses still used in interpreting the Wechsler intelligence scales.

With the signing of the armistice, Wechsler participated in AEF University, a program created by order of General John J. Pershing and other military leaders to serve the 2 million idle (and bored) American servicemen who remained stationed in Europe, waiting to be shipped home (Cornebise, 1997; "Education for American Soldiers in France," 1919). Although Wechsler had never served overseas, he arranged to spend time in France (December 1918–March 1919) and then in London (March 1919–July 1919) as part of this program. Some 2,000 soldiers attended the Sorbonne, while about 2,000 soldier-students attended British universities, with 725 going to University College London ("U.S. Maintains Great Schools on Foreign Soil," 1919). At University College London, Wechsler had the opportunity to work for 3 months with Charles E. Spearman and to meet Karl Pearson, becoming familiar with Spearman's work on the general intelligence factor and Pearson's correlation statistic, as well as to note their professional rivalry (Wechsler, Doppelt, & Lennon, 1975). Wechsler was honorably discharged from the military in July 1919. Given his efforts to avoid military service in 1917, it might be considered ironic that the skills he acquired and contacts he made during his military service would shape his career in assessment and test development.

From 1919 to 1921, Wechsler studied and conducted research at the University of Montpelier and principally at the Sorbonne, under the supervision of Henri Pieron and Louis Lapicque (Rock, 1956, p. 675; Wechsler, 1925, p. 8). Wechsler used the research to complete his doctorate at Columbia, under the guidance of Robert Woodworth (Wechsler, 1925, p. 8). The opportunity to study at the Sorbonne came through Wechsler's application for an American Field Service fellowship from the Society for American Fellowships in French Universities (Wechsler, 1918b). In its first year (1919–1920), there were eight fellows, one of whom was Wechsler.

Bellevue Psychiatric Hospital and Other Clinical Experiences

After completing his fellowship at the Sorbonne, Wechsler traveled through France, Switzerland, and Italy before reluctantly returning to the United States (Wechsler, 1921). Once he was settled in New York, he began practicing psychology, mostly conducting assessments, in a variety of clinical and industrial settings. His ambivalence about returning, as disclosed to Edwards (1974), was reflected in his 1922 paper on the psychopathology of indecision.

Wechsler spent the summer of 1922 working with F. L. Wells at the Psychopathic Hospital in Boston, followed by 2 years as a psychologist with the New York Bureau of Children's Guidance. The Bureau of Children's Guidance was a psychiatric clinic, operating under the aegis of the New York School of Social Work and reflecting the values of the popular child guidance movement. Directed by Bernard Glueck, the bureau served troubled children referred by school principals or selected teachers for problems in the areas of scholarship, attendance, behavior, or general welfare. It was staffed by social workers, psychiatrists, and psychologists. The bureau emphasized problems with delinquency, with the objective of "a keener understanding of the child as an individual, and assistance to the school in working out needed readjustments, whether they be physical, social or educational" ("Crime Clinics Growing," 1922).

From 1925 to 1927, Wechsler worked with J. McKeen Cattell as acting secretary and research associate of The Psychological Corporation (Wasserman & Maccubbin, 2002). Created by Cattell, The Psychological Corporation did not directly employ any psychologists at the time; instead, consulting psychologists worked in nonsalaried, commission-based arrangements, undertaking projects for businesses and dividing the payment between themselves and the corporation. A 29-year-old David Wechsler, having completed his dissertation, had difficulty finding a job and contacted his old professor, Cattell, who hired him; according to Wechsler, Cattell told him, "You can get the *pro tem* acting secretary here. You have to get your own business and whatever business you get, the company will get half of your remunerations" (Wechsler et al., 1975). Wechsler undertook two known projects at The Psychological Corporation: the development of an automobile driving simulator and psychometric tests for taxicab drivers (Wechsler, 1926) and a tabloid newspaper study with a *New York World* reporter to test the intelligence of Ziegfeld chorus girls with the Army Alpha.

In 1932, following the tragic death of two Bellevue Hospital staff psychologists in a boating accident ("*Sea Fox* Wreckage," 1931), Wechsler was hired as a psychologist by the Psychiatric Division of Bellevue Hospital, New York. Bellevue was the oldest public hospital in the United States, but its psychopathic wing was scheduled for replacement by the Bellevue Psychiatric Hospital, described at its groundbreaking as the "chief battle-ground in the war against diseases of the mind" ("Old Bellevue and New," 1930). When the new unit finally opened in 1933, its capacity was planned at 600 patients to "give wide scope and facility for modern methods of investigating and treating mental disorders" ("A Bellevue Unit Formally Opened," 1933). By 1941, Wechsler had become chief psychologist and a clinical faculty member at the New York University College of Medicine, supervising more than 15 clinical psychologists, five interns, and two research psychologists on grants (Weider, 2006). Wechsler would retire from Bellevue in 1967, after having pioneered the role of the psychologist in a psychiatric hospital (Wechsler, 1944), and his clinical experiences would help him remain oriented to the use of psychological testing as it relates to practical patient care.

Concept of Intelligence

In his earliest scholarly statement on intelligence in his brother's neurology book, Wechsler (1927) ventured a definition: "All definitions of intelligence refer essentially to ability to learn and adapt oneself to new conditions; that is, not knowledge and practical success, but ability to acquire knowledge and ability to cope with experience in a successful way" (p. 105). It is Wechsler's (1939) definition, which built on his previous efforts and borrowed elements from his predecessors, that remains best known among definitions of intelligence:

> Intelligence is the aggregate or global capacity of the individual to act purposefully, to think rationally and to deal effectively with his environment. It is global because it characterizes the individual's behavior as a whole; it is an aggregate because it is composed of elements or abilities which, though not entirely independent, are qualitatively differentiable. By measurement of these abilities, we ultimately evaluate intelligence. But intelligence is not identical with the mere sum of these abilities, however inclusive. (p. 3)

The long-standing popularity of this definition is probably due to the enduring popularity of the Wechsler intelligence scales with which it is associated. The definition reflects Wechsler's generally cautious writing style; it was exceptionally rare that he made any bold statement in writing that might alienate any colleagues. The phrase "aggregate or global capacity" appears to encompass Spearman's general factor, *g*—but Wechsler included an accommodation for the group factors, which, "though not entirely independent, are qualitatively differentiable." According to Wechsler (Wechsler et al., 1975), this definition also subsumes Binet's emphasis on adaptation. The phrase "to deal effectively with his environment" recapitulates Binet's (1911/1916) observation that "Intelligence marks itself by the best possible adaptation of the individual to his environment" (p. 301), as well as the use of adaptation in the definition of intelligence by others. In one of his final publications, Binet (1910) also took the position that intelligence is a dynamic synthesis, more than the different "pieces of the machine" that comprise it; this may have influenced Wechsler's statement that intelligence is more than the sum of its constituent abilities.

Creation and Development of the Wechsler Intelligence Scales

Of course, it is for his intelligence tests that David Wechsler is best remembered. Wechsler's gifts in the area of test development lay in his ability to synthesize the work of others—that is, to recognize clinically useful measurement procedures and to streamline and package them so as to be maximally useful for the practicing psychologist (Wasserman & Kaufman, 2015). His test work was unoriginal, and his intelligence tests consist entirely of tests (sometimes incrementally improved) that were originally devised by other psychologists. Several researchers have sought to trace the origins of the specific Wechsler intelligence subtests (e.g., Boake, 2002; Frank, 1983), a historically important endeavor, but it is notable that from the start Wechsler (1939) openly disclosed the sources he drew upon. As Boake (2002) suggested, it is most unfortunate that the names of the original innovators who created the Wechsler subtest procedures have been forgotten, omitted from mention in contemporary test manuals.

The Bellevue Intelligence Scale was originally subsidized by a Works Progress Administration grant during the Great Depression (Wechsler, 1981; Wechsler et al., 1975). Wechsler (1939, p. 137) reported that the test took 7 years to develop, and it first underwent trials in 1937 and 1938 at the Bellevue Psychiatric Hospital, the Court of General Sessions of New York City, and the Queens General Hospital. The need for a new adult test stemmed largely from the inadequacy of the Stanford–Binet, particularly its poor normative sample for adults, and the poor fit of the Army mental tests for clinical decision making. As the chief psychologist in a large public hospital, Wechsler had the opportunity to appreciate the needs and applications for an adult intelligence test. After careful review, Wechsler essentially cherry-picked his subtests from the most clinically useful and psychometrically adequate tests of his era; he thus provided practitioners with an easy transition to make from using many separate, independently normed tests with a variety of instructions and scoring rules to a single battery of co-normed tests, with streamlined administration and fairly uniform scoring rules. Wechsler acknowledged, "Our aim was not to produce a set of brand new tests but to select, from whatever source available, such a combination of them as would best meet the requirements of an effective adult scale" (1939, p. 78). Most of the standardization sample of 1,586 participants was collected in the city and state of New York; the sample was stratified by age, sex, education, and occupation, but was limited to English-speaking white examinees.

The Bellevue consisted of 10 subtests, with the Vocabulary subtest serving as an alternate. With the exception of a single speeded subtest (Digit Symbol), items on each subtest were sequenced in approximate order of difficulty, from easiest to hardest. Performance on the first five subtests contributed to the Verbal IQ, and performance on the second five subtests contributed to the Performance IQ. Full Scale IQ scores ranged from 28 to 195. Subtest raw scores were converted to a mean of 10 and standard deviation of 3, while IQ scores approximated a mean of 100 and standard deviation of 15. Wechsler's subtests dichotomized the composition of his test battery into Verbal and Performance/nonverbal, just as the Army mental tests had distinguished between the Alpha and the Beta/performance tests. This dichotomy remained of value for the same reasons it was helpful with Army mental testing: It permitted valid assessment of individuals whose intelligence was likely to be underestimated by verbal intelligence tests alone (i.e., those who were poorly educated, from non-English-language origins, or otherwise disadvantaged by language-dependent tests). Moreover, Wechsler considered distinctive Verbal and Performance intelligence tasks to sample behaviors in multiple areas of interest, generating important diagnostic information rather than representing different forms of intelligence (Wechsler, 1939). He considered the Verbal and Performance tests to be equally adequate measures of general intelligence, but he emphasized the importance of appraising people "in as many different modalities as possible" (Wechsler et al., 1975, p. 55).

The 1939 test battery (and all subsequent Wechsler intelligence scales) also offered a deviation IQ, the index of intelligence based on statistical distance from the normative mean in standardized units, as Arthur Otis (1917) had proposed. Wechsler deserves credit for popularizing the deviation IQ, although the Otis Self-Administering Tests and the Otis Group Intelligence Scale had already used similar deviation-based composite scores in the 1920s. Inexplicably, Terman and Merrill made the mistake of retaining a ratio IQ (i.e., mental age/chronological age) on the 1937 Stanford–Binet, even though the method had long been recognized as producing distorted IQ estimates for adolescents and adults (e.g., Otis, 1917). Terman and Merrill (1937, pp. 27–28) justified their decision on the dubious ground that it would have been too difficult to reeducate teachers and other test users familiar with the ratio IQ.

Wechsler first introduced the Bellevue Intelligence Scale at a meeting at the New York Academy of Medicine in 1937, and the first edition of *The Measurement of Adult Intelligence*—which would include the manual for the test soon known as the Wechsler–Bellevue Form I—was published in 1939. Early after its publication, Wechsler was approached by George K. Bennett, director of the Tests Division of The Psychological Corporation, who was impressed by the test and asked to produce the test materials (Edwards, 1974). Critics generally praised the "organization of well-known tests into a composite scale" with "considerable diagnostic as well as measurement value" (Lorge, 1943, p. 167), but Wechsler was faulted on technical errors (Anastasi, 1942; Cureton, 1941; McNemar, 1945) and theoretical shortcomings (e.g., Anastasi, 1942; Cronbach, 1949). Figure 1.14 shows Wechsler in the 1940s, after his test had become a success.

FIGURE 1.14. David Wechsler was chief psychologist at New York's Bellevue Psychiatric Hospital when he published his Bellevue Intelligence Scale (later known as the Wechsler–Bellevue), which quickly became the intelligence test of choice for adults. Reprinted by courtesy of the late Arthur Weider.

Among practicing psychologists and researchers working with adults, the Wechsler–Bellevue was a resounding success. In his review of research on the Wechsler–Bellevue in its first 5 years, Rabin (1945) concluded:

> The Wechsler–Bellevue Scales have stimulated considerable psychometric research and have supplanted some time-honored diagnostic tools. The reliability and validity of Wechsler's scales, as a whole and in part, have been proved in several studies. The consensus of opinion is that the test correlates highly with some of the best measures of intellect and that it tends to differentiate better than other measures between the dull and feebleminded. (p. 419)

In an update 6 years later, Rabin and Guertin (1951) noted the "vast popularity and wide usage of the test" (p. 239) and a "veritable flood" of research (p. 211), making the Wechsler–Bellevue "a commonly used measuring rod for comparison and validation, if not actual calibration of newer and more recent techniques" (p. 239).

From 1941 to 1945, Wechsler served as an expert civilian consultant to the Adjutant General's Office, preparing the Wechsler Mental Ability Scale, Form B (Wechsler, 1942, cited by Altus, 1945), also known as the Army Wechsler, and the Wechsler Self-Administering Test. These tests appear to have been of limited use for the military, in large part because they were too difficult for many Army recruits. The Wechsler Mental Ability Scale, Form B is of interest because it consisted of seven Verbal and nine Performance subtests, including Mazes and Series Completion (Altus, 1945), signaling possible additions to the battery. Wechsler also taught in the Army Psychological Training Program (Seidenfeld, 1942).

In the years and decades after the war, Wechsler developed the Wechsler–Bellevue Form II (Wechsler, 1946), the Wechsler Intelligence Scale for Children (WISC; Wechsler, 1949), the Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1955), and the Wechsler Preschool and Primary Scale of Intelligence (WPPSI; Wechsler, 1967). Although David Wechsler died in 1981, most of these tests have gone through multiple editions, with staff test development specialists and external expert advisors substituting for a living author in recent decades. In 1975, Wechsler expressed support for measuring intelligence in individuals older than age 65 "without exposing the older person to tests involving speed, perception, and so forth." He proposed to call this test the Wechsler Intelligence Scale for the Elderly, or the WISE (Wechsler et al., 1975; also D. O. Herman, personal communication, November 9, 1993). Wechsler never proposed or wrote about achievement tests or nonverbal tests like those that currently carry his name.

In creating his intelligence scales, Wechsler combined popular and clinically useful existing tests into a streamlined, well-organized, and psychometrically innovative battery. Although his tests have become established as industry standards over many decades, Chattin and Bracken (1989) surveyed practicing school psychologists and reported that efficiency and practicality remain the central reasons why the Wechsler intelligence scales remain popular.

LOOSE THREADS: RESOLVED AND UNRESOLVED ISSUES IN INTELLIGENCE TESTING

Students of history are likely to find intelligence and its assessment a fascinating and frustrating subject—full of remarkable characters and events like those I have described—but also with many problems that surface over and over again. Because intelligence testing is a young science, it should be no surprise that so many strands in its story remain loose and unresolved, and there is sufficient diversity in thought among psychologists that even the most scientifically proven ideas will have dissenters. At the same time, it does not seem scientifically unreasonable to expect at some point a consensus-based definition of *intelligence,* agreement on the existence of a general factor of intelligence, and establishment of a uniform framework for understanding the structure of human cognitive abilities (all of which are discussed below). The historical association of intelligence testing with eugenics, however, is an ideological problem that may be harder to resolve; it may forever taint the tests with the appearance of social inequity and racism, in spite of many efforts to enhance the fairness of intelligence tests. In this section, I describe a few of many loose thematic threads that have contributed to breaks in the fabric of applied intelligence testing from its early days.

Before I begin describing long-standing unresolved issues in intelligence, it may be helpful first to note areas that appear to be resolved. In response to the public controversy associated with Herrnstein and Murray's book *The Bell Curve* (1994), Linda S. Gottfredson of the University of Delaware contacted an editor at the *Wall Street Journal,* who agreed to publish a statement signed by experts about mainstream scientific thinking on intelligence. Gottfredson drafted the statement, had it reviewed by several authorities, and solicited signatures of agreement from experts across psychology and other disciplines. The resulting statement with 25 conclusions, "Mainstream Science on Intelligence," was published in late 1994 with 52 signatories (Gottfredson, 1994); it was later reprinted with supplemental information as an editorial in the journal *Intelligence* (Gottfredson, 1997). In another response to Herrnstein and Murray's book, the APA Board of Scientific Affairs created a task force to issue an authoritative scientific statement about intelligence and its assessment, titled "Intelligence: Knowns and Unknowns" (Neisser et al., 1996). These two statements represent relatively rare scientific consensus statements about intelligence in the history of psychology. Ironically, there are many areas in which they appear to disagree.

The Definition of *Intelligence*

An initial step in any scholarly endeavor is to define one's terms, but the term *intelligence* still has no consensus-based definition. Efforts to arrive at a consensus date back about a century, as do criticisms that "psychologists have never agreed on a definition" (Lippmann, 1922c, p. 213). In a frequently quoted but much reviled definition, E. G. Boring (1923) wrote:

> Intelligence as a measurable capacity must at the start be defined as the capacity to do well in an intelligence test. Intelligence is what the tests test. This is a narrow definition, but it is the only point of departure for a rigorous discussion of the tests . . . no harm need result if we but remember that measurable intelligence is simply what the tests of intelligence test, until further scientific observation allows us to extend the definition. (p 35)

The failure to arrive at a consensus on defining *intelligence* after a century of research constitutes one of the most surprising loose threads in the history of psychology. Terman (1916) demurred, essentially arguing that we can work with the construct of intelligence without arriving at a definition:

> To demand, as critics of the Binet method have sometimes done, that one who would measure intelligence should first present a complete definition of it, is quite unreasonable. As Stern points out, electrical currents were measured long before their nature was well understood. Similar illustrations could be drawn from the processes involved in chemistry, physiology, and other sciences. In the case of intelligence it may be truthfully said that no adequate definition can possibly be framed which is not based primarily on the symptoms empirically brought to light by the test method. (p. 44)

As demonstrated in the statements above, Boring and Terman expected that research would eventually lead to a definition of *intelligence*. How much longer must we wait?

As we have reported, the association of intelligence with evolutionary *adaptation* dates back to Spencer (1855), who described intelligence as "an adjustment of inner to outer relations" (p. 486). This definition may be understood as suggesting that intelligence confers a capacity to adapt to environmental change, but principles of neo-Darwinian evolution hold that natural selection favors adaptations that enhance survival and reproductive fitness. In order to validate a definition of intelligence featuring adaptation, then, the logical and empirical question is whether intelligence confers any advantages in terms of longer lifespans, fecundity, or other aspects of reproductive fitness. Studies relating intelligence to evolutionary fitness (e.g., family size, number of children) date back to the 1930s, and clearly a meta-analysis is needed to make sense of the many contradictory findings. Gottfredson (2007) recently reported evidence that higher intelligence may improve overall survival rate, and that lower intelligence may be associated with a disproportionately elevated risk of accidental death. Together with colleagues, she has also reported findings of a fitness factor that is related to intelligence (Arden, Gottfredson, Miller, & Pierce, 2009).

Several formal meetings or print symposia have sought a definition of *intelligence,* and the clear-cut conclusion from these efforts is that the experts do not agree on a definition. A list of proposed definitions for the term appears in Table 1.2. The earliest symposium I can identify, entitled "Instinct and Intelligence" (e.g., Myers, 1910), was held in London in July 1910, at a joint meeting of the Aristotelian and British Psychological Societies and the Mind Association, with resulting papers appearing in the *British Journal of Psychology*. The best-known print symposium is "Intelligence and Its Measurement: A Symposium," appearing in the *Journal of Educational Psychology* (Peterson, 1921; Pintner, 1921; Thorndike, 1921). The symposium asked 17 leading investigators explicitly what they conceived intelligence to be. Another symposium, "The Nature of General Intelligence and Ability," was conducted at the Seventh International Congress of Psychology, held at Oxford University in 1923 (e.g., Langfeld, 1924). In a follow-up to the 1921 *Journal of Educational Psychology* symposium, Sternberg and Detterman (1986) asked 25 authorities to write essays conveying what they believed intelligence to be. Sternberg and Berg tabulated facets of the definitions provided: In descending order, the most frequent attributes in definitions of intelligence were higher-level cognitive functions (50%), that which is valued by culture (29%), executive processes (25%), elementary processes (perception, sensation, and/or attention; 21%), knowledge (21%), and overt behavioral manifestations of intelligence (such as effective or successful responses; 21%). By comparison, the most frequent attributes in definitions from the 1921 symposium were higher-level cognitive functions (57%), adaptation (29%), ability to learn (29%), physiological mechanisms (29%), elementary processes (21%), and overt behavioral manifestations of intelligence (21%). Even efforts to seek definitions of intelligence among laypeople have found that definitions vary; moreover, people can be self-serving and seem to offer definitions that also capture some quality readily found in themselves (e.g., Gay, 1948).

Never one to embrace diverse perspectives, Charles E. Spearman (1927) disparaged "repeated recourse to symposia" (p. 8) and surveys of expert opinion in efforts to define intelligence:

> Chaos itself can go no further! The disagreement between different testers—indeed, even the doctrine and the practice of the selfsame tester—has reached its apogee. If they still tolerate each other's proceedings, this is only rendered possible by the ostrich-like policy of not looking facts in the face. In truth, "intelligence" has become a mere vocal sound, a word with so many meanings that it finally has none. (p. 14)

Jensen (1998) echoed Spearman's sentiment, recommending that psychologists "drop the ill-fated word from our scientific vocabulary, or use it only in quotes, to remind ourselves that it is not only scientifically unsatisfactory but wholly unnecessary" (p. 49).

TABLE 1.2. Selected Definitions of Intelligence (Arranged Chronologically)

Herbert Spencer (1855): “Instinct, Reason, Perception, Conception, Memory, Imagination, Feeling, Will, &c., &c., can be nothing more than either conventional groupings of the correspondences; or subordinate divisions among the various operations which are instrumental in effecting the correspondences. However widely contrasted they may seem, these various forms of intelligence cannot be anything else than either particular modes in which the adjustment of inner to outer relations is achieved; or particular parts of the process of adjustment” (p. 486).

Alexander Bain (1868): “The functions of Intellect, Intelligence, or Thought, are known by such names as Memory, Judgment, Abstraction, Reason, Imagination” (p. 82).

Hermann Ebbinghaus (1908): “Intelligence means organization of ideas, manifold interconnection of all those ideas which ought to enter into a unitary group because of the natural relations of the objective facts represented by them. The discovery of a physical law in a multitude of phenomena apparently unrelated, the interpretation of an historical event of which only a few details are directly known, are examples of intelligence thought which takes into consideration innumerable experiences neglected by the less intelligent mind. Neither memory alone nor attention alone is the foundation of intelligence, but a union of memory and attention” (pp. 150–151).

Charles S. Myers (1910): “As the organism becomes endowed with an increasingly larger number of mutually incompatible modes of reaction, the intelligent aspect apparently comes more and more to the fore while the instinctive aspect apparently recedes *pari passu* into the background” (p. 214).

C. Lloyd Morgan (1910): “I regard the presence of implicit expectation (in the lower forms) or explicit anticipation (in the higher forms) as distinguishing marks or criteria of intelligence. In other words for the intelligent organism the present experience at any given moment comprises more or less ‘meaning’ in terms of previously-gotten experience” (p. 220).

H. Wildon Carr (1910): “Intelligence is the power of using categories, it is knowledge of the relations of things. It is a knowledge that gives us the representation of a world of objects externally related to one another, a world of objects in space, or measurable actions and reactions. . . . Intelligence is an outward view of things, never reaching the actual reality it seeks to know” (pp. 232–233).

Alfred Binet and Théodore Simon (Binet, 1911/1916): “Intelligence serves in the discovery of truth. But the conception is still too narrow; and we return to our favorite theory; the intelligence marks itself by the best possible adaptation of the individual to his environment” (pp. 300–301).

William Stern (1914): “Intelligence is a general capacity of an individual consciously to adjust his thinking to new requirements: it is general mental adaptability to new problems and conditions of life” (p. 3).

M. E. Haggerty (1921). “In my thinking the word intelligence does not denote a single mental process capable of exact analytic definition. It is a practical concept of connoting a group of complex mental processes traditionally defined in systematic psychologies as sensation, perception, association, memory, imagination, discrimination, judgment and reasoning “(p. 212).

V. A. C. Henmon (1921): “Intelligence . . . involves two factors—the capacity for knowledge and knowledge possessed” (p. 195).

Joseph Peterson (1921): “Intelligence seems to be a biological mechanism by which the effects of a complexity of stimuli are brought together and given a somewhat unified effect in behavior. It is a mechanism for adjustment and control, and is operated by internal as well as by external stimuli. The degree of a person’s intelligence increases with his range of receptivity to stimuli and the consistency of his organization of responses to them” (p. 198).

Rudolf Pintner (1921): “I have always thought of intelligence as the ability of the individual to adapt himself adequately to relatively new situations in life. It seems to include the capacity for getting along well in all sorts of situations. This implies ease and rapidity in making adjustments and, hence, ease in breaking old habits and in forming new ones” (p. 139).

Lewis M. Terman (1921): “The essential difference, therefore, is in the capacity to form concepts to relate in diverse ways, and to grasp their significance: *An individual is intelligent in proportion as he is able to carry on abstract thinking*” (p. 128; emphasis in original).

Edward L. Thorndike (1921): “Realizing that definitions and distinctions are pragmatic, we may then define intellect in general as *the power of good responses from the point of view of truth or fact*, and may separate it according as the situation is taken in gross or abstractly and also according as it is experienced directly or thought of” (p. 124; emphasis in original).

L. L. Thurstone (1921): “Intelligence as judged in everyday life contains at least three psychologically differentiable components: a) the capacity to inhibit an instinctive adjustment, b) the capacity to redefine the inhibited instinctive adjustment in the light of imaginally experienced trial and error, c) the volitional capacity to realize the modified instinctive adjustment into overt behavior to the advantage of the individual as a social animal” (pp. 201–202).

Herbert Woodrow (1921): “Intelligence . . . is the capacity to acquire capacity” (p. 208).

(continued)

TABLE 1.2. *(continued)*

E. G. Boring (1923): "Intelligence as a measurable capacity must at the start be defined as the capacity to do well in an intelligence test. Intelligence is what the tests test" (p. 35).

Édouard Claparède (1924): "[Intelligence is] the ability to solve new problems" (quoted by Langfeld, 1924, p. 149).

Godfrey H. Thomson (1924): "[Intelligence is] the ability to meet new situations with old responses and to discard those responses which prove unsuccessful" (quoted by Langfeld, 1924, p. 149).

David Wechsler (1939): "Intelligence is the aggregate or global capacity of the individual to act purposefully, to think rationally and to deal effectively with his environment" (p. 3).

Anne Anastasi (1986): "Intelligence is not an entity within the organism but a quality of behavior. Intelligent behavior is essentially adaptive, insofar as it represents effective ways of meeting the demands of a changing environment" (pp. 19–20).

Jonathan Baron (1986): "I define intelligence as the set of whatever abilities make people successful at achieving their rationally chosen goals, whatever those goals might be, and whatever environment they are in. . . . To say that a person has a certain level of ability is to say that he or she can meet a certain standard of speed, accuracy, or appropriateness in a component process defined by the theory in question" (p. 29).

J. W. Berry (1986): "At the present time intelligence is a construct which refers to the end product of individual development in the cognitive-psychological domain (as distinct from the affective and conative domains); this includes sensory and perceptual functioning but excludes motor, motivational, emotional, and social functioning . . . it is also adaptive for the individual, permitting people to operate in their particular cultural and ecological contexts" (p. 35).

J. P. Das (1986): "Intelligence, as the sum total of all cognitive processes, entails planning, coding of information and attention arousal. Of these, the cognitive processes required for planning have a relatively higher status in intelligence. Planning is a broad term which includes among other things, the generation of plans and strategies, selection from among available plans, and the execution of those plans. . . . Coding refers to two modes of processing information, simultaneous and successive. . . . The remaining process (attention arousal) is a function basic to all other higher cognitive activities" (pp. 55–56).

Douglas K. Detterman (1986): "In my opinion, intelligence can best be defined as a finite set of independent abilities operating as a complex system" (p 57).

John Horn (1986): "'What do I conceive intelligence to be?' This is rather like asking me: 'What do I conceive invisible green spiders to be?' For current knowledge suggests to me that intelligence is not a unitary entity of any kind. Attempts to describe it are bound to be futile" (p. 91).

Earl Hunt (1986): "'Intelligence' is solely a shorthand term for the variation in competence on cognitive tasks that is statistically associated with personal variables. . . . Intelligence is used as a collective term for 'demonstrated individual differences in mental competence'" (p. 102).

James W. Pellegrino (1986): "The term intelligence denotes the general concept that individuals' responses to situations vary in quality and value as judged by their culture" (p. 113).

Sandra Scarr (1986): "To be an effective, intelligent human being requires a broader form of personal adaptation and life strategy, one that has been described in 'invulnerable' children and adults: They are copers, movers, and shapers of their own environments" (p. 120).

Richard E. Snow (1986): "[Intelligence can be defined in several ways:] . . . [1] the incorporation of concisely organized prior knowledge into purposive thinking—for short, call it *knowledge-based thinking.* . . . [2] *apprehension* captures the second aspect of my definition—it refers to Spearman's (1923, 1927) principle that persons (including psychologists) not only feel, strive, and know, but also *know* that they feel, strive, and know, and can anticipate further feeling, striving, and knowing; they monitor and reflect upon their own experience, knowledge, and mental functioning in the past, present, and future tenses. . . . [3] *adaptive purposeful striving.* It includes the notion that one can adopt or shift strategies in performance to use what strengths one has in order to compensate for one's weaknesses. . . . [4] agile, analytic reasoning of the sort that enables significant features and dimensions of problems, circumstances, and goals to be decontextualized, abstracted, and interrelated rationally . . . *fluid-analytic reasoning.* . . . [5] *mental playfulness* . . . able to find or create interesting problems to solve and interesting goals toward which to strive. This involves both tolerance of ambiguity and pursuit of novelty. . . . [6] *idiosyncratic learning* . . . Persons differ from one another in the way they assemble their learning and problem-solving performance, though they may achieve the same score. Persons differ *within* themselves in how they solve parts of a problem, or different problems in a series" (pp. 133–134; emphasis in original).

Robert J. Sternberg (1986): "Intelligence is mental self-government. . . . The essence of intelligence is that it provides a means to govern ourselves so that our thoughts and actions are organized, coherent, and responsive to both our internally driven needs and to the needs of the environment" (p. 141).

The argument has also been made that a structural/statistical understanding of intelligence may serve as an adequate substitute for a verbal/descriptive definition. Gottfredson and Saklofske (2009) suggest that definitional issues of intelligence are "now moot because the various empirical referents to which the term is commonly applied can be distinguished empirically and related within a common conceptual structure [i.e., the Cattell–Horn–Carroll model of human cognitive abilities]" (p. 188).

To *g* or Not to *g*?

Another long-standing unresolved thread in the history of intelligence testing has to do with the general factor of intelligence, psychometric *g*. General intelligence was affirmed in the 1994 "Mainstream Science on Intelligence" statement (Gottfredson, 1997), but the 1996 "Intelligence: Knowns and Unknowns" statement hedged on *g*, stating that "while the *g*-based factor hierarchy is the most widely accepted current view of the structure of abilities, some theorists regard it as misleading" (Neisser et al., 1996, p. 81). Here I describe some history for *g*.

In 1904, Charles E. Spearman (1863–1945) published a groundbreaking paper reporting the discovery of a factor of "general intelligence," derived from positive intercorrelations between individual scores on tests of sensory discrimination, musical talent, academic performance, and common sense. Although the correlation coefficient statistic was still relatively new, Spearman realized that previous studies (e.g., those by Gilbert and by Wissler) had failed to account for measurement error—that is, reduced score reliability, which invariably reduces the magnitude of correlations. He devised a method to correct the correlation coefficient for attenuation, reporting subsequently that his correlational analyses showed "all branches of intellectual activity have in common one fundamental function (or group of functions)" (p. 284), which he later described using concepts from physics such as "the amount of a general mental energy" (Spearman, 1927, p. 137). The *g* factor, or psychometric *g*, was a mathematically derived general factor, stemming from the shared variance that saturates batteries of cognitive/intelligence tests. Jensen (1998) has summarized the literature showing that correlates of *g* include scholastic performance, reaction time, success in training programs, job performance in a wide range of occupations, occupational status, earned income, and creativity, among others.

Critics of general intelligence appeared quickly. Edward L. Thorndike, who challenged Spearman's work for decades, reported no support for *g* on a set of measures similar to those originally used by Spearman, finding a weak correlation between sensory discrimination and general intelligence, and stating that "one is almost tempted to replace Spearman's statement by the equally extravagant one that there is *nothing whatever* common to all mental functions, or to any half of them" (Thorndike, Lay, & Dean, 1909, p. 368; original emphasis).

Until Spearman's death, Thorndike; a Scotsman, Godfrey Thomson; and two Americans, Truman L. Kelley and Louis L. Thurstone, participated in an ongoing scholarly debate with him on the existence and nature of *g*, as well as other aspects of the structure of intelligence. Spearman devoted the rest of his career to elaboration and defense of his theory, authoring *The Nature of "Intelligence" and the Principles of Cognition* (Spearman, 1923), *The Abilities of Man: Their Nature and Measurement* (Spearman, 1927), and *Human Ability: A Continuation of "The Abilities of Man"* (Spearman & Wynn Jones, 1950). A good account of this debate may be found in R. M. Thorndike and Lohman (1990). Newly discovered exchanges among Thorndike, Thomson, and Spearman in the 1930s serve to highlight Spearman's dogmatism (Deary, Lawn, & Bartholomew, 2008).

The leading intelligence test developers generally accepted the existence of a psychometric *g* factor. After initial reticence, Alfred Binet eventually embraced a general factor; in *Les Idées Modernes sur les Enfants,* Binet (1909/1975) wrote that "the mind is unitary, despite the multiplicity of its faculties . . . it possesses one essential function to which all the others are subordinated" (p. 117). In the 1916 Stanford–Binet, Lewis M. Terman accepted the concept of general intelligence and conceded that the IQ score provided a good estimate of *g*:

> It is true that more than one mental function is brought into play by the test. The same may be said of every other test in the Binet scale and for that matter of any test that could be devised. It is impossible to isolate any function for separate testing. In fact, the functions called memory, attention, perception, judgment, etc., never operate in isolation. There are no separate and special "faculties" corresponding to such terms, which are merely convenient names for characterizing mental processes of various types. In any test it is "general ability" which is operative, perhaps now *chiefly* in remembering, at another time

> *chiefly* in sensory discrimination, again in reasoning, etc. (p. 194; original emphasis)

David Wechsler, who had been deeply impressed with Spearman during his few months at University College London in 1919, wrote that Spearman's theory and its proofs constitute "one of the great discoveries of psychology" (1939, p. 6). He further noted that "the only thing we can ask of an intelligence scale is that it measures sufficient portions of intelligence to enable us to use it as a fairly reliable index of the individual's global capacity" (p. 11).

What is the current status of *g*? When Reeve and Charles (2008) surveyed 36 experts in intelligence, they found a consensus that *g* is an important, nontrivial determinant (or at least predictor) of important real-world outcomes, and that there is no substitute for *g* even if performance is determined by more than *g* alone. With the leading authors of intelligence tests accepting psychometric *g*, and with authorities in intelligence research consensually accepting its importance, the thread of general intelligence would appear to be well secured in our metaphorical tapestry of the history intelligence.

Yet the concept of general intelligence continues to be challenged, most often on theoretical grounds but also on statistical grounds. Stephen J. Gould (1996) forcefully challenged *g*, associating it with many of the historically negative (and shameful) applications of intelligence testing. Several intelligence theorists, including Raymond B. Cattell, J. P. Das, Howard Gardner, and Robert J. Sternberg, have also rejected the concept of general intelligence. The most cogent challenges to *g* have come from John L. Horn (Horn & Noll, 1994, 1997), who pointed out fallacies of extracting *g* from the *positive manifold* (i.e., the finding that almost all tests that reliably measure a cognitive ability correlate positively with all other such tests).

The Structure of Intelligence

The struggle to construct a complex model of intelligence probably began with the phrenologists, who specified individual faculties (each corresponding to an "organ" of the brain) that together constituted intelligence. For example, Combe (1830) described faculties of perception (e.g., form, size, weight, eventuality, language) and faculties of reflection (e.g., comparison, causality) that altogether constituted intellectual faculties; he also described a separate set of affective faculties. With the discovery of *g* by Spearman (1904), the notion of a unitary intelligence gained traction, but by the end of the 1930s, psychologists and educators were again embracing the complexity of the mind (e.g., Ackerman, 1995). Current hierarchical models of intelligence feature broad ability factors, which have grown steadily in number: from the two factors enumerated by Cattell (1941) and Vernon (1950) to the eight specified by Carroll (1993) to about 10 factors specified by Carroll (2003) to about 15 or 16 broad factors in 2010 (e.g., McGrew, 2009; Newton & McGrew, 2010). The question that appears to be unresolved in this thread is this: Just how many group factors constitute the structure of intelligence?

For much of the 20th century and into the 21st, the complex structure of intelligence has been revealed through statistical methodologies that discover and define sources of test performance variance, usually through factor analyses. Factor analysis is a statistical technique capable of reducing many variables into a few underlying dimensions. The foundation for use of factor analysis in understanding the structure of cognition was laid with Spearman (1904). Spearman's theory encompassing general intelligence was originally called *two-factor theory* because it partitioned performance variance into a *general factor* shared across tasks, and *specific factors* that were unique to individual tasks. Following the contributions of Kelley, Thorndike, and Thurstone (among others), Spearman (1927) reluctantly came to acknowledge the existence of *group factors* formed by clusters of tests that yielded higher-than-expected intercorrelations by virtue of similarities in their content, format, or response requirements: "Any element whatever in the specific factor of an ability will be turned into a group factor, if this ability is included in the same set with some other ability which also contains this element" (p. 82). The extraction of a general factor and group factors (now called *broad ability factors*) contributed to the development of *hierarchical* structural analyses of intelligence. In hierarchical factor analyses, a general factor is first extracted; the residual variance is factored to extract any group factors; and the remaining variance is often said to be specific.

Although there have been well over 1,000 factor-analytic investigations in the literature of intelligence and cognitive abilities (see Carroll, 1993), many of which remain important in understanding the structure of cognitive abilities, space only permits coverage of a few prototypal models with distinctive characteristics.

Thurstone's Primary Mental Abilities

Louis L. Thurstone (1887–1955) developed the statistical technique of multiple factor analysis and is best remembered for his theory of primary mental abilities, a factor-analysis-derived model of multiple cognitive abilities that effectively challenged Spearman's single general factor of intelligence. Thurstone developed factor analysis techniques permitting the extraction of factors that are orthogonal to each other (i.e., separate, independent, and unrelated). From a battery of 56 paper-and-pencil tests administered in about 15 hours to each of 240 superior, college-level students, Thurstone (1938) extracted seven primary factors: spatial/visual, perception of visual detail, numerical, two verbal factors (logic and words), memory, and induction. From a study of over 700 students age 14, who were given 60 tests in 11 sessions lasting 1 hour each, Thurstone and Thurstone (1941) extracted six factors: verbal comprehension, word fluency, space, number, memorizing, and reasoning/induction. By 1945, Thurstone had settled on eight primary mental abilities, each denoted by a letter: Verbal Comprehension (V), Word Fluency (W), Number Facility (N), Memory (M), Visualizing or Space Thinking (S), Perceptual Speed (P), Induction (I), and Speed of Judgment (J). Although Thurstone (1947) eventually accepted the existence of a general factor, he considered the use of a single score such as the IQ to be inadequate, and urged the use of cognitive profiles describing strengths and weaknesses among the fundamental abilities (Thurstone, 1945).

Vernon's Hierarchical Model

In what has been called the first truly hierarchical model of intelligence, Philip E. Vernon (1905–1987) proposed that a higher-order *g* factor dominates two lower-order factors, v:ed (verbal:educational) and k:m (spatial:mechanical); in turn, v:ed and k:m subsume various minor group factors, which in turn dominate very narrow and specific factors. Based on his review of factor-analytic investigations through 1950, Vernon (1950, 1961) considered v:ed to dominate verbal, number, reasoning, attention, and fluency factors, while k:m dominates spatial ability, mechanical ability, psychomotor coordination, reaction time, drawing, handwork, and various technical abilities. He considered it a likely oversimplification to assume that there are just two factors at the level below *g*, although his simple dichotomy may be seen as having supported the verbal–performance dichotomy traditionally associated with the Wechsler intelligence scales.

Cattell, Horn, and Carroll's Model of Fluid and Crystallized Intelligence

Arguably the most important contemporary structural and hierarchical model of intelligence is based on extensions of the theory of fluid (Gf) and crystallized (Gc) intelligence first proposed by Raymond B. Cattell (1905–1998) in a 1941 APA convention presentation. Cattell, who completed his doctorate in 1929 at University College London with Spearman, joined E. L. Thorndike's research staff at Columbia University in 1937, where he worked closely with proponents of multifactor models of intelligence. He authored over 500 articles and 43 books during his career. In his 1941 APA presentation, Cattell asserted the existence of two separate general factors: g_f (fluid ability or fluid intelligence) and g_c (crystallized ability or crystallized intelligence). The convention was later adopted that these factors would be represented by uppercase G, whereas a single general factor would be represented by lowercase *g*.

Fluid ability was described by Cattell (1963, 1971) and Horn (1976) as a facility in reasoning, particularly where adaptation to new situations is required and crystallized learning assemblies are of little use. Ability is considered to be fluid when it takes different forms or utilizes different cognitive skill sets according to the demands of the problem requiring solution. For Cattell, fluid ability is the most essential general-capacity factor, setting an upper limit on the possible acquisition of knowledge and crystallized skills. In contrast, *crystallized* intelligence refers to accessible stores of knowledge and the ability to acquire further knowledge via familiar learning strategies. It is typically measured by recitation of factual information, word knowledge, quantitative skills, and language comprehension tasks because these include the domains of knowledge that are culturally valued and educationally relevant in the Western world (Cattell, 1941, 1963, 1971, 1987; Horn & Cattell, 1966).

Cattell's model of fluid and crystallized intelligence was energized by the contribution of John L. Horn (1928–2006). Not only was Horn's (1965) dissertation the first empirical study of the theory since 1941; it also showed that fluid and crystallized abilities have different developmental trajectories over the lifespan (McArdle, 2007). Cattell and Horn expanded the number of ability factors from two to five (adding visualization, retrieval capacity, and cognitive speed; Horn & Cattell, 1966). In the next 25 years or so, Horn had arrived at nine ability factors (Horn & Noll, 1994, 1997), while Cattell's list had grown to six ability factors (adding distant memory and retrieval) plus three smaller provincial factors (visual, auditory, and kinesthetic; Cattell, 1998). The growth of the number of factors in this model continues, and a 2001 symposium at the University of Sydney enumerated even more potential ability factors (Kyllonen, Roberts, & Stankov, 2008). As noted earlier, McGrew (2009; see also Newton & McGrew, 2010) now lists 15 or 16 broad ability factors.

In 1993, John B. Carroll (1916–2003) built upon the work of Cattell and Horn by proposing a hierarchical, multiple-stratum model of human cognitive abilities with the general intelligence factor, *g*, at the apex (or highest stratum); eight broad factors of intelligence at the second stratum; and at least 69 narrow factors at the first (or lowest) stratum. Carroll was the author of nearly 500 books and journal articles over the span of 60 years; he had been mentored early in his career by L. L. Thurstone, and some years later after Thurstone's death he became director of the Thurstone Psychometric Laboratory at the University of North Carolina, Chapel Hill (Jensen, 2004). For a dozen years after his retirement, Carroll (1983, 1993, 1994) accumulated over a thousand archival datasets related to human cognitive test performance; 461 of the datasets were ultimately judged adequate for his analyses. He then conducted iterative principal-factor analyses requiring convergence to a strict criterion, followed by varimax rotation of the principal-factor matrix, with the requirement that each extracted factor contain salient loadings on at least two variables. If necessary, promax or other rotational procedures were used. Factorization was then carried up to the highest viable order. The data were subjected to the Schmid–Leiman orthogonalized hierarchical-factor procedure, and factor interpretations were based on the resulting hierarchical-factor matrix. Carroll's results showed general intelligence (*g*) as appearing in the highest stratum; the second stratum, listed in descending strength of association with *g*, consisted of fluid intelligence (Gf), crystallized intelligence (Gc), general memory and learning (Gsm), broad visual perception (Gv), broad auditory perception (Ga), broad retrieval ability (Gr), broad cognitive speediness (Gs), and processing speed (reaction time decision speed); finally, very narrow and specific factors were placed in the lowest stratum. Although Carroll's three-stratum model is historically young, its early reception suggests that it has quickly become a landmark study. The following samples from reviews are fairly representative:

- "Further research may alter details of the map, although it is unlikely that any research for some years to come will lead to a dramatic alteration in Carroll's taxonomy." (Brody, 1994, p. 65)
- "It is simply the finest work of research and scholarship I have read and is destined to be the classic study and reference work of human abilities for decades to come." (Burns, 1994, p. 35)
- "[It is] a truly monumental work." (Jensen, 2004, p. 3)
- "Carroll's work represents what may well be the most extensive, indeed, exhaustive analysis of a data case that has ever been attempted in the field of intelligence. The theory deserves to be taken seriously." (Sternberg, 1994, p. 65)

A note of caution for applied practitioners, however, comes from Carroll himself: He indicated that his survey of cognitive abilities "paid very little attention to the importance, validity, or ultimate usefulness of the ability factors that have been identified" (1993, p. 693). Carroll's three-stratum theory has been integrated with extended Gf-Gc theory to form the Cattell–Horn–Carroll (CHC) framework, a name to which Horn and Carroll both agreed a few years after Cattell's death (Newton & McGrew, 2010). The CHC framework already appears to have exerted a strong influence upon the development of contemporary intelligence tests (e.g., Keith & Reynolds, 2010). Shortly before his death, Carroll (2003) expanded his model to include 10 second-stratum factors, indicating that even this definitive model may be expanded.

Intelligence and Eugenics

We have seen more than once that the public welfare may call upon the best citizens for their lives. It would be strange if it could not call upon those who already sap the strength of the State for these lesser sacrifices, often not felt to be such by those concerned, in order to prevent our being swamped with incompetence. It is better for all the world, if instead of waiting to execute degenerate offspring for crime, or to let them starve for their imbecility, society can prevent those who are manifestly unfit from continuing their kind. The principle that sustains compulsory vaccination is broad enough to cover cutting the Fallopian tubes. Three generations of imbeciles are enough.

—OLIVER WENDELL HOLMES (*Buck v. Bell,* 1927)

So wrote Justice Oliver Wendell Holmes, Jr., for the majority opinion of the U.S. Supreme Court in 1927, in the case of Carrie Buck versus James Hendren Bell, Superintendent of the Virginia State Colony for Epileptics and Feeble Minded. Carrie Buck was an 18-year-old woman with the mental age equivalent of 9 when the superintendent of the Virginia State Colony petitioned to have her sterilized. She was reported to be the daughter of a feeble-minded mother in the same institution and the mother of a feeble-minded child—hence Holmes's statement that "Three generations of imbeciles are enough." By an 8-to-1 margin, the court upheld the 1924 Virginia statute, the Eugenical Sterilization Act of 1924, authorizing the compulsory sterilization of "mental defectives," including individuals who were "feeble-minded" (i.e., intellectually disabled). On October 19, 1927, Carrie Buck was sterilized. Although the Supreme Court ruling has never been challenged or reversed, the Commonwealth of Virginia repealed the 1924 sterilization law in 1974. Historian Paul A. Lombardo (2008) recently reexamined this case, finding that there was insufficient evidence ever to assert cognitive impairment in Buck or her daughter, based on their school records.

For our purposes, it may be enough to cite compulsory sterilization laws for those with intellectual disabilities as a historical illustration of how intelligence test results may be (mis)used. In the broader context are questions about the wisdom of making legal, political, and public policy decisions on the basis of intelligence test research. Scholars in intelligence are at risk when they stray too far from psychological science into the realm of social engineering.

Francis Galton coined the term *eugenics* in 1883, describing it as "the science of improving stock" and defining it as "all influences that tend in however remote a degree to give to the more suitable races or strains of blood a better chance of prevailing speedily over the less suitable than they otherwise would have had" (p. 25). In *Hereditary Genius* (1869), he had already presented evidence that superior abilities are found more often among eminent families (i.e., those of judges, statesmen, premiers, commanders, scientists, scholars, etc.), and he proposed to increase the proportion of individuals with superior genetic endowments and thereby benefit the national intelligence through selective early marriages. "A man's natural abilities are derived by inheritance," Galton wrote, "under exactly the same limitations as are the form and physical features of the whole organic world" (1869, p. 1). He related his vision of a eugenics-practicing society in an unpublished fictional tale entitled "Kantsaywhere" (Galton, 1930). In this utopia, an individual's hereditary worth was measured by anthropometric tests, genetic failures were placed in labor colonies, enforced celibacy was the rule, and childbirth for the "unfit" was a crime. Karl Pearson noted in a footnote to this tale (p. 416 in Galton, 1930) that Galton's fictional laboratory in Kantsaywhere bears an uncanny resemblance to his anthropometric laboratory at South Kensington, one of the places where intelligence testing began. A photograph of Galton toward the end of his life, with his friend, colleague, and biographer, Karl Pearson, appears in Figure 1.15. Pearson, the renowned statistician, was also a dedicated eugenicist.

Almost all of the early authorities in the field of intelligence either wrote favorably about eugenics or belonged to organizations advocating eugenics. Some of the authorities on record as favoring eugenics in one form or another include J. McKeen Cattell, Raymond B. Cattell, Henry H. Goddard, Lewis M. Terman, Edward L. Thorndike, and Robert M. Yerkes. Until the horrors of Nazi genocide were exposed, including euthanasia of individuals with intellectual disabilities or mental disorders, eugenics was commonly seen as a contribution of

FIGURE 1.15. Francis Galton at age 87 with his biographer, Karl Pearson. Both were dedicated eugenicists. Photo from Pearson (1930, Plate 36). Reprinted by permission of The Pearson Papers, UCL Library Services, Special Collections.

science to human (and national) improvement. Lewis M. Terman, author of the Stanford–Binet, took a particularly active role in advocating for eugenics. For example, in a report to the California state legislature, Terman (1917) saw those with intellectual disabilities as having only negative impacts on society:

> Feeble-mindedness has always existed; but only recently have we begun to recognize how serious a menace it is to the social, economic, and moral welfare of the state. Extensive and careful investigations, in large numbers and in diverse parts of the United States, have furnished indisputable evidence that it is responsible for at least one-fourth of the commitments to state penitentiaries and reform schools, for the majority of cases of chronic and semi-chronic pauperism, and for much of our alcoholism, prostitution, and venereal diseases. (p. 45)

Terman's solutions were to segregate "feeble-minded" students in special classes so as not to "interfere with instruction" or "be a source of moral contagion" for other students (p. 51). He did not overtly recommend sterilization, but he implied that some action was necessary to prevent reproduction: "Three-fourths of the cases of feeble-mindedness are due to a single cause, heredity; and the one hopeful method of curtailing the increasing spawn of degeneracy is to provide additional care for our higher-grade defectives during the reproductive period" (p. 52).

Two of the most important 20th-century figures in applied intelligence testing, however, Alfred Binet and David Wechsler, are on record as having rejected perspectives associated with eugenics. Binet argued that intelligence can be changed, and he even developed a program of "mental orthopedics" to make educational interventions:

> I have often observed, to my regret, that a widespread prejudice exists with regard to the educability of intelligence. . . . A few modern philosophers seem to lend their moral support to these deplorable verdicts when they assert that an individual's intelligence is a fixed quantity, a quantity which cannot be increased. We must protest and react against this brutal pessimism. We shall attempt to prove that it is without foundation. (1909/1975, pp. 105–106)

David Wechsler found a more oblique way to criticize the eugenicists—by associating them with totalitarianism. In a 1961 paper, shortly after defining the terms *eugenes* and *apartheid,* he wrote, "The belief in class distinctions, whether considered innate or acquired, is . . . an essential tenet of all groups who are afraid of being ousted or displaced, and in particular of totalitarian governments" (p. 421). As Wechsler was a member of an oppressed immigrant group (Eastern European Jews) threatened with genocide in Romania and Germany, his condemnation of eugenics should not be surprising.

How does eugenics constitute a loose thread in the history of intelligence? Although no mainstream authorities today advocate for eugenics of the type that led to tragedies in the past, scholarship in the biology and heredity of intelligence remains extremely controversial, with recent accounts including threats to the academic freedom and even loss of lifetime recognition of achievements in psychology for those who conduct research in associated areas, including heritability (e.g., APA, 1997; Gottfredson, 2010; Horn, 2001; Tucker, 2009). Moreover, it might be argued that the history of intelligence and eugenics has contributed to a public perception that intelligence is about elitism, racism, and exclusion. In spite of over a century of research, the study of intelligence remains controversial for its social applications and implications.

TOWARD THE FUTURE

It may be beyond the scope of a historical chapter to look to the future, especially because this entire volume represents diverse visions for the future of intellectual assessment. At the same time, there are enough recurring events in our field that it sometimes seems as if we do not learn from mistakes (or, worse, as if we do not know our own history). For example, the concept of a general ability factor proposed by Spearman in 1904 has achieved as much of a consensus as is possible in psychology (e.g., Reeve & Charles, 2008), but still proponents of new theories (and tests) of intelligence often try to deny *g*—although their work usually proves to be saturated with *g*. Examples include Howard Gardner's (1983) theory of *multiple intelligences* and Keith Stanovich's newly proposed *rationality quotient* (Stanovich, West, & Toplak, 2016), each of which has been shown to be quite *g*-loaded (Ritchie, 2017; Visser, Ashton, & Vernon, 2006).

The critics of intellectual assessment return time and time again to issues of perceived bias against racial, ethnic, and linguistically different minorities. From a historical perspective, concerns about the effects of socioeconomic conditions on intelligence test performance were first openly recognized and articulated by Alfred Binet (1911/1916):

> The little children of the upper classes understand better and speak better the language of others. We have also noted that when they begin to compose, their compositions contain expressions and words better chosen than those of poor children. This verbal superiority must certainly come from the family life; the children of the rich are in a superior environment from the point of view of language; they hear a more correct language and one that is more expressive. (p. 320)

Issues of fairness have persisted for a century, perhaps reaching a low point in Carl C. Brigham's *A Study of American Intelligence* (1923), based on data from the Army mental tests. Brigham (1930), who created the SAT for the College Board, later recanted, acknowledging serious methodological flaws in his study of racial differences. Even now, a very active literature addresses the fairness of intelligence tests, often emitting more heat than light. Nancy M. Robinson (2003) has wisely pointed out that poverty and social inequities are longstanding problems in our society, with intelligence tests reflecting (but not causing) societal barriers and inequitable outcomes.

Sadly, psychologists do not receive credit for historical lessons learned, beginning with the terrible consequences of eugenics. But these shameful aspects of our history are still used to condemn intelligence testing, nearly 70 years after beliefs in eugenics were discarded. Moreover, support of eugenics is considered by some as a reason to discard the massive bodies of research accumulated by early 20th-century intelligence scholars like Lewis M. Terman, lead author of the Stanford–Binet. Among historians, the fallacy of *presentism* refers to the act of imposing the views of the present onto the past, instead of making a serious attempt to understand how historical figures themselves understood the world in their time (e.g., Fischer, 1970). Denigration of important scientific figures for advocacy of eugenics is a form of presentism—because no proponents of eugenics in the 1920s and 1930s knew what we now know, that Galton's (1883) concept of eugenics would ultimately prove to be a terrible, tragic, and malignant idea.

The study of history can yield some guidance in clearing the way going forward. Sage advice may be found in Edward L. Thorndike's constant admonition from the early history of psychology, "Look to the evidence!" (quoted in Goodenough, 1950, p. 301). To borrow from Leta S. Hollingworth, a pioneer in the psychology of women and exceptional children, the best solution to ongoing myths and controversies is to trust the "literature of fact" ascertained experimentally over the "literature of opinion" expressed by experts (Hollingworth, 1916). The most productive future for intelligence must be grounded in evidence-based research, not sociocultural ideology. This statement may seem self-evident to most readers, but leading figures have expressed concerns about the potential for public policy to be ideology-driven rather than data-driven where intelligence is involved (e.g., Sternberg, 2005).

Evidence that is undergirded by psychological theory will be more explanatory and predictive than research that is absent a theory. Again, this may be self-evident, but what passes for theory is often a list of factor-derived abilities and not a coherent account of mental processing that goes beyond factor structure. Recognizing this, John B. Carroll (1983) identified a number of additional forms of validation that transcend factor analysis, including establishing the nature of a factor, its psychometric characteristics, its place in a hierarchy of abilities, its developmental characteristics, its genetic and environmental determinants, the presence of any demographically based group mean differences, its susceptibility to intervention or more transient influences such as drugs or fatigue, its relationship to noncognitive variables, its ecological relevance and validity, and its implications for psychological theory as a whole. I also believe that any theory of intelligence must be meaningfully anchored in the functioning of the human brain. E. L. Thorndike (1901) was among the first psychologists to specify that any theory of intelligence must offer "some sort of brain correlate for ideational life and reasoning" (p. 61). Few contemporary theories of intelligence meet Thorndike's criterion.

Although there are certainly benefits to be obtained from bottom-up, data-driven tests, some caution needs to be exerted with regard to intelligence tests developed *sans* theories. Wasserman and Kaufman (2016) recently reported that intelligence tests without substantive associated theories (e.g., the Wechsler scales, which borrow from many theories but subscribe to none) may be more resilient to scholarly criticism because they cannot be tested and falsified. They stay popular for longer periods of time because it is harder to conduct research to challenge them. Some scientific courage is required to create a new intelligence measure with a testable (and therefore disprovable) theory, if the absence of a theory promises that the test will have a longer shelf life.

As readers of this book know, the practice of intelligence assessment is an *applied* science, used for decision making in clinical, educational, and vocational settings. From the introduction of Binet and Simon's (1908/1916b, 1905/1916c; Binet, 1911/1916) scales, intelligence tests have been used to guide placements for exceptional students, although their remarkable diagnostic and predictive capacities have shown them to be of value for many other kinds of decisions. Test developers would be well advised to attend to the "ultimate usefulness" of scores from their measures, following Carroll's (1993, p. 693) caution. Intelligence test scores that are most meaningful relative to the type of decisions being made need to be given the greatest emphasis in reporting. Not every factor or score from an intelligence test is clinically or educationally meaningful, and research is continually needed to discern which scores are most valid for predictive and decision-making purposes.

It remains to note a few contemporary exemplar test developers who have boldly tried to build bridges among these many roads forward. Alan S. Kaufman—coauthor with his wife, Nadeen L. Kaufman, of numerous mental tests—published *Intelligent Testing with the WISC-R* in 1979, becoming the leading authority on applied interpretation and utility of the Wechsler scales. While some of the score interpretive methods he advocated have been challenged (e.g., Watkins, 2000), his approaches to the clinical use of intelligence tests have become industry standards. Just 4 years after *Intelligent Testing* was published, the Kaufmans released the Kaufman Assessment Battery for Children (K-ABC; Kaufman & Kaufman, 1983), a theory-based battery anchored in Luria's model of brain functioning. This is one of the few 20th-century intelligence tests meeting Thorndike's (1901) criterion. In the words of his students Randy W. Kamphaus and Cecil R. Reynolds (2009), Kaufman's contribution that has had the greatest long-term impact is his "joining of the two disciplines of measurement science and clinical assessment practice" (p. 148).

Another pioneer test developer bridging multiple paths forward is Richard W. Woodcock, an early advocate for what came to be known as CHC theory. Woodcock included both John L. Horn and John B. Carroll among his advisors in developing the Woodcock–Johnson—Revised Tests of Cognitive Ability (WJ-R; Woodcock & Johnson, 1989), recognizing the emergence of Gf-Gc theory. In 1990, Woodcock published the first cross-battery factor analysis, demonstrating that the inclusion of new marker subtests in factor analyses of existing cognitive test batteries may fundamentally alter a battery's factor structures in the direction of the CHC model. Woodcock was also a pioneer in the use of item response theory to build his tests, experimenting with multiple types of Rasch-derived scores in order to extract more useful applied information from test scores. Woodcock's development-referenced and criterion-referenced test scores (e.g., *W* scores, Relative Proficiency Index) represent efforts to move psychology beyond its overdependence on norm-referenced measurement (see Woodcock, 1999, for a complete discussion of these types of scores).

It is not obvious whether any contemporary thinkers will have lasting influence into the 21st century, and history seems to demonstrate that the United States is not an easy residence for intelligence testing. In *Democracy in America,* written nearly two centuries ago, French historian Alexis de Tocqueville (1835/1839) described the "great equality" (p. 42) that takes precedence over all other values and social conditions in American culture. The American people were uncomfortable with social or intellectual distinctions among people, he explained, and there was a fixed "middling standard" of expectations (p. 48) for learning and acquired knowledge because every citizen had access to the same educational opportunities. While God-given "gifts of intellect" (p. 49) might account for different capacities among individuals, he observed, American people see themselves and are seen by others "on a greater equality in point of fortune and intellect . . . than in any other country of the world, or, in any age of which history has preserved the remembrance" (p. 49).

CHAPTER 2

A History of Intelligence Test Interpretation

Randy W. Kamphaus
Anne Pierce Winsor
Ellen W. Rowe
Sangwon Kim

In this chapter, we focus exclusively on a historical account of dominant methods of intelligence test interpretation. Although the thoroughness of our research coverage is limited by space available, a historical overview offers important practical knowledge for the psychologist practicing today, and tomorrow. As E. G. Boring (1929) wisely observed long ago, "Without such [historical] knowledge he sees the present in distorted perspective, he mistakes old facts and old views for new, and he remains unable to evaluate the significance of new movements and methods" (p. vii). Boring's wisdom remains valuable today, even when we consider the date and context in which his work was written, as reflected by his exclusive use of the masculine pronoun. In recent decades, we have seen the emergence of "new" methods of intelligence test interpretation that are in fact merely reverberations of strategies that were considered either failed or questionable in a bygone era. Take, for example, the relatively widespread adoption of Howard Gardner's multiple-intelligences theory by schools around the United States and the world (see Chen & Gardner, Chapter 4, this volume). This potential "breakthrough" may yet be proven to be just that, but Gardner's theory is definitely a classic example of multiple-intelligence theory from the 1930s (Kamphaus, 2009), with the same attendant challenges of demonstrating valid inferences of test scores.

As would be expected, formal methods of intelligence test interpretation emerged soon after Binet and Simon's creation of the first successful intelligence scale (Kamphaus, 2001). These early interpretive methods, sometimes referred to colloquially as the "dipstick approach," attempted primarily to quantify a general level of intelligence—or, as Binet referred to it, a *developmental level*. He preferred this qualitative description to yielding a test score (Kamphaus, 2001). With the addition of subtest scores to clinical tests and the emergence of group tests measuring different abilities, *clinical profile analysis* replaced the "dipstick approach" as the dominant heuristic for intelligence test interpretation. All scores were deemed appropriate for interpretation, in the hope of providing more "insight" into an individual's cognitive strengths and weaknesses. *Psychometric profile analysis* soon followed. However, as measurement approaches to intelligence test interpretation developed, validity problems with the interpretation of the panoply of subtest scores and patterns surfaced. Today the gap between intelligence theory and test development has narrowed, and more validity evidence associated with score inferences is available; thus test interpretation is becoming both easier and more accurate. We trace all of these developments in this chapter and conclude with a look to the future.

QUANTIFICATION OF A GENERAL LEVEL: THE FIRST WAVE

The process of analyzing human abilities has intrigued scientists for centuries. Indeed, some method for analyzing individual's abilities has existed for over 2,000 years. The Chinese are credited with instituting civil service examinations and formulating a system to classify individuals according to their abilities (French & Hale, 1990). Early work in interpretation of intelligence tests focused extensively on classification of individuals into groups, often using terms no longer considered acceptable today. Early classification provided a way to organize individuals into specified groups based on scores obtained on intelligence tests—an organization that was dependent on the acceptance of intelligence tests by the public as well as by professionals. Today professionals in the fields of psychology and education benefit from the use of increasingly well-researched and objective instruments developed according to precise plans and test specifications. In order to put early intelligence test interpretation into context, the following section provides a brief description of some of the early work leading to the development of the tests themselves.

The Work of Early Investigators

At the beginning of the 20th century, practitioners in the fields of psychology and education were beginning to feel the compelling influence of Alfred Binet and his colleagues in France, most notably Théodore Simon. Binet's studies of the mental abilities of children for the purposes of school placement led to the first genuinely successful method for classifying persons with respect to their cognitive abilities (Goodenough, 1949). Binet and Simon's development of the first empirical and practical intelligence test for applied use in the classification of students represented a technological breakthrough in the field of intelligence assessment. The first version of the Binet–Simon Intelligence Scale (Binet & Simon, 1905) would lead to future scales and, according to Anastasi (1988), an overall increase in the use of intelligence tests for a variety of purposes.

Binet's efforts reflected his great interest in certain forms of cognitive activity. These included abilities related to thinking and reasoning, the development and application of strategies for complex problem solving, and the use and adaptation of abilities for success in novel experiences (Pintner, 1923). His work was rooted in an interest in measuring the complex cognitive processes of children and would eventually lead to a series of popular instruments, most recently represented in the Stanford–Binet Intelligence Scales, Fifth Edition (SB5; Roid, 2003).

At the same time, scientists such as James McKeen Cattell in the United States were conducting equally important work of a different kind. Cattell's investigations frequently focused on measures of perception and motor skills. Although different in scope and purpose from that of Binet and Simon, Cattell's work would ultimately have a profound effect on the popularization and use of intelligence tests (Pintner, 1923). Cattell's experimentation resulted in the appointment of a special committee whose members, with the assistance of the American Psychological Association, were charged with developing a series of mental ability tests for use in the classification and guidance of college students (Goodenough, 1949). The development of these tests placed great emphasis on the need for standardized administration and scoring procedures to improve the reliability of obtained scores.

Procedures for standardized test administration were introduced, with the idea that the measurements associated with an individual would be even more informative when compared to the measurements of another person in the same age group who was administered the same test under the same standard conditions (Pintner, 1923). Controlled and consistent conditions of test administration were considered prerequisite to advancing the goal of making interpretation of test scores more scientific (Anastasi, 1988). The earliest methods of test interpretation centered on the idea that individuals could be classified into groups according to their cognitive abilities, which would form the foundation for improved psychological diagnosis and educational classification. Of course these groups would need descriptive labels, which led in turn to the creation of classification systems as described in the next section.

Classification Schemes

The first well-documented efforts at intelligence test interpretation emphasized the assignment of a descriptive classification based on an overall intelligence test composite score. This practice seemed a reasonable first step, given that (1) the dominant scale of the day, the Stanford–Binet (Stanford Revisions and Extension of the Binet–Simon Scale [Terman, 1916] or the Revised Stanford–Binet [Terman & Merrill, 1937]), yielded only a single overall score; and (2) Spearman's (1927) general intelligence theory, the dominant theory of the day, was premised on the existence of a singular *mental energy*, or general intellectual ability.

According to Goodenough (1949), the identification of mental ability was regarded as a purely biological/physical/medical concern, given that intelligence was presumed to be genetically based and unmalleable. Wechsler (1944) made a similar statement, noting that the vocabulary of choice for a descriptive classification system included medical–legal terms such as *idiot, imbecile,* and *moron.* Levine and Marks (1928, p. 131) provided an example of a classification system incorporating terms of this ilk (see Table 2.1), which, fortunately and necessarily, have fallen into disuse and disfavor.

This classification system used descriptive terms that were evaluative and pejorative (especially when employed in the vernacular), leading to stigmatization of examinees. In addition, the many category levels contained bands of scores with different score ranges. The top and bottom three levels comprised bands of 24 score points each, while those in the middle, from *borderline* to *very bright,* comprised bands of 9 points each. Although the band comprising the *average* range was not far from our present conceptions of *average* (except for this example's upper limit), the use of numerous uneven levels was potentially confusing to the layperson.

TABLE 2.1. The Levine and Marks Intelligence Test Score Classification System

Level	Range in IQ
Idiots	0–24
Imbeciles	25–49
Morons	50–74
Borderline	75–84
Dull	85–94
Average	95–104
Bright	105–114
Very bright	115–124
Superior	125–149
Very superior	150–174
Precocious	175 or above

TABLE 2.2. Wechsler's Intelligence Classification According to IQ

Classification	IQ limits	% included
Defective	65 and below	2.2
Borderline	66–79	6.7
Dull normal	80–90	16.1
Average	91–110	50.0
Bright normal	111–119	16.1
Superior	120–127	6.7
Very superior	128 and over	2.2

Wechsler (1944) introduced another classification scheme that attempted to formulate categories according to a specific structural rationale. This system was based on a definition of intelligence levels related to statistical frequencies (i.e., percentages under the normal curve), in which each classification level was based on a range of intelligence scores lying specified distances from the mean (Wechsler, 1944). In an effort to move away from somewhat arbitrary qualities, his classification scheme incorporated estimates of the prevalence of certain intelligence levels in the United States at that time (see Table 2.2).

Components of Wechsler's system of bands of IQ limits has proved enduring. Some of the bands are close to those we use at the present time. Both the Levine and Marks (1928) and Wechsler (1944) schemes provide a glimpse at procedures used in early attempts at test interpretation. The potential for stigmatization has been lessened in the period since World War II; both scientists and practitioners have moved to a less evaluative vocabulary that incorporates parallel terminology around the mean, such as *above average* and *below average* (Kamphaus, 2001).

Considerations for Interpretation Using Classification Systems

We have made progress regarding the use of classification schemes in the evaluation of human cognitive abilities. The structure of classification systems appears to be more stable today than in the past. Previous practitioners often applied Terman's classification system, originally developed for interpretation of the Stanford–Binet, in their interpretation of many different tests that measured a variety of different abilities (Wechsler, 1944). Fortunately, many test batteries today provide their own classification schemes within the test manuals, providing an opportunity to choose among appropriate tests and classify the results accordingly. In addition, these classification systems are often based on deviations from a mean of 100, providing consistency across most intelligence tests and allowing easier comparison of an individual's performance on them.

Calculation of intelligence test scores, or IQs, became a common way of describing an individual's cognitive ability. However, test score calculation is only the first step in the interpretive process, which has been the case since the early days of testing (Goodenough, 1949). Although scores may fall neatly into classification categories, additional data should be considered when clinicians are discussing an individual's cognitive abilities. For example, individuals in the population who are identified as having below-average intellectual abilities do not necessarily manifest the same degree of disability, and in fact may demonstrate considerable variability in abilities (Goodenough, 1949). Wechsler's (1958) own view of classification schemes was that their use could remind clinicians that intelligence test scores are the results of comparisons to a normative population and not absolute quantities.

The early views of Goodenough and Wechsler have influenced intelligence test interpretation for decades. Clinicians continue to use classification schemes based on overall composite IQ scores for diagnosis and interpretation, and the concerns of Goodenough and Wechsler are still reflected in various texts on intelligence test interpretation (including this one). With the understanding that global IQ scores represent the most robust estimates of ability, they are frequently used in the diagnosis of intellectual disabilities, giftedness, learning disabilities, and other conditions. Still, we caution that global cutoff scores may not always be appropriate or adequate for the decisions typically made on the basis of intelligence test scores (Kaufman, 1990), since these scores constitute only one component of understanding an individual's range of developed cognitive abilities.

CLINICAL PROFILE ANALYSIS: THE SECOND WAVE

Rapaport, Gil, and Schafer's (1945–1946) seminal work has exerted a profound influence on intelligence test interpretation to the present day. These authors, recognizing an opportunity provided by the publication of the Wechsler–Bellevue Scale (Wechsler, 1939), advocated interpretation of the newly introduced subtest scores to achieve a more thorough understanding of an individual's cognitive skills; in addition, they extended intelligence test interpretation to include interpretation of individual test items and assignment of psychiatric diagnoses.

Profiles of Subtest Scores

Rapaport and colleagues (1945–1946) espoused an entirely new perspective for the interpretation of intelligence tests, focusing on the shape of subtest score profiles in addition to an overall general level of intellectual functioning. Whereas the pre–World War II psychologist was primarily dependent on the Binet scales and the determination of a general level of cognitive attainment, the post-Rapaport and colleagues psychologist became equally concerned with the shape of a person's profile of subtest scores. Specifically, patterns of high and low subtest scores could presumably reveal diagnostic and psychotherapeutic considerations:

> In our opinion, one can most fully exploit intelligence tests neither by stating merely that the patient was poor on some and good on other subtests, nor by trying to connect directly the impairments of certain subtest scores with certain clinical-nosological categories; but rather only by attempting to understand and describe the psychological functions whose impairment or change brings about the impairment of scores. . . . Every subtest score—especially the relationship of every subtest score to the other subtest scores—has a multitude of determinants. If we are able to establish the main psychological function underlying the achievement, then we can hope to construct a complex psychodynamic and structural picture out of the interrelationships of these achievements and impairments of functions . . . (Rapaport et al., 1945–1946, p. 106)

Rapaport and colleagues' (1945–1946) system had five major emphases, the first of which involved interpretation of item responses. The second emphasis involved comparing a subject's item responses within subtests. Differential responding to the same item type (e.g., information subtest items assessing U.S. vs. international knowledge) was thought to be of some diagnostic significance. The third emphasis suggested that meaningful interpretations could be based on within-subject comparisons of subtest scores. Rapaport and colleagues introduced the practice of deriving diagnostic information from comparisons between Verbal and Performance scales, the fourth interpretive emphasis. They suggested, for example, that a specific Verbal–Performance profile could be diagnostic of depression (p. 68). The fifth and final emphasis involved the comparison of intelligence test findings to other test findings. In this regard, they noted, "Thus, a badly impaired intelligence test achievement has a different diagnostic implication if the Rorschach test indicates a rich endowment or a poor endowment" (p. 68).

The work of Rapaport and colleagues (1945–1946) was a landmark due to its substantial scope. It provided diagnostic suggestions at each interpretive level for a variety of adult psychiatric populations. Furthermore, their work introduced an interpretive focus on intraindividual differences—a focus that at times took precedence over interindividual comparisons in clinical work with clients.

In addition to the breadth of their approach, the structure of Rapaport and colleagues' (1945–1946) approach gave clinicians a logical, step-by-step method for assessing impairment of function and for making specific diagnostic hypotheses. These authors directed clinicians to calculate a mean subtest score that could be used for identifying intraindividual strengths and weaknesses, and they gave desired difference score values for determining significant subtest fluctuations from the mean subtest score. The case of so-called "simple schizophrenia" (see Table 2.3) provides an example of the specificity of the diagnostic considerations that could be gleaned from a subtest profile.

Because of its thorough and clinically oriented approach, Rapaport and colleagues' (1945–1946) work provided a popular structure for training post–World War II clinical psychologists in the interpretation of intelligence test scores (i.e., the Wechsler–Bellevue Scale). This structure lingers today (Kamphaus, 2001).

TABLE 2.3. Diagnostic Considerations for the Case of "Simple Schizophrenia"

Subtest	Considerations
Vocabulary	Many misses on relatively easy items, especially if harder items are passed Relatively low weighted scores Parallel lowering of both the mean of the Verbal subtest scores (excluding Digit Span and Arithmetic) and the Vocabulary score
Information	Two or more misses on the easy items Relatively well-retained score 2 or more points above Vocabulary
Comprehension	Complete failure on any (especially more than one) of the seven easy items Weighted score 3 or more points below the Vocabulary score (or below the mean of the other Verbal subtests: Information, Similarities, and Vocabulary) Great positive Comprehension scatter (2 or more points superior to Vocabulary) is not to be expected
Similarities	Failure on easy items Weighted score 3 points below Vocabulary
Picture Arrangement	Tends to show a special impairment of Picture Arrangement in comparison to the other Performance subtests
Picture Completion	Weighted score of 7 or less
Object Assembly	Performance relatively strong
Block Design	No significant impairment from Vocabulary level Tends to be above the Performance mean
Digit Symbol	May show some impairment, but some "bland schizophrenics" may perform well

Verbal–Performance Differences and Subtest Profiles

Wechsler (1944), perhaps inadvertently, reinforced the practice of profile analysis by advocating a method of interpretation that also placed a premium on shape over a general level, with particular emphasis on subtest profiles and Verbal–Performance differences (*scatter*). His interpretive method is highlighted in a case example presented as a set of results for what he called "adolescent psychopaths" (see Table 2.4). It is noteworthy that Wechsler did not provide a Full Scale IQ (FSIQ) for this case example, focusing instead on shape rather than level. Wechsler offered the following interpretation of this "psychopathic" profile of scores:

> White, male, age 15, 8th grade. Continuous history of stealing, incorrigibility and running away. Several admissions to Bellevue Hospital, the last one after suicide attempt. While on wards persistently created disturbances, broke rules, fought with other boys and continuously tried to evade ordinary duties. Psychopathic patterning: Performance higher than Verbal, low Similarities, low Arithmetic, sum of Picture Arrangement plus Object Assembly greater than sum of scores on Blocks and Picture Completion. (p. 164)

This case exemplifies the second wave of intelligence test interpretation. This second wave was more sophisticated than the first, suggesting that intelligence test interpretation should involve more than mere designation of a general level of intelligence. However, methodological problems existed, eliciting one central question about these approaches: How do we know that these various subtest profiles accurately differentiate between clinical samples, and thus demonstrate diagnostic utility? The next wave sought to answer this salient question by applying measurement science to the process of intelligence test interpretation.

TABLE 2.4. Wechsler's Case Example for "Adolescent Psychopaths"

Subtest	Standard score
Comprehension	11
Arithmetic	6
Information	10
Digits	6
Similarities	5
Picture Arrangement	12
Picture Completion	10
Block Design	15
Object Assembly	16
Digit Symbol	12
Verbal IQ (VIQ)	90
Performance IQ (PIQ)	123

PSYCHOMETRIC PROFILE ANALYSIS: THE THIRD WAVE

The availability of computers and statistical software packages provided researchers of the 1960s and 1970s greater opportunity to assess the validity of various interpretive methods and the psychometric properties of popular scales. Two research traditions—*factor analysis* and *psychometric profile analysis*—have had a profound effect on intelligence test interpretation.

Factor Analysis

Cohen's (1959) seminal investigation addressed the second wave of intelligence test interpretation by questioning the empirical basis of the intuitively based "clinical" methods of profile analysis. He conducted one of the first comprehensive factor analyses of the standardization sample for the Wechsler Intelligence Scale for Children (WISC; Wechsler, 1949), analyzing the results for 200 children from three age groups of the sample. Initially, five factors emerged: Factor A, labeled Verbal Comprehension I; Factor B, Perceptual Organization; Factor C, Freedom from Distractibility; Factor D, Verbal Comprehension II; and Factor E, quasi-specific. Cohen chose not to interpret the fourth and fifth factors, subsuming their loadings and subtests under the first three factors. Hence the common three-factor structure of the WISC was established as the de facto standard for conceptualizing the factor structure of the Wechsler scales. Eventually, Kaufman (1979) provided a systematic method for utilizing the three factor scores of the WISC-R (Wechsler, 1974) to interpret the scales as an alternative to interpreting the Verbal IQ (VIQ) and Performance IQ (PIQ), calling into question the common clinical practice of interpreting the Verbal and Performance scores as if they were measures of valid constructs. Cohen's labels for the first three factors were retained as names for the index scores through the third revision of the WISC (WISC-III; Wechsler, 1991). In addition, Cohen's study popularized the Freedom from Distractibility label for the controversial third factor (Kamphaus, 2001).

Cohen (1959) also introduced the consideration of subtest specificity prior to making subtest score interpretations. Investigation of the measurement properties of the subtests was crucial, as Cohen noted:

> A body of doctrine has come down in the clinical use of the Wechsler scales, which involves a rationale in which the specific intellective and psychodynamic trait-measurement functions are assigned to each of the subtests (e.g., Rapaport et al., 1945–1946). Implicit in this rationale lies the assumption that a substantial part of a test's variance is associated with these specific measurement functions. (p. 289)

According to Cohen (1959), *subtest specificity* refers to the computation of the amount of subtest variance that is reliable (not error) and specific to the subtest. Put another way, a subtest's reliability coefficient represents both reliable specific and shared variance. When shared variance is removed, a clinician may be surprised to discover that little reliable specific variance remains to support interpretation. Typically, the clinician may draw a diagnostic or other conclusion based on a subtest with a reliability estimate of .80, feeling confident of the interpretation. However, Cohen cautioned that this coefficient may be illusory because the clinician's interpretation assumes that the subtest is measuring an ability that is only measured by this subtest of the battery. The subtest specificity value for this same subtest may be rather poor if it shares considerable variance with other subtests. In fact, its subtest specificity value may be lower than its error variance (.20).

Cohen (1959) concluded that few of the WISC subtests could attribute one-third or more of their variance to subtest-specific variance—a finding that has been replicated for subsequent revisions of the WISC (Kamphaus, 2001; Kaufman, 1979). Cohen pointedly concluded that adherents to the "clinical" rationales would find no support in the factor-analytic studies of the Wechsler scales (p. 290). Moreover, he singled out many of the subtests for criticism; in the case of the Coding subtest, he concluded that Coding scores, when considered in isolation, were of limited utility (p. 295).

This important study set the stage for a major shift in intelligence test interpretation—that is, movement toward an emphasis on test interpretation supported by measurement science. Hallmarks of this approach are exemplified in Cohen's work, including the following:

1. Renewed emphasis on interpretation of the FSIQ (harkening back to the first wave), as a large second-order factor accounts for much of the variance of the Wechsler scales.
2. Reconfiguration of the Wechsler scales, proposing the three factor scores as alternatives or supplements to interpretation of the Verbal and Performance scales.
3. Deemphasis on individual subtest interpretation, due to limited subtest reliable specific variance (specificity).

Kaufman's Psychometric Approach

Further evidence of the influence of measurement science on intelligence test interpretation and the problems associated with profile analysis can be found in an influential book by Kaufman (1979), *Intelligent Testing with the WISC-R*. Kaufman provided a logically appealing and systematic method for WISC-R interpretation that was rooted in sound measurement theory. He created a hierarchy for WISC-R interpretation, which emphasized interpretive conclusions drawn from the most reliable and valid scores yielded by the WISC-R (see Table 2.5).

TABLE 2.5. Kaufman's Hierarchy for WISC-R Interpretation

Source of conclusion	Definition	Reliability	Validity
Composite scores	Wechsler IQs	Good	Good
Shared subtest scores	Two or more subtests combined to draw a conclusion	Good	Fair to poor
Single subtest scores	A single subtest score	Fair	Poor

Although such interpretive methods remained "clinical," in the sense that interpretation of a child's assessment results was still dependent on the child's unique profile of results (Anastasi, 1988), the reliance on measurement science for the interpretive process created new standards for assessment practice. Application of such methods required knowledge of the basic psychometric properties of an instrument, and consequently required greater psychometric expertise on the part of the clinician.

These measurement-based interpretive options contrasted sharply with the "clinical" method espoused by Rapaport and colleagues (1945–1946)—an approach that elevated subtest scores and item responses (presumably the most unreliable and invalid scores and indicators) to prominence in the interpretive process. The measurement science approach, however, was unable to conquer some lingering validity problems.

Diagnostic and Validity Problems

Publication of the Wechsler scales and their associated subtest scores created the opportunity for clinicians to analyze score profiles, as opposed to merely gauging an overall intellectual level from one composite score. Rapaport and colleagues (1945–1946) popularized this method, which they labeled *scatter analysis*:

> Scatter is the pattern or configuration formed by the distribution of the weighted subtest scores on an intelligence test . . . the definition of scatter as a configuration or pattern of all the subtest scores implies that the final meaning of the relationship of any two scores, or of any single score to the central tendency of all the scores, is derived from the total pattern. (p. 75)

However, Rapaport and colleagues began to identify problems with profile analysis of scatter early in their research efforts. In one instance, they expressed their frustration with the Wechsler scales as a tool for profile analysis, observing that "the standardization of the [Wechsler–Bellevue] left a great deal to be desired so that the average scattergrams of normal college students, Kansas highway patrolmen . . . and applicants to the Menninger School of Psychiatry . . . all deviated from a straight line in just about the same ways" (p. 161).

Bannatyne (1974) constructed one of the more widely used recategorizations of the WISC subtests into presumably more meaningful profiles (see Table 2.6). Matheson, Mueller, and Short (1984) studied the validity of Bannatyne's recategorization of the WISC-R, using a multiple-group factor analysis procedure with three age ranges of the WISC-R and data from the WISC-R standardization sample. They found that the four categories had high reliabilities, but problems with validity. For example, the Acquired Knowledge category had sufficiently high reliabilities, but it was not independent of the other three categories, particularly Conceptualization. As a result, Matheson and colleagues advised that the Acquired Knowledge category not be interpreted as a unique entity; instead, they concluded that the Acquired Knowledge and Conceptualization categories were best interpreted as one measure of verbal intelligence, which was more consistent with the factor-analytic research on the WISC-R and other intelligence test batteries.

Similarly, Kaufman (1979) expressed considerable misgivings, based on a review of research designed to show links between particular profiles of subtest scores and child diagnostic categories (although he too had provided detailed advice for conducting profile analysis). Kaufman noted that the profiles proved to be far less than diagnostic:

> The apparent trends in the profiles of individuals in a given exceptional category can sometimes provide one piece of evidence to be weighed in the diagnostic process. When there is ample support for a diagnosis from many diverse background, behavioral, and test-related (and in some cases medical) criteria, the emergence of a reasonably characteristic profile can

TABLE 2.6. Bannatyne's Recategorization of WISC-R Subtests

Spatial	Conceptualization	Sequencing	Acquired knowledge
Block Design	Vocabulary	Digit Span	Information
Object Assembly	Similarities	Coding	Arithmetic
Picture Completion	Comprehension	Arithmetic	Vocabulary
		Picture Arrangement	

> be treated as one ingredient in the overall stack of evidence. However, the lack of a characteristic profile should not be considered as disconfirming evidence. In addition, no characteristic profile, in and of itself, should ever be used as the primary basis of a diagnostic decision. We do not even know how many normal children display similar WISC-R profiles. Furthermore . . . the extreme similarity in the relative strengths and weaknesses of the typical profiles for mentally retarded, reading-disabled, and learning-disabled children renders differential diagnosis based primarily on WISC-R subtest patterns a veritable impossibility. (pp. 204–205)

Profile analysis was intended to identify intraindividual strengths and weaknesses—a process known as *ipsative interpretation*. In an ipsative interpretation, the individual client was used as his or her own normative standard, as opposed to making comparisons to the national normative sample. However, such seemingly intuitive practices as comparing individual subtest scores to the unique mean subtest score and comparing pairs of subtest scores are fraught with measurement problems. The clinical interpretation literature often fails to mention the poor reliability of a *difference score* (i.e., the difference between two subtest scores). Anastasi (1985) has reminded clinicians that the standard error of the difference between two scores is larger than the standard error of measurement of the two scores being compared. Thus interpretation of a 3- or 5-point difference between two subtest scores becomes less dependable for hypothesis generation or making conclusions about an individual's cognitive abilities. Another often-cited problem with ipsative interpretation is that the correlations among subtests are positive and often high, suggesting that individual subtests provide little differential information about a child's cognitive skills (Anastasi, 1985). Furthermore, McDermott, Fantuzzo, Glutting, Watkins, and Baggaley (1992), studying the internal and external validity of subtest strengths and weaknesses, found these measures to be wholly inferior to basic norm-referenced information.

Thus the long-standing practice of using profile analysis to draw conclusions about intraindividual strengths and weaknesses did not fare well in numerous empirical tests of its application. The lack of validity support for profile analysis remains unresolved (Kamphaus, 2009). Measurement problems remained, many of which were endemic to the type of measure used (e.g., variations on the Wechsler tradition). These validity challenges indicated the need for the fourth wave, wherein theory and measurement science became intermingled with practice considerations to enhance the validity of test score interpretation.

APPLYING MODERN FACTOR-ANALYTIC MODELS TO TEST DEVELOPMENT: THE FOURTH WAVE

Kaufman (1979) identified a disjuncture between the development of intelligence tests on the one hand and theories and research undergirding the intelligence construct on the other. A colleague of David Wechsler, he knew that Wechsler's measures were built to assess general intelligence, and included two subscales (Verbal and Performance) based not on theory or research findings supporting the existence of such constructs, but on the requirements of everyday assessment practice in linguistically diverse New York City. Wechsler's practical breakthrough allowed psychologists to use the Performance scale to assess the general intelligence of individuals with limited English fluency and comprehension.

Kaufman simultaneously noted that intelligence tests' lack of alignment with factor-analytic research compromised the validity of test score interpretations. He proposed reorganizing subtests into clusters that conformed to widely accepted theories of intelligence, thus allowing clinicians to produce more meaningful conclusions. This seminal insight has encouraged test developers over the past three decades to ensure that the scores offered are grounded in the known factor structure of intelligence. The fourth wave has addressed intelligence test validity through the development of contemporary instruments better grounded in theory, through research findings, and through integration of test results with multiple sources of information—hypothesis validation, as well as testing of rival hypotheses (Kamphaus, 2001).

Test Design for Interpretation

The history of intelligence test interpretation has been characterized by a disjuncture between the design of the tests and inferences made from those tests. A test, after all, should be designed a priori with a strong theoretical foundation, and supported by considerable validity evidence in order to measure a particular construct or set of constructs (and *only* those constructs). Prior to the 1990s, the interpretive process was conducted by clinicians who sometimes applied relatively subjective clinical acumen in the absence of empirically supported theoretical bases to interpret scores for their consumers. For more valid and reliable interpretation of intelligence tests, instrument improvement would now need to focus on constructing tests designed to measure a delimited and well-defined set of intelligence-related constructs.

During the second half of the 20th century, several theories of the structure of intelligence were introduced, promoting a shift to seeking theoretical support for the content of intelligence tests. Among the most significant theories have been Carroll's three-stratum theory of cognitive abilities, the Horn–Cattell fluid–crystallized (Gf-Gc) theory, the Luria–Das model of information processing, Gardner's multiple intelligences, and Sternberg's triarchic theory of intelligence (see Chapters 3–6 of the present volume for reviews).

Two popular theoretical models of intelligence have had the primary distinction of fostering this shift. First, the factor-analytic work of Raymond Cattell and John Horn (Horn & Cattell, 1966) describes an expanded theory founded on Cattell's (1943) constructs of *fluid intelligence* (Gf) and *crystallized intelligence* (Gc). Cattell described fluid intelligence as representing reasoning and the ability to solve novel problems, whereas crystallized intelligence was thought to constitute abilities influenced by acculturation, schooling, and language development. This fluid–crystallized distinction was supported by Horn (1988), who delineated additional contributing abilities such as visual–spatial ability, short-term memory, processing speed, and long-term retrieval.

Subsequent to this research was John Carroll's (1993) integration of findings from more than 460 factor-analytic investigations that led to the development of his three-stratum theory of intelligence. The three strata are organized by generality. Stratum III, the apex of the framework, consists of one construct only—general intelligence or *g*, the general factor that has been identified in numerous investigations as accounting for the major portion of variance assessed by intelligence test batteries. Stratum II contains eight broad cognitive abilities contributing to the general factor *g*, and is very similar to Gf-Gc abilities as described by Horn. Carroll's model proposes numerous narrow (specific) factors subsumed in stratum I. The two models are sometimes used together and are referred to in concert as the *Cattell–Horn–Carroll* (CHC) model of intelligence (see Schneider & McGrew, Chapter 3, this volume).

Merging Theory and Test Design

Most modern intelligence tests are based in part or whole on a few widely accepted theories of intelligence—theories built upon and consistent with decades of factor-analytic studies of intelligence test batteries (Kamphaus, 2001). The commonality of theoretical development is demonstrated in the following brief descriptions of several widely used tests. All are examples of a greater emphasis on theory-based test design. The intelligence tests are described in great detail in individual chapters of this book.

Among contemporary intelligence tests, the Woodcock–Johnson IV (WJ IV; Woodcock & Mather, 2014) is closely aligned with the Cattell–Horn (Cattell, 1943; Horn, 1988; Horn & Cattell, 1966) and Carroll (1993) theories of intelligence. According to the WJ III technical manual (McGrew & Woodcock, 2001), Cattell and Horn's Gf-Gc theory was the theoretical foundation for the Woodcock–Johnson Psycho-Educational Battery—Revised (WJ-R; Woodcock & Johnson, 1989). Four years after publication of the WJ-R, Carroll's text was published; professionals interested in theories of intelligence began to think in terms of a combination or extension of theories, the CHC theory of cognitive abilities (McGrew & Woodcock, 2001). CHC theory, in turn, served as the blueprint for the WJ III (Woodcock, McGrew, & Mather, 2001). The WJ III developers designed their instrument to broadly measure seven of the eight stratum II factors from CHC theory, providing the following cognitive cluster scores: Comprehension–Knowledge (crystallized intelligence), Long-Term Retrieval, Visual–Spatial Thinking, Auditory Processing, Fluid Reasoning (fluid intelligence), Processing Speed, and Short-Term Memory. Moreover, individual subtests are intended to measure several narrow abilities from stratum I. Finally, the General Intellectual Ability score serves as a measure of overall *g*, representing stratum III.

Similarly, the SB5 (Roid, 2003) is based on the CHC model of intelligence. The SB5 can be considered a five-factor model, in that it includes five of the broad stratum II factors having the highest loadings on *g*: Fluid Reasoning (fluid intelligence), Knowledge (crystallized knowledge), Quantitative Reasoning (quantitative knowledge), Visual–Spatial Processing (visual processing), and Working Memory (short-term memory). Among these factors, Visual–Spatial Processing is new to this revision—an attempt to enrich the nonverbal measures of the SB5, aiding in the identification of children with spatial talents and deficits. Moreover, the SB5 is constructed to provide a strong nonverbal IQ by creating nonverbal measures for all five factors.

The Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014) continues to improve the alignment of its scales with the factor-analytic work of Carroll and Horn. Among the primary index scales, the differentiation of Visual Spatial from Fluid Reasoning is just one example. The primary index scales now include:

- Verbal Comprehension Index (VCI)
- Visual Spatial Index (VSI)
- Working Memory Index (WMI)
- Fluid Reasoning Index (FRI)
- Processing Speed Index (PSI)

The factor-analytic work of Carroll (1993) also informed the creation of the Reynolds Intellectual Assessment Scales (RIAS; Reynolds & Kamphaus, 2003) and RIAS-2 (Reynolds & Kamphaus, 2015) by demonstrating that many of the latent traits assessed by intelligence tests are test-battery-independent. The RIAS focuses on the assessment of stratum III and stratum II abilities from Carroll's three-stratum theory. The RIAS-2 is designed to assess five important aspects of intelligence: general intelligence (stratum Ill), verbal intelligence (stratum II, crystallized abilities), nonverbal intelligence (stratum II, visualization/spatial abilities), and memory (stratum II, working memory, short-term memory, or learning) and processing speed. These five constructs are assessed by combinations of eight RIAS-2 subtests.

The effects of basing intelligence tests on the confluence of theory and research findings are at least threefold. First, test-specific training is of less value: A psychologist who knows the commonly accepted factor-analytic findings can interpret most modern intelligence tests with confidence. Second, priorities in pre- and inservice psychologist training can shift to developing knowledge of foundational factor-analytic findings that inform modern test construction and interpretation. Third, as intelligence tests seek to measure similar core constructs, they increasingly resemble commodities (Kamphaus, 2009). In other words, a psychologist's decision to use a particular test may be based less on differences in validity (because the validity of score inferences is similar for different tests measuring the same construct) as on differences in personal preferences for administration time, scoring and reporting options, packaging, price, and other practical considerations. The days of clearly inferior or superior tests are largely gone as publishing houses converge their efforts on assessing core accepted constructs as assessed by tests that adhere to the standards of the profession (American Educational Research Association [AERA], American Psychological Association [APA], & National Council on Measurement in Education [NCME], 2014).

Interpretation of Results

With tests based on strong factor-analytic evidence in place, the job of the assessing psychologist is made easier, but there is still ample room for making flawed test score interpretations. Like all tests, intelligence test results can only be interpreted meaningfully in the context of other assessment results, clinical observations, background/demographic information, and other sources of quantitative and qualitative information. Second, all interpretations made should be supported by research evidence and theory. Presumably, these two premises should mitigate against uniform interpretations that do not possess validity for a particular case (i.e., standard interpretations that are applied to case data but are at odds with information unique to an individual), as well as against interpretations that are refuted by research findings (i.e., interpretations that are based on a psychologist's unique observations or training but are nevertheless contradicted by research findings).

Failure to integrate intelligence test results with other case data (e.g., an examinee's history) is the primary culprit in flawed test interpretation that has been documented by many researchers and practitioners over numerous decades. Matarazzo (1990) offered the following example from a neuropsychological evaluation in which the clinician failed to interpret test results in the context of an individual's background information. This example has the additional advantage of demonstrating the problem of making test score interpretations that are not based on sound validity evidence (e.g., using selected intelligence test subtest results to assess preinjury general intelligence).

> There is little that is more humbling to a practitioner who uses the highest one or two Wechsler subtest scores as the only index of a patient's "premorbid" level of intellectual functioning and who therefore interprets concurrently obtained lower subtest scores as indexes of clear "impairment" and who is then shown by the opposing attorney elementary and

> high school transcripts that contain several global IQ scores, each of which were at the same low IQ levels as are suggested by currently obtained lowest Wechsler subtest scaled scores. (p. 1003)

There are many practical ways to protect against inaccurate test score interpretations. An example provided by Kamphaus (2001) suggested that the intelligence test user establish a standard for integrating intelligence test results with other contextual information by requiring. two pieces of corroborating evidence for each test interpretation made. Such a standard simply provides a helpful rubric that requires the examiner to carefully consider other findings and information before offering conclusions. A clinician, for example, may calculate a WISC-V FSIQ score of 84 (below average) for a young girl and conclude that she possesses below-average intelligence. Even this seemingly obvious conclusion should be corroborated by two external sources of information. If the majority of the child's achievement scores fall into this range, and her teacher reports that the child seems to be progressing more slowly than the majority of the children in her class, the conclusion of below-average intelligence has been corroborated by two sources of information external to the WISC-V. On the other hand, if this child has previously been diagnosed with an anxiety disorder, and if both her academic achievement scores and her progress as reported by her teacher are average, the veracity of the WISC-V scores may be in question. If she also appears highly anxious and agitated during the assessment session, the obtained scores may be even more questionable.

The requirement of research (i.e., validity) support for test-based interpretation is virtually mandatory in light of the publication of the *Standards for Educational and Psychological Testing* (AERA et al., 2014) and the increased expectations of consumers for assessment accuracy (Kamphaus, 2001). Clinical "impressions" of examiners, although salient, are no longer adequate for supporting interpretations of a child's intelligence scores (Matarazzo, 1990). Consider again the example above in which the young child obtains a WISC-V FSIQ score of 84. Let us assume that she has been independently found to have persistent problems with school achievement. Given the data showing the positive relationship between intelligence and achievement scores, the results seem consistent with the research literature and lend support to the interpretation of below-average developed cognitive abilities. Should it become necessary to support the conclusion of below-average intelligence, the clinician could give testimony citing studies supporting the correlational relationship between intelligence and achievement test scores (Matarazzo, 1990).

TESTING RIVAL HYPOTHESES

Some research suggests that clinicians routinely tend to overestimate the accuracy of their conclusions. There is virtually no evidence to suggest that clinicians underestimate the amount of confidence they have in their conclusions (Dawes, 1995). Therefore, intelligence test users should check the accuracy of their inferences by challenging them with alternative inferences.

A clinician may conclude, for example, that a client has a personal strength in verbal intelligence relative to nonverbal. An alternative hypothesis is that this inference is merely due to chance. The clinician may then use test manual discrepancy score tables to determine whether the difference between the two standard scores is likely to be reliable (i.e., statistically significant) and therefore not attributable to chance. Even if a difference is reliable, however, it may not be a "clinically meaningful" difference if it is a common occurrence in the population. Most intelligence test manuals also allow the user to test the additional hypothesis that the verbal–nonverbal score inference is reliable, but too small to be of clinical value for diagnosis or intervention, by determining the frequency of the score difference in the population. If a difference is also rare in the population, the original hypothesis (that the verbal–nonverbal difference reflects a real difference in the individual's cognitive abilities) provides a better explanation than the alternative rival hypothesis (that the verbal–nonverbal difference is not of importance) for understanding the examinee's cognitive performances.

Knowledge of theory, grounded in research, is important above and beyond isolated research findings, as theory allows the clinician to do a better job of conceptualizing an individual's scores. Clear conceptualization of a child's cognitive status, for example, allows the clinician to better explain the child's test results to parents, teachers, colleagues, and other consumers of the test findings. Parents will often want to know the etiology of the child's scores. They will question, "Is it my fault for not reading to her?" or "Did he inherit this problem? My father had the same problems in school." Without adequate theoretical knowledge, clinicians will find themselves unprepared to give reasonable answers to such questions.

CONCLUSIONS

In this chapter, we have presented several overarching historical approaches to the interpretation of intelligence test scores. For heuristic purposes, these approaches are portrayed as though they were entirely separate in their inception, development, and limitations. In the reality of clinical practice, however, much overlap exists.

Aspects of each of these approaches continue to influence modern test interpretation. For example, since Spearman's (1927) publication of findings in support of a central ability underlying performance on multiple tasks, clinicians typically have interpreted a single general intelligence score. Most intelligence tests yield a general ability score, and research continues to provide evidence for the role of a general ability or *g* factor (McDermott & Glutting, 1997). In Carroll's (1993) hierarchical theory, *g* remains at the apex of the model. Therefore, the ongoing practice of interpreting this factor is warranted. At the same time, clinicians continue to interpret an individual's profile of scores. For the most part, the days of making psychiatric diagnoses or predictions of psychiatric symptoms on the basis of intelligence test scores, as Rapaport and his colleagues (1945–1946) suggested, are past; however, profiles are still discussed—that is, in terms of ability profiles related to achievement or educational outcomes. Profile interpretations, however, have generally been superseded by factor-analytic evidence of the existence of stratum II and stratum III factors. Clinicians are on more solid research ground when they make "profile" interpretations based not on ad hoc or conceptual groupings of subtest scores, but rather on the "groupings" made by consistent factor-analytic evidence.

Furthermore, as was the case in what we describe as the third wave, results from psychometric analyses still inform and guide interpretations. Now, however, they are also integrated into broad descriptions and theories of intelligence. Carroll's theory is the result of factor-analytic research, and writers have labeled many of the dominant theories of intelligence as *psychometric* in their approach (Neisser et al., 1996). Thus we see progress in the area of intellectual assessment and interpretation as an evolution, rather than a series of disjointed starts and stops. This evolution has culminated in the integration of empirical research, theory development, and test design, resulting in more accurate and meaningful test interpretation.

What Will Be the Fifth Wave of Intelligence Test Interpretation?

What seems safe to predict is that ongoing educational reform and public policy mandates will continue to shape intellectual assessment and their associated interpretations. The influence of educational test and public policy were present when the first formal intelligence tests were introduced over a century ago, and their influence has not abated.

We hypothesize that the next wave will focus on the publication of new tests with stronger evidence of content validity; if the ultimate purpose of intelligence testing is to sample behavior representing a construct and then to draw inferences about that construct, the process of interpretation is limited by the clarity of the construct(s) being measured. It may also be time to apply a broader concept of *content validity* to intelligence test interpretation (e.g., Flanagan & McGrew, 1997). Cronbach (1971) suggested such an expansion of the term more than four decades ago, observing:

> Whether the operations that finally constitute the test correspond to the specified universe is the question of content validity. It is so common in education to identify "content" with the subject matter of the curriculum that the broader application of the word here must be stressed. (p. 452)

The nature–nurture debate in intelligence testing will continue to fade, thanks to findings indicating that cognitive ability is essentially "developed" through experience (Hart & Risley, 1995). Although the use of the term *IQ* has lessened, it is still popular among the general public. It has been replaced by terms such as *cognitive ability* and others, which have indirectly muted debates about the "excessive meanings" that have accompanied the IQ score, particularly its "native ability" interpretation among some segments of the public. It may now be time, in light of recent evidence, to adopt Anastasi's (1988) preferred term of long ago: *developed cognitive ability*.

We will also be likely to interpret intelligence tests in a more evidence-based manner. The evidence for the overall intelligence test score yielded by measures of developed cognitive ability is among the most impressive in the social sciences.

Lubinski (2004) summarizes some enduring findings:

> Measures of *g* covary .70–.80 with academic achievement measures, .70 with military training assignments, .20–.60 with work performance (correlations are moderated by job complexity), .30–.40 with income, and –.20 with unlawfulness. General intelligence covaries .40 with SES of origin and .50–.70 with achieved SES. As well, assortative mating correlations approach .50. These correlations indicate that *g* is among the most important individual differences dimensions for structuring the determinants of Freud's two-component characterization of life, *lieben* and *arbeiten,* working and loving (or resource acquisition and mating). (p. 100)

As intelligence tests incorporate current research-based theories of intelligence into their design, psychological interpretations will become more valid. This trend will be modified as changes occur in intelligence-testing technology, fostered by breakthrough theories (e.g., neurological) or empirical findings. Although it is difficult to draw inferences about the vast and somewhat undefined "universe" of cognitive functioning, it is also *de rigueur.* Psychologists routinely make such interpretations about the complex universe of human behavior. The emergence of tests that better measure well-defined constructs will allow psychologists to provide better services to their clients than were possible even a decade ago.

ACKNOWLEDGMENTS

We would like to express our gratitude to Martha D. Petoskey and Anna W. Morgan for their contributions to the first edition of this chapter.

PART II

Contemporary Theoretical Perspectives

CHAPTER 3

The Cattell–Horn–Carroll Theory of Cognitive Abilities

W. Joel Schneider
Kevin S. McGrew

The Cattell–Horn–Carroll theory of cognitive abilities (CHC theory) is a comprehensive taxonomy of abilities embedded in multiple overlapping theories of cognition. Like all good taxonomies, its purpose is to orient the user toward distinctions that are meaningful and productive, and away from those that are irrelevant and pointless.

If CHC theory had a personality, it would be open-minded, ambitious, and polite. It does not explain everything about intelligence, but it wants to. It has a lot to say and is perhaps a bit long-winded, but it also listens to other theories. It has a "big-tent" mindset, tolerating ambiguities and disagreements wherever there are reasonable grounds for disagreement (e.g., the nature of general intelligence). It likes to cooperate with other theories when it can and enjoys a good debate when it cannot. Our hope for CHC theory is that it provides a common framework and nomenclature for intelligence researchers to communicate their findings without getting bogged down in endless debates about whose version of this or that construct is better.

A BASIC DESCRIPTION OF CHC THEORY

The basic idea of CHC theory is that intelligence is both multidimensional and functionally integrated. The dimensions of intelligence can be measured, studied, and understood in terms of their shared and separate antecedents, correlates, and causal effects. The source theorists of CHC theory, Raymond Cattell, John Horn, and John Carroll, worked primarily within the psychometric tradition of intelligence theory. That is, they measured individual differences and inferred truths about intelligence by studying the patterns of covariation among these differences. For example, they would try to make sense of the facts that all tests of cognitive ability are strongly correlated, but that there are many clusters of highly correlated tests that are weakly correlated with other clusters of highly correlated tests. The source theorists attempted to infer theoretical entities that would explain such patterns and at the same time be consistent with known facts from biological, cognitive, developmental, and personality psychology, as well as from other disciplines (e.g., genetics, neuroscience, and linguistics).

In CHC theory, the dimensions of ability have a hierarchical structure, meaning that some have a broader scope than others (see Figure 3.1). At the bottom of the hierarchy are *specific abilities,* which are tied to a specific task or test, such as the ability to repeat sentences back after hearing them once or the ability to discern whether two lines are parallel or skewed. Specific abilities are the only abilities that can be measured directly. Other types of

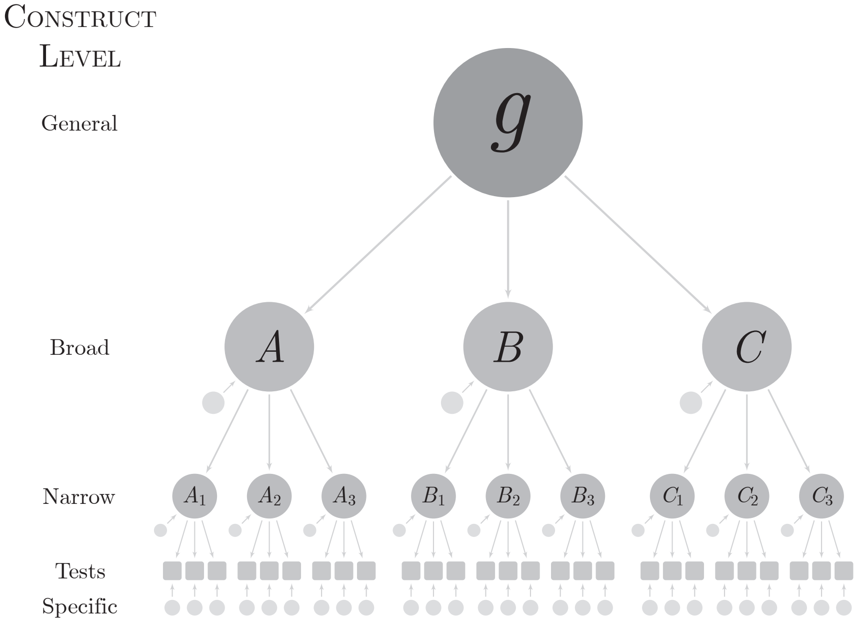

FIGURE 3.1. A tidy hierarchical structure.

abilities—narrow, broad, and general abilities—are theoretical entities inferred from the observed relations among specific abilities.

Narrow abilities are clusters of highly correlated specific abilities. For example, the ability to repeat back sentences is highly correlated with the ability to repeat back single words. These specific abilities are highly correlated with the ability to repeat back digits, letters, and nonsense words. What theoretical entity might explain this fact? Borrowing from cognitive psychology, we might hypothesize that this cluster of highly correlated abilities corresponds to individual differences in *auditory short-term memory storage capacity*.

If we also measure tests that require remembering different kinds of visual information over short periods, we might find that these also correlate highly with each other, prompting us to hypothesize the existence of a different narrow ability, *visual–spatial short-term memory storage capacity*. If we give tests requiring people not only to repeat back the information but also to manipulate it (e.g., repeat words backward, sort them alphabetically, group them by size), we might find that such tests form a separate cluster of highly correlated tests, and that the sensory modality (auditory vs. visual) does not matter much in distinguishing which tests correlate with other tests in this cluster. We might hypothesize that this cluster represents individual differences in a domain-general capacity to direct the focus of attention to process information, such as Baddeley and Hitch's (1974) *central executive* in their model of *working memory*.

Broad abilities are clusters of narrow abilities that are mutually more correlated with each other than with abilities in other broad-ability clusters. For example, auditory short-term storage, visual short-term storage, and attention control form a cluster of narrow abilities that are mutually more correlated with each other than with other kinds of abilities. We can call this collection of narrow abilities *working memory capacity* (Unsworth & Engle, 2007). By convention, all broad abilities in CHC theory have an abbreviation that starts with a capital G, followed by lowercase letters. In this case, the broad ability of working memory capacity would be abbreviated as *Gwm*. The letter G stands for *general*, though not all broad abilities are truly general. Cattell (1971) tried to fix his nomenclature by using the letters *g* and *p* to distinguish between domain-general capacities and "provincial" capacities, but this innovation never caught on.

Carroll (1993) found strong evidence for 8–10 broad clusters of narrow abilities. There may be as many as 20 of them. We are being coy about the exact number not only because of incomplete evidence, but because some ability clusters are difficult to categorize. The terms *broad* and *narrow* are not hard categories, but useful ways of describing degrees of breadth. As our understanding of intelligence has become more nuanced, we have added as many intermediate categories between broad and narrow as needed until the domain is adequately described. In this regard, CHC theory is becoming increasingly like Vernon's (1950) hierarchical group factor theory of intelligence of ability, and by extension, its successor, Johnson and Bouchard's (2005) verbal–perceptual–rotation model.

A full description of CHC theory's broad- and narrow-ability factors appears at the end of the chapter. As an advance organizer, we present the CHC broad abilities grouped conceptually in Figure 3.2. Fluid reasoning (Gf) is a domain-general reasoning capacity. There are several acquired-knowledge capacities, including comprehension–knowledge (Gc), domain-specific knowledge (Gkn), reading and writing (Gw), and quantitative knowledge (Gq). There are several domain-specific sensory abilities corresponding to each of the major senses: visual (Gv), auditory (Ga), olfactory (Go), tactile (Gh), and kinesthetic (Gk), as well as the psychomotor ability factor (Gp). There are three factors related to memory: working memory capacity (Gwm), learning efficiency (Gl), and retrieval fluency (Gr). Finally, there are several abilities related to speed: reaction/decision time (Gt), processing speed (Gs), and psychomotor speed (Gps).

If CHC theory were simply a list of abilities, it would not be much of a theory. The broad and narrow abilities are distinct, yet form an integrated system of problem solving (Schneider & McGrew, 2013). We conclude the chapter with a model of cognition that incorporates the CHC broad abilities as parameters of information processing.

BEYOND CHC: THE EVOLUTION OF THE THEORY AND ASSESSMENT OF COGNITIVE ABILITIES

Historical accounts of the evolution of the psychometric approach to the study of human individual differences abound (Brody, 2000; Carroll, 1993; Cudeck & MacCallum, 2007; Horn & Noll, 1997). We cannot possibly convey the depth, breadth, and subtlety of thought that characterizes the work of the great early theorists. In our chapter in the third edition of this book (Schneider & McGrew, 2012), we presented a visual-graphic timeline and narrative description of significant historical CHC theory and assessment events. The timeline ended with the heading "Beyond CHC theory (the next generation?)." This final phase included the subheadings of "CHC neuropsychological assessment" and "CHC theory impact and extensions."

The question mark in the heading title was prophetic. We initially planned to update this time-

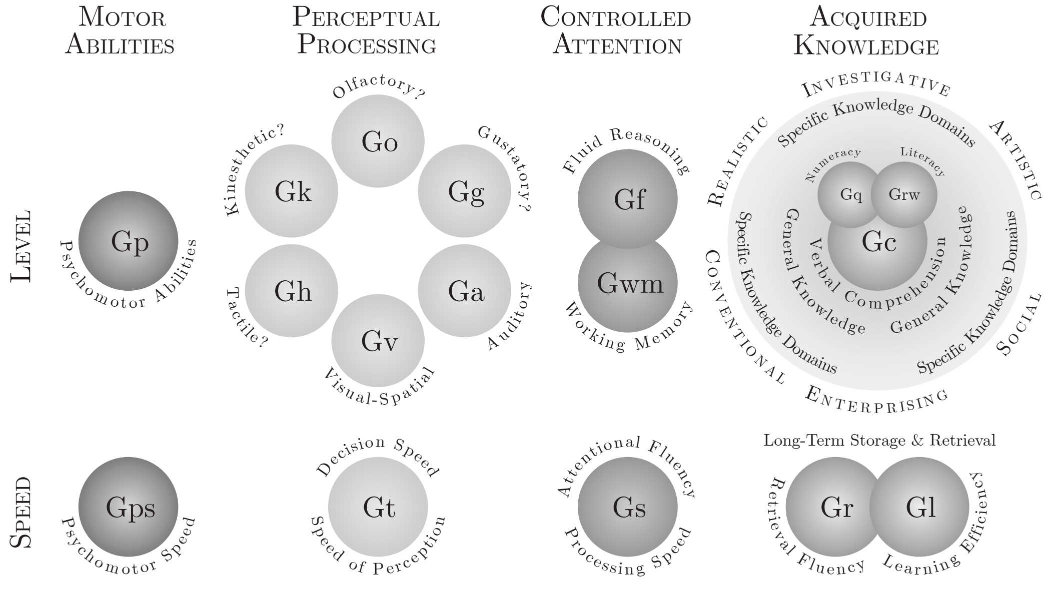

FIGURE 3.2. Conceptual groupings of CHC broad abilities.

line in the current chapter, but found, after numerous frustrating false starts, that distinct crystallized milestones were difficult to identify after 2012. Borrowing from the literature in design innovation (Norman & Verganti, 2014), we believe that CHC theory and assessment developments since 2012 have been more *incremental* or "hill-climbing" innovations (gradual improvements within a given frame of reference; "doing better what we already do") and not *radical* innovations (a novel, unique, and somewhat abrupt change in a frame of reference; "doing what we did not do before"). As a result, instead of providing a revised visual-graphic timeline, we present a list of notable CHC developments. We also provide updates on our prior discussions of CHC-based neuropsychological research and assessment, and of the theory's impact and extension. With the passage of time, we expect that a more focused picture of the "Beyond CHC theory" phase will emerge.

The reader is referred to our chapter in the third edition (Schneider & McGrew, 2012), as well as to several other excellent resources for in-depth descriptions of the history of intelligence theory and testing and CHC theory and assessment (A. S. Kaufman, 2009; Schneider & Flanagan, 2015; Wasserman, 2012 and Chapter 1, this volume).

THE CONTINUING IMPACT OF CHC THEORY

CHC's Global Reach

CHC theory is now officially a globetrotter, with a large bank of frequent flier miles. An indicator of the spread of CHC theory is reflected in the globalization of CHC assessment activities in countries beyond the United States. We highlight some of the major global developments.

The influence of CHC theory, primarily via university assessment training in the use of the CHC-based Batería III Woodcock–Muñoz (Muñoz-Sandoval, Woodcock, McGrew, Mather, & Schrank, 2005), is prominent in Spanish-speaking countries south of the U.S. border. This includes training, research or clinical use of the Batería III in Cuba, Mexico, Chile, Costa Rica, Panama, and Guatemala.[1] Farther south, researchers in Brazil were early adopters of CHC theory as a guide for intelligence test development (Primi, 2003; Wechsler & Nakano, 2016). For example, S. M. Wechsler and colleagues (Wechsler & Schelini, 2006; Wechsler et al., 2010; Wechsler, Vendramini, & Schelini, 2007) completed several studies to adapt the CHC-based Woodcock–Johnson III (WJ III) to Brazil. More recently, Wechsler and colleagues (2014) developed the Brazilian Adult Intelligence Battery, which, although only measuring Gf and Gc, is grounded in CHC theory. Other Brazilian researchers have focused on the nature and measurement of Gf (Primi, 2014; Primi, Ferrão, & Almeida, 2010), with their research couched in the context of CHC theory.

CHC influences are also present north of the U.S. border in Canada. The CHC-based WJ III has been used by practitioners in Canada, based on a U.S.–Canadian matched-sample comparison study (Ford, Swart, Negreiros, Lacroix, & McGrew, 2010). The WJ IV is now sold and used in Canada. In addition, a school-based group-administered CHC test (Insight; Beal, 2011) measuring Gf, Gc, Gv, Ga, Gwm, Glr, Gs, and CDS (Gt) is available in Canada. CHC theory and testing has a prominent place in school psychology assessment courses in several major Canadian universities (e.g., the University of British Columbia, the University of Alberta).[2]

One of the first systematic global CHC test development outreach projects was an effort, led by Richard Woodcock and the Woodcock–Muñoz Foundation, to provide Eastern European countries with cost-effective brief versions of the CHC-based WJ III Tests of Cognitive Abilities. The WJ III-IE (International Editions) project started in the early 2000s and continued until approximately 2015. WJ III-IE norming efforts occurred in the Czech Republic, Hungary, Latvia, Romania, and Slovakia. Other European efforts include the Austrian-developed computerized Intelligence Structure Battery (Arendasy et al., 2009),[3] which measures six broad CHC abilities (Gf, Gq, Gc, Gw, Gv, Glr). The spread of CHC theory has also reached France and Spain. French researchers have analyzed French versions of the various Wechsler scales from the perspective of the CHC framework (Golay, Reverte, Rossier, Favez, & Lecerf, 2013; Lecerf, Rossier, Favez, Reverte, & Coleaux, 2010). In Spain, researchers in computer science education have used the CHC taxonomy to analyze the components of the Computational Thinking Test (Román-González, Pérez-González, & Jiménez-Fernández, 2017).[4] German intelligence research has also been influenced by the CHC model (e.g., see Baghaei & Tabatabaee, 2015), as best illustrated by its incorporation in the German-based Berlin Intelligence Structure (BIS) program of research literature (Beauducel, Brocke, & Liepmann, 2001; Süß & Beauducel, 2015), In addition, the Wuerzburger Psychologische Kurz-Diagnostik

(WUEP-KD), a neuropsychological battery used in German-speaking countries, is grounded in the CHC model (Ottensmeier et al., 2015).

Additional emerging CHC outposts in northern Europe include the Netherlands and Belgium. Hurks and Bakker (2016) reviewed the influence of CHC theory, as well as the neuropsychological planning, attention, simultaneous, successive (PASS) processing theory (see Naglieri & Otero, Chapter 6, this volume), in a historical overview of intelligence testing in the Netherlands. A strong indicator of the growing interest in CHC theory was a CHC theory and assessment conference at Thomas More University, Antwerp, Belgium, in February 2015. Faculty at Thomas More University have developed a CHC assessment battery for children in Flanders that measures the CHC domains of Gf, Gc, Gv, Gwm, and Gs.[5]

Transported via the Chunnel to the United Kingdom and Northern Ireland, the CHC flame has been lit, but has not yet resulted in significant CHC test development. In the 1990s, the WJ III author team was consulted to develop Irish norms for the WJ III. One of the WJ III authors (Fredrick Schrank) visited with several universities in Ireland (University College Dublin, in particular) and continues to do so with regard to the WJ IV (F. A. Schrank, personal communication, March 2, 2017). The CHC theory is now the dominant cognitive taxonomy taught in Irish psychology departments (T. James, personal communication, March 3, 2017).

In the Middle East, known CHC activities have been occurring in Jordan and Turkey. Under the direction of Bashir Abu-Hamour (Abu-Hamour & Al-Hmouz, 2014, 2017; Abu-Hamour, Al Hmouz, Mattar, & Muhaidat, 2012),[6] the CHC-based WJ III has received considerable attention, and the WJ IV was recently translated into Arabic, adapted, and nationally normed in Jordan (Abu-Hamour & Al-Hmouz, 2017). In Turkey, the first national intelligence test (Anatolu–Sak Intelligence Scale, or ASIS)[7] was developed between 2015 and 2017. Although the ASIS composite scores are not couched in the CHC nomenclature, the theories listed as the foundation for the Turkish ASIS are general intelligence, CHC, and PASS. Also, one of us (Kevin S. McGrew) worked with two universities in 2016 in the preparation of government-sponsored grant proposals for additional national intelligence test development in Turkey; both proposals involved using the CHC taxonomy.

Pivoting toward Asia and the world "down under" reveals major CHC test development efforts. Since the publication of the CHC-based WJ III, several key universities and an Australian publisher have delved deep into CHC theory and assessment. Psychological Assessments Australia[8] has translated, adapted, and normed the CHC-based WJ III and WJ IV in Australia and New Zealand. The Melbourne area has been a flashpoint for CHC training and research. Neuropsychologist and researcher Stephen Bowden and his students at the University of Melbourne have produced a series of multiple-sample confirmatory factor analysis (CFA) studies with markers of CHC abilities to investigate the constructs measured by neuropsychological tests (see "CHC-Based Neuropsychological Research and Assessment," below). The University of Monash, initially under the direction of John Roodenburg, and subsequently by his students, placed the CHC model at the core of their assessment course sequence and have infused the CHC framework into the assessment practices of Australian psychologists (James, Jacobs, & Roodenburg, 2015).

Finally, one of the most ambitious CHC test development projects has been occurring in Indonesia since 2013.[9] Sponsored and directed by the Yayasan Dharma Bermakna Foundation, a nationally normed (over 4,000 individuals), individually administered CHC-based battery of tests for school-age children (ages 5–18) is, at this writing, nearing completion. The AJT Cognitive Assessment Test (AJT-CAT) will be one of the most comprehensive individually administered tests of cognitive abilities in the world. The AJT-CAT currently consists of 27 individual cognitive tests designed to measure 21 different narrow CHC abilities (and two psychomotor tests to screen for motor difficulties). Preliminary CFA indicated that the battery measures eight broad CHC cognitive domains (Gf, Gc, Gv, Gwm, Ga, Gs, Gl, Gr) and the Gp motor domain.[10]

CHC Cross-Disciplinary Research and Applied Impact

Not only has CHC theory had a major impact on psychological assessment contexts in the United States and abroad; the usefulness of the taxonomy has been recognized for other important research functions in psychology, other disciplines, and applied settings. The common CHC taxonomic coding system allows for a diverse variety of cognitive measures to be synthesized in theoretically meaningful comparisons across extant research literature bases. Several examples are presented.

The CHC taxonomy has been used to organize meta-analyses that investigate the relations between cognitive ability constructs and other variables across numerous studies. An excellent example is Loughman, Bowden, and D'Souza's (2014) use of the CHC taxonomy to classify a diverse set of cognitive tests used across 26 different studies of idiopathic generalized epilepsy. By classifying the dependent cognitive variables according to the CHC taxonomy, these researchers used meta-analytic methods to present cognitive deficit effect sizes associated with idiopathic generalized epilepsy by the CHC domains of Gc, Gf, Glr, Gs, Gwm, and Gv, as well as executive functions.

Other examples come from health researchers studying the links among nutritional enhancements, cancer, and prenatal exposure to pathogens and cognitive functioning. Pase and Stough (2014; Stough & Pase, 2015) have conducted and reviewed research on pharmacological methods for improving cognitive functioning with a focus on dietary and herbal supplements. Like researchers in many areas of psychology, Stough and Pase (2015) noted:

> It is often hard to compare and contrast the results of individual trials given the differences in the cognitive tests, sample demographics, and products used across studies . . . there is little consensus in the field about how to select, analyze, and report on cognitive outcomes. Cognitive composite scores are often created by combining tenuously related cognitive tasks without adequate justification. We recently suggested that the Cattell–Horn–Carroll (CHC) cognitive framework could be applied to help organize cognitive outcomes in clinical trials according to validated latent cognitive factors . . . the CHC model can help researchers measure and categorize the effects of a specific intervention against the full spectrum of human cognitive abilities. Although the utility of the CHC is in helping individuals categorize cognitive tests into broad and narrow abilities, one could also use the CHC to examine the effects of a pharmacological intervention on general intelligence (g). (p. 180)

Researchers at the U.S. National Cancer Institute have also conceptualized measures of cognitive functioning according to CHC theory in research focused on the impact of specific types of cancer on cognitive outcomes (Padgett, 2015). Finally, clinical epidemiologists have used the CHC model in causal modeling studies focused on the impact of prenatal exposure to methylmercury in cognitive functioning in young adulthood in longitudinal datasets (Debes, Weihe, & Grandjean, 2016).

Psychologists working in military and defense settings have recognized the value of the CHC taxonomy in military selection and classification research as well (Rumsey & Arabian, 2014). A National Research Council (2015) report titled *Measuring Human Capabilities: An Agenda for Basic Research on the Assessment of Individual and Group Performance for Military Accession* referenced the CHC-related research of both John Horn and John Carroll. Research on the selection and training of Canadian military pilots has also used the CHC model to categorize cognitive and aptitude measures (Forgues, 2014; Herniman, 2013). The U.S. Federal Aviation Administration has conducted research on the aptitude requirements needed for air traffic control specialists and utilized the CHC taxonomy in the analysis of the various aptitude measures (Broach, 2013).

Recognition of the CHC taxonomy has also played a role in stimulating new debates in the field of industrial–organizational (I-O) psychology. Several I-O psychologists have argued for the I-O field's need to reconsider its relatively long-standing neglect of the construct of intelligence. In the target article of a special issue of *Industrial and Organizational Psychology,* Scherbaum, Goldstein, Yusko, Ryan, and Hanges (2012) challenged I-O researchers—in part because of the progress made in building validated psychometric (CHC) and other models of intelligence—to reengage in the study of intelligence, since contemporary research on general intelligence and specific cognitive abilities has shown greater promise than the older "all there is is *g*" I-O consensus. Schneider and Newman (2015) echoed the same messages articulated by Murphy (2017) and Scherbaum and colleagues (2012) in the human resource management literature.

Moreover, the CHC model is now involved in life-or-death decisions.[11] Recognizing the variability in forensic intelligence-testing practice and resulting diagnostic chaos, several forensic psychologists have argued for the use of the CHC taxonomy to better organize forensic research and to provide stronger validity for the interpretation of intelligence test results in *Atkins* cases and other criminal procedures (Habets, Jeandarme, Uzieblo, Oei, & Bogaerts, 2015; Uzieblo, Winter, Vanderfaeillie, Rossi, & Magez, 2012). Although the latest classification manual of the American Association on Intellectual and Developmental Disabilities (AAIDD; 2010) focused primarily on IQ as a deficit in general intelligence and did not recognize the CHC model, AAIDD has subsequently published a guidebook specifically on the death penalty (Polloway, 2015) that, in the chapters on intellectual functioning (McGrew, 2015) and intelligence testing (Watson, 2015), places the CHC model front and center as the cognitive taxonomy for understanding intelligence test scores in *Atkins* cases. We believe that this publication sets the stage for AAIDD's formal recognition of the importance of understanding multiple cognitive abilities (viz., CHC theory) and reducing the exclusive focus on the global IQ score in the next revision of the official AAIDD classification manual.

Other uses of the CHC taxonomy have been reported in such diverse contexts as international Paralympic athletics; computer science education and the Internet; and the search for extraterrestrial (ET) life. Van Biesen, Mactavish, McCulloch, Lenaerts, and Vanlandewijck (2016) investigated the relation between nine CHC-classified cognitive measures and tactile proficiency in well-trained table tennis players with intellectual disabilities (members of the International Federation for Para-Athletes with Intellectual Disabilities). Tsianos and colleagues (2013) used the CHC taxonomy to organize the individual-differences user profile layer, the adaptation mapping layer, and the web content layer in an "ontological adaptation mechanism" for designing personalized web environments. Also in the field of computer science, Román-González and colleagues (2017) used the CHC model to investigate the cognitive abilities (Gf, Gv, Gwm) measured by the Computational Thinking Test, a measurement of computer science knowledge in educational settings.

CHC theory's role in the search for ET does not reference any real practical application of the CHC taxonomy in astrobiology. It is mentioned here simply to indicate that the CHC theory received honorable mention (viz., a citation of the McGrew [2009] CHC article in *Intelligence*) in the article "Astrobiology in Culture: The Search for Extraterrestrial Life as 'Science'" (Billings, 2012) when the problem of defining ET life was compared with that of the problem of defining intelligence in psychology.

Finally, the CHC model of "intelligence" is informing another important type of "intelligence"—national security intelligence. The U.S. Office of the National Director of Intelligence sponsors research programs focused on increasing the critical problem solving and analytic thinking of U.S. intelligence analysts. One is the Strengthening Human Adaptive Reasoning and Problem-Solving (SHARP) Program, focused on the advancement of the science for optimizing human adaptive reasoning and problem solving.[12] "The goal of the program is to test and validate interventions that have the potential to significantly improve these capabilities, leading to improvements in performance for high-performing adults in information-rich environments" (*https://tinyurl.com/n7ww3zc*). CHC-organized research and models have been incorporated in the conceptualization, implementation, and evaluation of the SHARP research program (Hartman et al., 2017).[13]

A CONVERGENCE IN INTELLIGENCE TEST BATTERY THEORETICAL FRAMEWORKS?

It is official. Pigs are flying. Hell has frozen over. Why? Because, as astutely pointed out by A. S. Kaufman, Raiford, and Coalson in *Intelligent Testing with the WISC-V* (2016), a form of rapprochement in theory as applied to test construction has occurred among the authors and publishers of the primary individualized intelligence batteries used in the field. There has always been a healthy degree of competition among the authors and publishers of the most frequently used intelligence batteries. Despite obvious differences in the latest versions of the competitive Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V) and WJ IV, the foundational frameworks for the respective batteries may reveal more similarities than differences (A. S. Kaufman et al., 2016).

Clearly, the Sputnik-like CHC moment among intelligence test publishers was the 1989 publication of the WJ-R (A. S. Kaufman, 2009; McGrew, 2005; Schneider & McGrew, 2012). The WJ-R caught the rest of the intelligence test development community largely off guard when it appeared as an operationalization of the extended Cattell–Horn Gf-Gc theory and included John Horn and John Carroll (the HC in CHC) as intelligence theory consultants. Since that moment, the authors and publisher of the subsequent WJ III and WJ IV batteries have been the standard bearers of the CHC structural test development movement. Other intelligence batteries quickly followed suit, either by explicitly organizing revisions of intelligence batteries according to CHC theory (e.g., the Stanford–Binet Intelligence Scales, Fifth Edition [SB5] and the Kaufman Assessment Battery for Children—Second Edition [KABC-II]), or by implicitly providing CHC interpretation material in their manuals (e.g., the Differential Ability Scales–II [DAS-II]) (Keith & Reynolds, 2010).

The publisher of the traditional leaders in sales of intelligence tests (viz., the Wechsler scales) has been more cautious in its reaction to the CHC testing movement launched by the WJ-R. However, the incremental shift in recognizing the CHC model and incorporating it into the Wechslers can be seen—first in the revision of the WISC-III to the WISC-IV four-index model (Verbal Comprehension, Gc; Working Memory, Gwm; Processing Speed, Gs; and Perceptual Organization, Gv/Gf), and then in the further changes to the WISC-V, which has a much cleaner CHC structural model. Specifically, the WISC-V has Verbal Comprehension (Gc), Visual–Spatial (Gv), Fluid Reasoning (Gf), Working Memory (Gwm), and Processing Speed (Gs) index scales, together with the select ancillary index scales of Quantitative Reasoning (Gf-RQ), Naming Speed (Gr-LA), and Storage and Retrieval (Gl and Gr) (Flanagan & Alfonso, 2017). A. S. Kaufman and colleagues (2016) acknowledged that CHC theory has had a significant impact on the WISC-V. However, they noted that this theory "is not the sole or primary force behind revisions of the Wechsler scales" (p. 13). The Wechsler research directors remained true to the historical and traditional foundations of the Wechslers by also placing focus on clinical utility and other functional theories, "including processing theories from the fields of cognitive psychology, as well as various theories related to more specific aspects of working memory, attention, and executive function" (p. 13).

While the WJ III was the most structurally pure approach to measuring the CHC model, A. S. Kaufman and colleagues (2016) correctly note that the WJ IV authors added similar functional theoretical research to the rationale for some of the new WJ IV tests. The WJ IV authors refer to the incorporation of neuroscience and working memory research in the WJ IV test development framework as going "beyond CHC" (McGrew, LaForte, & Schrank, 2014). Although the publishers and authors of the WISC-V and WJ IV may not explicitly acknowledge this apparent theoretical framework convergence (WISC-V = functional theories + CHC theory; WJ IV = CHC theory + functional theories), we believe that A. S. Kaufman and colleagues are largely correct when they state that "the theoretical basis for the development of the Wechsler intelligence scales (as well as the theoretical foundations for the WJ IV) would be more correctly termed a theoretical framework, with content reflecting aspects of both structural (e.g., CHC theory) and functional (e.g., neuropsychological processing theory) theories of intelligence or cognitive ability as well as current, relevant research related to theory and practice" (p. 14). Although the Wechsler and WJ batteries have probably not arrived on the same street or block of the theoretical framework neighborhood, it does appear that a form of theoretical framework convergence is occurring in the field of intelligence test development. CHC theory has played a fundamental role in this convergence.

The major exception to the advance of CHC theory into the major test batteries is the Cognitive Assessment System—Second Edition (CAS2; Naglieri, Das, & Goldstein, 2014), which marches to the beat of its own PASS theory drummer. We believe that PASS theory (Das, Naglieri, & Kirby, 1994) has much to add to CHC theory. For example, we believe that the simultaneous–successive distinction in PASS theory is valid, and we do not believe that it competes with the kind of distinctions made in CHC theory. Despite differences in labels and emphasis, there is already considerable overlap between PASS and CHC theory constructs (Flanagan, Alfonso, & Dixon, 2014; A. S. Kaufman & Kaufman, 2004; Keith, Kranzler, & Flanagan, 2001; Keith & Reynolds, 2010; Kranzler & Keith, 1999; Schneider & Flanagan, 2015).

CHC-BASED NEUROPSYCHOLOGICAL RESEARCH AND ASSESSMENT

In our 2012 chapter, we indicated that neuropsychological assessment was the most active CHC assessment "spillover." This judgment was based on the appearance of several texts on school neuropsychological assessment (Hale & Fiorello, 2004; Miller, 2007, 2010). We continue to believe that CHC theory has the potential to help neuropsychologists generalize their interpretations beyond specific test batteries and give them greater theoretical unity. Previously, we referenced a limited number of CHC-organized factor-analytic studies of joint neuropsychological and CHC-validated batteries (Floyd, Bergeron, Hamilton, & Parra, 2010; Hoelzle, 2008), and concluded that there was a critical need for more research. Several important CHC-based CFA analyses of neuropsychological and cognitive batteries have occurred since our last foray into the neuropsychological sandbox. A number of these analyses have focused on asking whether executive functions have a place in the CHC model.

In a sample of nondisabled school-age children, Ottensmeier and colleagues (2015) used the short version of the WUEP-KD battery to examine the CHC factor structure of common cognitive and neuropsychological specific measures. Although only using single indicators to represent Gf, Gv, Ga, and Gwm in an exploratory factor analysis, multiple subcomponent scores from a continuous-performance test (CPT) and a finger-tapping measure revealed three distinct factors the authors interpreted as Gs (CPT speed and hits), Gt (CPS visual and auditory reaction time), and Gps/Gp (finger-tapping speed and steadiness scores). The interpretation of neuropsychological tests (CPT, finger tapping) as measuring CHC constructs instead of common neuropsychological constructs (e.g., planning, attention, executive functions) suggests that the CHC and neuropsychological nomenclature systems may represent an example of the *jingle–jangle* fallacy.[14] The psychometrically driven CHC taxonomy describes abilities measured from an individual differences construct trait framework, while traditional neuropsychological assessment describes abilities as reflecting functional neuropsychological constructs (see Hoelzle, 2008, for explanation of the historically different origins of these two approaches to assessment).

The most important recent CHC/neuropsychological research has been conducted by Stephen Bowden and colleagues at the University of Melbourne (see "CHC's Global Reach," above). These researchers completed three sets of Carroll-like (1993) CHC-based mini-meta-analytic CFA studies across multiple samples and multiple assessment instruments (Jewsbury & Bowden, 2016; Jewsbury, Bowden, & Duff, 2017; Jewsbury, Bowden, & Strauss, 2016).

In the Jewsbury and Bowden (2016) study, five datasets were analyzed. These analyses demonstrated that a variety of tests of narrow CHC fluency abilities (e.g., associative fluency, expressional fluency, ideational fluency, word fluency) loaded on a single broad CHC ability (broad retrieval fluency, or Gr). This Gr factor was distinct from the current notion of Glr, which consists of both learning efficiency (associative memory or meaningful memory; Jewsbury and Bowden used Gy as per Carroll's original model) and retrieval fluency (associative fluency, expressional fluency, etc.; Gr) components (Schneider & McGrew, 2012). A possible semantic versus orthographic Gr narrow-ability substructure was also suggested. This set of integrated studies indicated that most common neuropsychological tests of fluency (e.g., Boston Naming Test, Controlled Oral Word Association Test, Letter Fluency, Category Fluency), which are typically interpreted as measuring executive functioning, are measuring constructs similar to those assessed in cognitive test batteries (e.g., WJ IV Retrieval Fluency; WISC-V Naming Speed and Naming Quantity) and should be interpreted as indicators of a broad retrieval ability (Gr) according to the CHC framework. This research also suggests that the ability of retrieval fluency may be a specific component of the construct of executive functioning.

As in Jewsbury and Bowden's (2016) Gr analysis, Jewsbury and colleagues (2017) used the CHC model as the framework for a secondary CFA of nine different datasets that included multiple measures of cognitive and neuropsychological abilities (viz., executive functions). After systematically evaluating different CFA models specified to answer their primary research questions, Jewsbury and colleagues reported that

> the CHC model fit well across all data sets . . . the CHC model is an excellent fitting model that is replicable and consistent across diverse tests and populations. In particular, the data sets together provided replicated evidence for the CHC construct validity for many of the most popular neuropsychological tests and batteries. . . . Furthermore, the CHC construct validity was supported across a range of clinically relevant populations . . . the CHC model was found to apply equally well to traditional instruments such as the WAIS and putative executive function measures that are commonly believed to measure constructs beyond the CHC constructs. (p. 557)

These researchers found that common executive function measures loaded across the CHC abilities of Gf, Gwm, Gv, or Gs. Jewsbury and colleagues (2017) concluded that executive function is not a unitary construct and should not be considered as a separate CHC domain of cognition similar to other broad CHC constructs: "Averaging or combining various executive function test scores potentially leads to results that confound cognitive constructs" (p. 560).

In a third set of analyses, Jewsbury and colleagues used CHC-organized CFA in seven datasets to evaluate the validity of the executive function subcomponents of updating (replacing old information in short-term memory span with new information), inhibition (inhibiting responses when necessary), and switching (switching between multiple tasks) (Miyake et al., 2000). The authors reported no support for a separate updating factor distinct from Gwm or a separate inhibition factor distinct from Gs. The researchers did conclude that switching may represent a new narrow ability under Gs. The authors suggested that (1) all Gs tests may involve the ability to inhibit; (2) the ability to inhibit may be a function of Gs; or (3) a third variable (e.g., maintenance of a goal state) may underlie both inhibition and Gs.

The convergence of conclusions across the collective CHC-organized research on executive functioning cannot be ignored. Executive functioning does not represent an individual differences trait construct that should be incorporated in the CHC taxonomy. Also, as noted by Salthouse (2005), "the outcomes of these analyses therefore suggest that measures currently used by neuropsychologists to assess executive functioning may not represent novel aspects of functioning in normal adults. Instead they appear to reflect the same dimensions of differences assessed by more traditional cognitive tests that may have superior psychometric properties (in terms of reliability and sensitivity)" (p. 542). The use of the term *executive functioning* in the interpretation of cognitive and neuropsychological assessments should be restricted in future research (Floyd et al., 2010).

Additional research is needed to determine whether the components of executive functions mentioned in the neuropsychological literature represent combinations, blends, or amalgams of different CHC abilities in a distributed system, or some yet-to-be-validated executive function processes that are also part of certain CHC abilities. It is also possible that executive functioning does not represent a real "thing" or psychological trait construct; instead, it may be an emergent variable reflecting "control and controlled processes [which] are colocalized within larger numbers of dispersed computation agents" (Eisenreich, Akaishi, & Hayden, 2017, p. 1684), not a factor-analytic individual-differences variable (Kovacs & Conway, 2016).

CRITERIA FOR UPDATING CHC THEORY

A theory that can only be updated by one person is more like a copyrighted work of art than a product of open science. Yet to let just anyone alter CHC theory would lead to chaos, conflict, and Wikipedia-style "edit wars," with contributors constantly overwriting each other's amendments. To keep the peace, we will continue to curate CHC theory for as long as we can, but we would like to make the updating process more open and transparent, so that any researcher can contribute to the evolution of CHC theory. Here we outline a tentative set of guidelines for making future amendments to CHC theory.

Robust Evidence Required for Overturning the Measured Opinions of Cattell, Horn, and Carroll

A theory named after Cattell, Horn, and Carroll should reflect the ideas of the source theorists except when persuasive evidence contradicts their ideas. In the initial formulation of CHC theory (McGrew, 1997), most of the nomenclature was borrowed directly from Carroll (1993) rather than from Horn and Cattell. The reason for this choice was that Carroll's work was largely congruent with or even explicitly derivative of the work of Horn and Cattell, and yet was more comprehensive and persuasive. A work that summarizes hundreds of datasets is hard to beat!

Of course, Carroll's is not the final word on the nature of intelligence, as he was careful to point out himself (Carroll, 1998). Although we do not treat Carroll's work as inerrant scripture, we nevertheless cannot think of a better starting point than his 1993 masterwork. Going forward, our default hypothesis is that Carroll's theorizing is more likely to be correct than any other single person's speculations, including our own. As various sections of this chapter indicate, we have often found it necessary to reread Carroll's original work when contemplating new questions about existing or possible new abilities. Bestowing this power on Carroll's treatise should not stop us or anyone else from speculating—but making a better theory than Carroll's requires evidence Carroll did not have. Researchers hoping to amend CHC theory should think of Carroll's work as providing a kind of "null hypothesis" to which their results can be compared.

Introducing New Ability Constructs to CHC Theory

We are not the first to wrestle with ideas about amending established taxonomies. We have borrowed liberally from criteria laid out by Gardner (1983) and Mayer, Caruso, and Salovey (1999), and we have been guided by principles laid out by

Cronbach and Meehl (1955). Using a more specific proposal by Schneider, Mayer, and Newman (2016) as our model, we suggest that the following criteria be applied:

1. *The content domain of the new ability must be laid out clearly.* Researchers who might study the new ability should have a shared understanding of the new construct, so that they can independently develop new measures of the construct.

2. *The new construct must be measurable with performance tests and with multiple test paradigms.* Although it is possible to estimate abilities with nonperformance tests (e.g., questionnaires), performance tests remain the clearest indicators of ability constructs. The new construct must also be measurable with a variety of test formats; otherwise, useless method factors would invade and overwhelm the taxonomy.

3. *Measures of the new ability construct must demonstrate convergent and discriminant validity.* In general, measures of the same ability should correlate more highly with each other than they do with measures of other abilities. A rigorous evaluation of this criterion is usually conducted via some form of covariance structure modeling, such as CFA.

4. *Measures of the new ability must demonstrate incremental validity over measures of more established constructs.* Categorizing new abilities must not be an end in itself. Ability constructs exist because they help us understand relevant outcomes. A new ability construct should improve our prediction of at least one outcome widely considered to be important (e.g., academic, occupational, or creative achievement).

5. *The new ability construct should be linked to specific neurological functions.* Evidence that a new ability is linked to specific neurological functions might include the demonstration that localized brain injuries cause selective impairments in the new ability, that distinct brain networks are distinctly associated with the ability, or that specific genetic variants are selectively associated with extremes of the ability.

6. *The new ability construct should be linked plausibly to functions that evolved to help humans survive and reproduce.* This criterion prevents an endless proliferation of theoretical entities linked to specific areas of achievement. With little effort, one could postulate a separate intelligence for each identifiable achievement domain (e.g., business intelligence, medical intelligence, gaming intelligence, sports intelligence, fashion intelligence, computer programming intelligence), until the taxonomy is so cluttered that it no longer serves its purpose. Certainly, cognitive abilities are relevant in all these domains, but most likely they require complex mixtures or amalgams of more basic cognitive abilities rather than qualitatively distinct abilities.

We acknowledge the role of subjectivity in the evaluation of each of these criteria. To satisfy each of these criteria requires many studies and a lengthy process of scientific deliberation before consensus is achieved. To wait until the evidence is so compelling that no sensible scholar could possibly disagree with the decision to include a new construct would unnecessarily hamper the development of CHC theory. To strike a balance between creative risk and proper prudence, new abilities that have reasonable but not yet compelling evidence will be given tentative status in the CHC taxonomy. When evidence comes from many high-quality studies from independent teams of scholars, the provisional status will be removed, with the proviso that in science all constructs are provisional.

Nearly all of Carroll's broad and narrow factors have met the first four criteria, some more convincingly than others. Many meet the latter two criteria as well, but many have yet to do so. In this chapter, we have not attempted a thorough review of the evidence supporting each ability construct, but such a review will be needed to give CHC a firmer scientific foundation. To date, olfactory processing (Go), tactile/haptic processing (Gh), kinesthetic processing (Gk), psychomotor abilities (Gp), and psychomotor speed (Gps) are broad abilities with tentative status (McGrew, 2009). In this chapter, we argue that emotional intelligence (Gei) also tentatively meets criteria for inclusion in CHC theory. It would satisfy our aesthetic sense if every sensory modality had its own broad factor, but we have no empirical justification for hypothesizing a broad gustatory factor (Gg).

Reorganizing CHC Theory

With each update of CHC theory, not only have new abilities been added; we have deleted, consolidated, reorganized, and renamed ability constructs. For example, short-term memory (Gsm) has been renamed as working memory capacity (Gwm), to keep pace with current theoretical developments (Schrank, McGrew, & Mather, 2014).

Some abilities have been reclassified on logical grounds. For example, geography knowledge was moved from comprehension–knowledge (Gc) to domain-specific knowledge (Gkn) because it is a specific knowledge factor (Schneider & McGrew, 2012). After a closer reading of Carroll's evidence, the language development factor was elevated from a narrow ability to a factor intermediate between Gc and specific aspects of language (Schneider & McGrew, 2012). The cloze (reading) ability was deleted because it appears to be a method factor rather than a distinct ability. For example, cloze ability is the ability to do well on tests that make use of the cloze paradigm (Schneider & McGrew, 2012).

In this chapter, we propose several further modifications to the current CHC theory. We argue for the need to split the long-term storage and retrieval (Glr) factor into separate components of long-term storage and learning (Gl) and retrieval fluency (Gr). The Gl-Gr divorce is the most dramatic change we suggest, and the one with the most solid line of historical and contemporary research evidence. We propose several other small modifications in other domains. We propose that perceptual speed (P) is most likely an intermediate-level processing speed ability, and that two distinct subtypes of narrow perceptual speed abilities exist, differentiated by degree of information-processing complexity required and stimulus content characteristics (facets). In regard to Ga, we suggest that a speech versus nonverbal facet distinction should be considered in interpreting Ga abilities and measures. In regard to Gv, we recognize the importance of efforts to add large-scale spatial navigation abilities to the wealth of small-scale Gv abilities. For some of the tentative and more or less ignored domains (Gh, Gk, Gt), we suggest that their status might be elevated when they are viewed from the relatively recent research and theorization in embodied cognition.

It is likely that future reorganizations will be needed as future evidence accumulates. Although the goal is to have an elegant, parsimonious theory, the process of tidying can itself be a bit messy. In many respects, the process of reorganizing CHC theory is like that of adding new constructs. That is, the criteria must be clear and tied to performance; the proposal must reference convergent, discriminant, and incremental validity; and there should be some reference to biological functions that have a plausible evolutionary history.

Beyond these criteria, however, there are additional considerations of parsimony, coherence, utility, and aesthetics. Here we cannot offer an enumerated list of principles to guide this process. Offering hard and fast principles would be as dangerous as being infected by *statisticism*, which is "a way of thinking in psychology that invests virtually boundless trust in the aptness of statistical concepts and methods to reveal the 'lawfulness' of human psychological functioning and behavior" (Lamiell, 2013, p. 65). Although the fathers of CHC theory were clear statistical wizards and believers in factor analysis, a thorough reading of their writings (as well as informal discussions) reveals that advocacy for a specific form of statistical factor-analytic method to support or defend CHC theory (e.g., the bifactor vs. hierarchical intelligence debate), devoid of clarity of theoretical context (e.g., genetic, neurocognitive, developmental, or outcome criterion evidence) and well-reasoned thought, will never provide a reasonable taxonomy of human intelligence that represents "intelligence in the wild." We can say that we will be as open in the future as we have in the past to persuasion via reason and evidence.

CHC MODEL REVISIONS AND EXTENSIONS

CHC Cross-Battery Research

A pivotal foundation of CHC cross-battery assessment (XBA; Flanagan, Ortiz, & Alfonso, 2013), which has contributed significantly to the extant construct validity evidence for the CHC model, has been CHC-organized XBA research. In XBA factor studies, typically two different cognitive test batteries (e.g., the WJ-R and WISC-III) are jointly factor-analyzed, and the results are interpreted according to the CHC model. CHC-organized XBA studies originated with Woodcock's (1990) seminal series of joint analyses of the WJ-R with all other major intelligence batteries at the time. This eventually resulted in the formalization of the XBA approach to assessment (for historical overviews, see McGrew, 2005; Schneider & McGrew, 2012). Although exploratory factor analysis and CFA studies of individual intelligence test batteries have continued unabated during recent years, there has been a noticeable drop since our 2012 chapter in joint intelligence test XBA studies. There have been studies that included an intelligence test (e.g., one of the Wechsler Adult Intelligence Scale [WAIS] series of tests) and neuropsychological measures (see "CHC-Based Neuropsychological Research and Assessment," above), but we could only find two CHC-organized or CHC-interpreted XBA studies of intelligence batteries.

Primi, Nakano, and Wechsler (2012) completed a Brazilian-based XBA study that included five individual tests from the Battery of Reasoning Abilities (BPR-5) and three individual tests from a Brazilian adaptation of the WJ III. The study provided validity evidence for the BPR-5 tests as measures of Gf, Gv, and Gc. The other study was an impressive demonstration of a CHC-model-driven methodological advance in XBA research. Reynolds, Keith, Flanagan, and Alfonso (2013) completed a CHC-organized, XBA, reference-variable CFA of five different cognitive or achievement test batteries (the KABC-II, WISC-III, WISC-IV, WJ III, and Peabody Individual Achievement Test—Revised/Normative Update [PIAT-R/NU]). In this study, the CHC taxonomy was married with the sophisticated reference-variable CFA methods advanced by McArdle (1994). This methodology allowed for the analysis of data from the five different test batteries in five separate KABC-II concurrent validity studies (with various KABC-II tests serving as common reference-variable links or anchors across studies) in a single combined joint analysis (as if all five batteries had been administered to all participants). That is, this CHC-organized analysis made it possible to evaluate the CHC abilities measured by 39 different tests across test batteries in a single grand analysis. The final model supported the CHC constructs of Gc, Gv, Gf, Gl-MA, and Gwm.

For the CHC XBA approach to assessment and interpretation to evolve, more CHC-designed XBA studies are needed. Stand-alone or joint intelligence battery CHC CFA studies have focused only on the broad (stratum II) CHC domain level. Yet the interpretation of CHC-based intelligence tests or XBA-organized test data has, at its core foundation, the valid classification of the individual tests at the narrow (stratum I) level. There is a serious need for CHC studies that allow for the evaluation of individual tests as indicators of CHC narrow-ability constructs. We recognize that such studies are prohibitively resource-intensive in terms of cost and time (including participant response burden) and may not be practical. Instead, we suggest designing a series of smaller XBA studies that do not attempt to include indicators of all the primary CHC domains. Instead, these more focused studies would include sufficient indicators to specify key narrow CHC abilities for two or three broad domains in a single analysis. If properly designed, a series of narrow-ability-focused studies could be linked with the reference-variable methods demonstrated by Reynolds and colleagues (2013). Such a program of research would provide important insights into the narrow CHC abilities measured by individual tests.

The Glr Divorce: Gl and Gr

In our 2012 chapter, we presided over the formal separation of Glr into Glr-learning efficiency and Glr-retrieval fluency. We recognized that the marriage of these two components of Glr was a union in name only. As we stated in that chapter, "there is a major division within Glr that was always implied in CHC theory, but we are making it more explicit here. Some Glr tests require efficient learning of new information, whereas others require fluent recall of information already in long-term memory" (p. 117). In our functional conceptualization of the CHC model, Glr-learning efficiency (hereafter labeled Gl) and Glr-retrieval fluency (hereafter labeled Gr) were considered parameters of cognitive efficiency. Gl determines how much effort is needed to store new information (of various kinds) in long-term memory, and Gr represents the speed at which information in long-term storage can be loaded into working memory structures for further cognitive processing and use. It is now clear not only that the original Glr marriage was a mistake, but that the trial separation of Gl and Gr was not the long-term solution to the marital mismatch. Therefore, we now formally grant the parties a divorce in the eyes of CHC theory. It is our belief that the separate households named Gl and Gr represent distinct broad CHC domains.

Dissecting why a marriage has gone wrong is not always beneficial. However, in this case, we briefly explain the mistake in the original Glr partnership, as it provides an important cautionary tale in the pursuit of science. The Glr marriage was presided over by McGrew (1997) in his chapter for the first edition of this book, wherein individual tests from all major intelligence batteries were first classified according to the original integration of the Cattell–Horn and Carroll models of cognitive abilities (then called a "proposed synthesized Carrell and Horn–Cattell Gf-Gc framework"). McGrew then used both logical analysis and the results from a special CFA of the WJ-R standardization battery in an attempt to resolve a number of differences between the Carroll and Cattell–Horn models: For instance, is Gq a separate domain from Gf? And should Grw be included under Gc or as a separate broad domain? The question most relevant to the current discussion was whether short-term memory, learning efficiency, and retrieval fluency abilities should be organized under Gsm (Horn's short-term acquisition and retrieval, SAR), Glr (Horn's tertiary storage and retrieval, TSR), Gy (Carroll's memory and learning), or Gr (Carroll's broad retrieval). With no fluency indicators present in the WJ-R, McGrew found support for a narrow associative memory (MM) factor that he considered a proxy for the broad Glr factor, based primarily on the belief that the Cattell–Horn conceptualization of the TSR factor was more correct than Carroll's overly broad Gy factor (which was judged more untenable). In hindsight, the lack of fluency indicators in the WJ-R analysis was a significant contributing factor to the incorrect combination of learning efficiency (e.g., associative memory, meaningful memory) and retrieval fluency (e.g., ideational fluency, naming speed). Despite appropriate caveats that his initial synthesized framework was "only an initial attempt" and only a "proposed framework," McGrew's Glr union stuck and was crystallized in all subsequent CHC articles and book chapters by multiple scholars. The weak foundation upon which it rested was not reevaluated until 15–20 years later.

With the benefit of hindsight, we can see that cracks in the Glr construct were present in the CHC-grounded norm-based CFAs reported in the WJ III technical manual (McGrew & Woodcock, 2001). In the CFAs of the WJ III, the Glr factor had moderate (.60s) to strong (.70s to .80s) loadings for four indicators of associative memory (Memory for Names, Memory for Names—Delayed; Visual–Auditory Learning, Visual–Auditory Learning—Delayed), while the new WJ III Glr fluency tests (Retrieval Fluency, Rapid Picture Naming) had relatively weak loadings (.33, .18) on the Glr factor, and stronger loadings on the Gs factor (.33, .41). Furthermore, significant correlated residuals (.23) between Retrieval Fluency and Rapid Picture Naming suggested unexplained shared variance between these two retrieval fluency measures. Finally, the Glr factor had an unexpectedly high loading (.95) on the *g* factor. Collectively, these findings could have been interpreted as indicating that the WJ III tests of associative memory and retrieval fluency did not form a cohesive Glr factor, and that separate Gl and Gr factors might be present.

The WJ III authors found similar results in the WJ IV (Schrank et al., 2014) and separated these dimensions into the Cognitive battery Glr cluster (it would have been better to call this Gl), comprising two measures of learning efficiency (Visual–Auditory Learning, associative memory; Story Recall, meaningful memory), and the Oral Language battery Speed of Lexical Access cluster (Glr-LA, which could be interpreted as a proxy for Gr; Retrieval Fluency, ideational fluency; Rapid Picture Naming, naming speed). McGrew and colleagues (2014) reported a series of alternative WJ IV broad + narrow CHC CFA models in which the speed of lexical access (LA) factor, defined by salient loadings for Retrieval Fluency, Rapid Picture Naming, and Phonological Processing, did not load on the Glr factor but instead loaded on the broad Gwm and Gc factors. A model with a stand-alone Gr factor (as defined above) was not reported by McGrew and colleagues. Subsequently, McGrew (2015) completed an unpublished CFA model where the separate broad Gr factor was specified (as per the three-indicator LA factor described above) in the WJ IV norm data for ages 6–19. Although the model fit was not significantly different from that of the broad + narrow CHC model presented in the WJ IV technical manual, the model supported the viability of separate Gl and Gr factors. Gl was defined primarily by Story Recall, Visual–Auditory Learning, Memory for Names,[9] and to a lesser extent Reading Recall and Writing Samples; Gr was defined primarily by Retrieval Fluency, and to a lesser extent Rapid Picture Naming and Phonological Processing (which also had loadings on Gs and Ga, respectively). The reduction of the original combined Glr factor loading on the *g* factor (.95) to .85 (Gl) and .56 (Gr) is more theoretically reasonable. Also, noticeably different cross-sectional growth curves for the WJ IV Glr (Gl-learning efficiency) and LA (Gr-retrieval fluency) clusters (McGrew et al., 2014) provide developmental evidence supportive of these measures as representing different CHC ability domains. The practical implications for the WJ IV Glr and Speed of Lexical Access clusters are discussed in the "CHC Theory Described and Revised" section of this chapter.

Other recent structural analysis studies support separate Gl and Gr broad abilities. In the first official recognition of the separate Gl and Gr factors in the CHC model, Affrunti, Schneider, Tobin, and Collins (2014) found support for separate Gl and Gr factors, along with validation for the broad CHC factors of Gc, Ga, Gv, Gs, and Gwm (and a narrow memory span factor) in a large clinical dataset of university students (*n* = 865) who were administered the WJ IV Cognitive and Achievement batteries and the WAIS-III. In a sample of

317 healthy adults and a separate sample of 280 adults with clinical disorders, both of which were administered a battery of neuropsychological tests, Vannorsdall, Maroof, Gordon, and Schretlen's (2012) exploratory factor analysis found a clear ideational fluency factor (Gr). Also, the WISC-V battery includes supplementary Naming Speed and Symbol Translation indexes, which, according to a recent structural analysis of the standardization data (multidimensional scaling or MDS), measure aspects of Gr and Gl (MA, associative memory), respectively (Meyer & Reynolds, 2017). A preliminary CFA of the Indonesian AJT-CAT test also provides support for separate Gl and Gr factors (see "CHC's Global Reach," above). Finally, the previously described Jewsbury and Bowden (2016) CHC-organized CFA of five datasets that included cognitive and neuropsychological tests supports the separation of Glr into distinct Gl and Gr factors.

We would be remiss if we did not recognize the decades of research in which the concept of broad retrieval fluency has always been featured as a cornerstone of creativity. Carroll (1993) included many of the extant Gr studies in his seminal survey—studies that used a variety of fluency measures to define this core feature of divergent thinking (J. C. Kaufman, 2016). Several recent creativity studies provide additional evidence for a fluency or Gr factor (Beaty, Christensen, Benedek, Silvia, & Schacter, 2017; Beaty & Silvia, 2013; Beaty, Silvia, Nusbaum, Jauk, & Benedek, 2014; Silvia, 2015; Silvia & Beaty, 2012), distinct from other CHC factors (Gf, Gc). Although these studies are supportive of a broad Gr ability, they are not 100% decisive, as these studies suffer from a lack of indicators that would allow for the representation of a Gl factor and comparison of this factor to the Gr factor.

Finally, clear evidence for the Gr broad ability is present in the writings of two of the fathers of the CHC model—evidence that should have been more clearly investigated in the original 1997 Glr marriage. As noted by Carroll (1993), the existence of an ability represented by various measures of fluency has been present in research traced to Spearman and others in the late 1920s to 1950s. Cattell (1987) described this broad ability as "a general fertility or facility of memory retrieval in regard to any kind of material" (p. 46). He continued: "General retrieval, g_r, is considered an *ability* concerned with the fluency-retrieval performances, and having to do with storage and accessibility facility" (p. 447; original emphasis). Carroll was correct in his seminal treatise, where he included a Gr (broad retrieval ability) in his model. He discussed this domain in depth in a separate chapter on "Abilities in the Domain of Idea Production." According to Carroll, factors representing Gr "involve the active production of ideas as opposed to the recognition, identification, selection or comparison of ideas as represented in stimuli presented to subjects" (p. 394). Furthermore, "in describing this domain as one of idea production, I mean the term idea to be taken in the broadest possible sense. An idea can be expressed in a word, a phrase, a sentence, or indeed any verbal proposition, but it may be something expressed in a gesture, a drawing, or a particular action" (p. 394).

Tentative CHC Broad Sibling: Gei

It might seem as if adding emotional intelligence to CHC theory is a radical step. It is not. In fact, emotional intelligence has been present in CHC theory under a different name since the beginning. Carroll (1993, p. 513) was convinced by Guilford's work on social intelligence (Guilford, 1967; Guilford & Hoepfner, 1971; O'Sullivan & Guilford, 1975) that comprehending the social and emotional behavior of others is an important aspect of intelligence. Though Carroll (1993, p. 513) did not find the term *knowledge of behavioral content* to be satisfactory, he retained Guilford's nomenclature to refer to sensitivity to nonverbal communication via gestures and facial expressions. Whatever the label, this ability falls squarely within the domain currently referred to as *emotional intelligence*.

The idea that intelligence involves understanding social and emotional behavior has a long history, going back to John Dewey (1909) and E. L. Thorndike (1920). Most of the early attempts to measure social intelligence failed to distinguish it clearly from verbal ability (Hunt, 1928; Landy, 2006; R. L. Thorndike, 1936; R. L. Thorndike & Stein, 1937; Walker & Foley, 1973). However, Guilford's prodigious talent for test construction allowed him to create a novel set of social intelligence measures that were clearly distinct from measures of verbal ability, convincing even previously skeptical critics like Cronbach (1970, p. 343) that social intelligence was a worthy object of study.

There have been several attempts to integrate the large literature on the "hot" intelligences (i.e., related to personality, emotion, and interpersonal processes) with the gigantic literature on more traditional "cool" intelligences, including Guilford's

(1967) structure-of-intellect model, Gardner's (1983) theory of multiple intelligences (see Chen & Gardner, Chapter 4, this volume), and Sternberg's (1985, 1997, 1999b) theory of successful intelligence (see Sternberg, Chapter 5, this volume). Here we briefly review the relevant issues involved in such an integration, but thorough discussions can be found elsewhere (Davies, Stankov, & Roberts, 1998; Matthews, Emo, Roberts, & Zeidner, 2006; Matthews, Zeidner, & Roberts, 2004, 2005; Mayer et al., 1999; Mayer, Caruso, & Salovey, 2016; Mayer, Panter, & Caruso, 2012; Mayer, Roberts, & Barsade, 2008; Mayer, Salovey, & Caruso, 2008; Mayer, Salovey, Caruso, & Sitarenios, 2001; Schneider et al., 2016). In our review, we leave aside emotional intelligence research that draws largely on self-report questionnaires (i.e., research on so-called "trait emotional intelligence") and focus entirely on ability-based measures of emotional intelligence.

The term *emotional intelligence* gained traction upon being introduced by Salovey and Mayer (1990). Operationalized in the Mayer–Salovey–Caruso Emotional Intelligence Test (MSCEIT; Mayer, Salovey, & Caruso, 2002), their concept has four major components: perceiving emotions, understanding emotions, facilitating thought by using emotions, and managing emotions in oneself and in others. Consistent with the criteria we have proposed for introducing new constructs into CHC theory, this model of emotional intelligence has a well-defined content domain, so that independent researchers can develop new measures of the construct that correlate with each other well (Mayer et al., 2016). This criterion is best satisfied by measures of the ability to perceive emotions (Wilhelm, Hildebrandt, Manske, Schacht, & Sommer, 2014), but multiple measures of emotional understanding and emotional management are now available (Allen, Weissman, Hellwig, MacCann, & Roberts, 2014; Austin, 2010; Billings, Downey, Lomas, Lloyd, & Stough, 2014; Brackett & Mayer, 2003; Krishnakumar, Hopkins, Szmerekovsky, & Robinson, 2016; MacCann, Matthews, Zeidner, & Roberts, 2003; MacCann & Roberts, 2008; Maul, 2012; Mayer et al., 2002; Mayer, Salovey, & Caruso, 2014; Mayer, Salovey, Caruso, & Sitarenios, 2003; Palmer, Gignac, Manocha, & Stough, 2005; Schultz, Izard, Ackerman, & Youngstrom, 2001). Mayer and colleagues (2016) have conceded that measures of the facilitation factor have not been found to be psychometrically distinct from the other factors, but remain hopeful that new measures can be developed to validate that component of the model.

Well-constructed ability tests of emotional intelligence have undergone a through construct validation process (Allen et al., 2014; Brackett & Mayer, 2003; Joseph & Newman, 2010; MacCann, Joseph, Newman, & Roberts, 2014; MacCann & Roberts, 2008; Maul, 2012; Mayer et al., 1999, 2002, 2016; Schneider et al., 2016). Although there are controversies about scoring procedures to be sorted out (Zeidner, Roberts, & Matthews, 2008), it appears that these measures compare favorably with measures of traditional intelligences in terms of reliability, stability, and predictive validity (Mayer et al., 1999, 2001, 2016; Mestre, MacCann, Guil, & Roberts, 2016).

Emotional intelligence ability tests correlate with traditional measures of intelligence, generally in the range of .20 to .60, with higher correlations between the component of understanding emotions and Gc (Brackett, Rivers, & Salovey, 2011). Evidence for the predictive validity of emotional intelligence has been accumulating steadily since 1990 from the findings of dozens of independent scholars (Mayer, Roberts, et al., 2008). Ability-based emotional intelligence predicts job performance, leadership ability, negotiation skill, and salary beyond the five-factor model of personality and general intelligence measures (Blickle et al., 2009; García & Costa, 2014; Iliescu, Ilie, Ispas, & Ion, 2012; Rosete & Ciarrochi, 2005; Sharma, Bottom, & Elfenbein, 2013). Ability measures of emotional intelligence predict social competence beyond verbal ability and questionnaire measures of personality (Brackett, Rivers, Shiffman, Lerner, & Salovey, 2006; Lopes et al., 2004).

For us, the tipping point for tentatively expanding the role of emotional intelligence in CHC theory was the CFA research of MacCann and colleagues (2014). In this study, emotional intelligence measures from the MSCEIT (Mayer et al., 2002, 2003) were given alongside traditional intelligence tests. The results were consistent with the hypothesis that emotional intelligence is a broad ability in the same sense as other CHC abilities.

CHC THEORY DESCRIBED AND REVISED

In the sections that follow, we have multiple aims. First, we hope to define each of the constructs in CHC theory in terms that clinicians will find useful. Second, we hope to give some guidance as to which constructs are more central to the theory or have more validity data available. Third, we wish to alert readers to existing controversies and raise some questions of our own. Fourth, we propose a number of additions, deletions, and rearrangements in the list of CHC theory abilities.

General Intelligence (*g*)

In 1904, Spearman was the first to observe what is perhaps the most consistent and frequently replicated finding in all psychological research: all mental abilities are positively correlated. The simplest explanation of this finding is that all mental abilities have a common cause: general intelligence or *g*. Spearman's (1904) efforts to understand *g* led him to invent factor analysis. To put it mildly, Spearman's explanation of the positive correlations he observed has proved controversial. When the goddess of discord attends intelligence conferences, before tossing in her golden apple, she writes on it, "Quick question. I was curious about your opinion about *g* . . ."

Many researchers have alternative explanations of the finding that mental ability tests are positively correlated, but so far no explanation has proved persuasive to our entire field. Carroll (1993, 1998, 2003) believed that the evidence for the existence of *g* is clear. As explained later, Cattell and Horn believed just as strongly that something else is going on.

We accept that a general factor exists, but we are skeptical that it is an ability. That is, there are many factors that can simultaneously influence the entire brain, such as malnutrition, exposure to toxic substances, blunt-force trauma, large strokes, infections of the brain, and thousands of genes that independently influence the functioning of neurons. These general influences make it possible to evaluate the overall level of a person's intelligence without necessarily referring to a causal force called *general intelligence*. Analogously, there are factors that influence the quality of an automobile, such as the manufacturer's commitment to excellence, the maintenance habits of the owner, the car's collision history, and so forth. We can describe the overall quality and condition of the car, but we would not say that there is a causal force called *general car quality*.

That said, the challenge for *g* skeptics is to explain why the general factor of intelligence is such a powerful predictor of life outcomes, and why the remaining factors usually explain only a few percentage points of additional variance in most outcomes (Canivez, 2013; Glutting, Watkins, Konold, & McDermott, 2006; Gottfredson, 1997; Jensen, 1998; McDermott, Fantuzzo, & Glutting, 1990; Schmidt & Hunter, 1998). We believe that meeting this challenge is possible (Ackerman, 1996b; Benson, Kranzler, & Floyd, 2016; Evans, Floyd, McGrew, & Leforgee, 2002; Horn, 1985; Horn & Cattell, 1966; Horn & McArdle, 2007; Outtz & Newman, 2010; Schneider & Newman, 2015; Wee, Newman, & Joseph, 2014), but we concede that neither side of this controversy has compelling evidence.

There is considerable debate currently about whether *g* has direct effects on performance or indirect effects through broad and narrow abilities. The bifactor model (with direct effects of *g*) usually fits better than the hierarchical model (with indirect effects of *g*). The problem is that unless the theorist has specified exactly the right model, the bifactor model fits better even when the true model is hierarchical (Murray & Johnson, 2013). We agree with Mansolf and Reise's (2017) conclusion that no conclusion is possible on this matter yet. We take solace in our observation that there are no current practical concerns that hinge on our knowing the answer to this question. We suspect that neither the bifactor nor the hierarchical model of *g* is correct, but that the true structure of intelligence is far more interesting and far weirder than any theorists, including ourselves, have imagined.

Domain-Free General Capacities

Some CHC factors (Gf, Gwm, Gl, Gr, Gs, and Gt) are not associated with specific sensory systems. These diverse factors may reflect, respectively, different parameters of brain functioning that are relevant in most or all regions of the brain (Cattell, 1987). The fact that they are grouped together does not mean that clinicians should create composite scores with names like "Domain-Free General Capacity" because this is a conceptual grouping, not an implied functional unity.

Gf-Gc Theory

If you are unfamiliar with a problem, you can apply reason to find a solution. If you have seen the problem before, you simply need to recall whatever solution was successful in the past. These two ways of solving problems, deliberate reasoning and recalling past solutions, correspond to what Raymond Cattell (1941, 1943) called *fluid* and *crystallized intelligence,* respectively.

Fluid intelligence refers to the ability to perceive conceptual relationships. People with high fluid intelligence are able to respond insightfully to unfamiliar situations by observing complex phenomena, inferring the unstated rules that govern their behavior, and exploiting this knowledge to deduce the best course of action to take (Cattell & Horn, 1978). *Crystallized intelligence* refers to the accumulated knowledge generated via fluid intelligence. Crystallized intelligence helps us find efficient solutions from the past that best match the needs of the present. People with high crystallized intelligence have broad, deep knowledge and an extensive repertoire of skills that are useful in their cultural context.

The Fluid–Crystallized Metaphor

Cattell was a creative theorist who was playful with metaphors, and his use of the terms *fluid* and *crystallized* was nuanced and multilayered. For our purposes, we can say that fluid intelligence is "fluid" in the sense that it can be applied to any situation, no matter how unfamiliar. Crystallized intelligence is so named because it consists of fixed bits of knowledge (initially acquired via fluid intelligence) that are now "crystallized" in memory.

Evidence for the Distinction between Fluid and Crystallized Intelligence

There are three primary lines of evidence that Cattell (1941, 1943, 1971, 1987) cited to support the distinction between fluid and crystallized intelligence:

1. The two types of intelligence can be distinguished with factor analysis, meaning that tests of crystallized intelligence correlate more strongly with each other than they do with tests of fluid intelligence. Likewise, tests of fluid intelligence correlate more strongly with each other than they do with tests of crystallized intelligence. This is called *structural evidence*.

2. The two abilities have different developmental growth curves. That is, fluid intelligence declines steadily starting in early adulthood, whereas crystallized intelligence increases until late adulthood. This is called *developmental evidence*.

3. Different types of brain injury have differential effects on the two types of intelligence. This has been called *neurocognitive evidence*. Cattell's evidence suggested that almost any lesion in the cortex decreases fluid intelligence in proportion to the size of the lesion, whereas most brain injuries have little effect on crystallized intelligence unless the lesions are in regions of the brain known to affect language. For this reason, Cattell believed that fluid intelligence represents the mass action of the entire cortex. Although it is true that fluid intelligence declines in response to injury in many different regions of the cortex, it appears that Cattell was not entirely correct that any lesion anywhere will decrease fluid intelligence. For example, it appears that particular regions of the frontal and parietal lobes are particularly important for fluid reasoning (Woolgar et al., 2010). Nevertheless, it is largely true that crystallized intelligence is more robust to brain injury than fluid intelligence.

Cattell's g_f and g_c as Elaborations of Spearman's g

Cattell's (1941, 1943) distinction between fluid and crystallized intelligence is sometimes seen as a challenge to Spearman's (1904) theory of general intelligence. However, it is clear from Cattell's initial formulation of his theory that he was not contradicting Spearman, but elaborating on his mentor's theory. Cattell was presenting psychometric, developmental, and neurological evidence that Spearman's *g* arose because of two different processes, and thus should be split into at least two general factors of ability, general fluid intelligence (g_f) and general crystallized intelligence (g_c). Indeed, the idea that there might be more than one general factor of intelligence comes from Spearman's (1904) first paper on general intelligence, though Spearman never developed this idea any further himself.

Note that Cattell could have chosen other ways to abbreviate his constructs (F and C, for example). In patterning his abbreviations g_f and g_c after Spearman's solitary *g*, Cattell (1971) emphasized the continuity of his thinking with that of his mentor (p. 299). The similarities are not merely typographical, though. Unlike other multifactor theories of intelligence in which there was a hierarchy of ever-narrower abilities, Cattell's g_f-g_c theory described his two constructs as true *general* factors of intelligence. In what sense are these factors general? Both factors are expected to influence performance in every mental activity, but to different degrees, depending on the task.

Cattell's g_f-g_c versus Horn's Gf-Gc

From his first publications about fluid intelligence (Cattell, 1941, 1943) to his last major work on the subject (Cattell, 1987), Cattell's thinking about fluid intelligence became increasingly elaborate, culminating in his triadic theory of intelligence (1971, 1987)—a dramatic reworking of his original g_f-g_c theory. The nuances of this underappreciated theory are not covered in this chapter, but in rough sketch Cattell believed that there are four *general capacities* (fluid reasoning, memory, retrieval fluency, and speed); a handful of *provincial powers* corresponding to sensory and motor domains (e.g., visual, auditory, olfactory, gustatory, tactile, and cerebellar); and a large number of environmentally developed capacities he called *agencies* (e.g., mechanical ability, literacy, numeracy, and so forth). One developed agency, crystallized intelligence, is so broad in scope that it behaves like a general capacity (Cattell, 1987).

Cattell's theoretical elaborations were motivated in part by the empirical results he obtained in collaboration with his student John Horn (Cattell, 1963; Cattell & Horn, 1978; Horn & Cattell, 1966, 1967). Even after Horn became a major theorist in his own right, Cattell and his former student were largely in agreement about most matters. Nevertheless, the two theorists have subtle differences of interpretation and emphasis, which can be detected in careful readings of works they wrote independently of each other (Cattell, 1980, 1987, 1998; Hakstian & Cattell, 1974, 1978; Horn, 1982, 1985; Horn & Blankson, 2005; Horn & McArdle, 2007; Horn & Noll, 1997). Whereas Cattell continued to maintain that fluid and crystallized intelligence are general abilities, Horn's description of the constructs suggested they are abilities with a narrower scope, closer to that of Thurstone's (1935, 1938) primary ability factors of reasoning and verbal ability, respectively.

The two variants of fluid and crystallized ability can be distinguished typographically, using each theorist's preferred abbreviation style (g_f-g_c vs. Gf-Gc). Horn's fluid reasoning factor (Gf) is a broad ability, but not a true general factor like Cattell's g_f. Horn's crystallized intelligence factor (Gc) is likewise broad, but not as general as Cattell's g_c. Whereas Cattell's g_f and g_c affect every aspect of intelligence, Horn's Gf and Gc affect only those aspects of intelligence that directly involve reasoning and acquired knowledge. Carroll (1993, 1998, 2003) largely drew from Horn's version of fluid and crystallized intelligence; Gf and Gc are extremely broad in scope, but not truly general in the sense that they, like Spearman's *g*, simultaneously influence all abilities to some degree.

Cattell's Investment Theory

If fluid and crystallized intelligence are different constructs, why are they correlated? In what Cattell (1987) called *investment theory*, the correlation results from the consistent application of fluid reasoning generating new knowledge, which, as it accumulates, becomes crystallized knowledge. In wealthy societies with relatively enlightened policies, people with manifest talents, whatever the circumstances of their birth, are given opportunities to develop those talents via public schooling, scholarships, informal mentoring, and so forth. All else equal, people with greater fluid ability acquire greater crystallized ability. However, all else is not equal, even in societies that aggressively promote equality. People with the same level of fluid intelligence live in different eras, cultures, regions, cities, neighborhoods, and families. Furthermore, everyone has a unique physiology and life story, giving rise to the rich array of individual differences we can observe in any population, no matter how homogeneous it might at first appear. Thus, having the same level of fluid intelligence does not imply the same opportunities to learn, the same incentives to learn, or the same drive to learn. Individuals with ambition and drive often create opportunities to maximize whatever gifts they might have. In rigidly stratified societies, talent is carefully cultivated among those at the top of the social hierarchy and lies fallow among those at the bottom. In "Elegy Written in a Country Churchyard," poet Thomas Gray (1716–1771) lamented the untapped potential and undeveloped talents of his countrymen who lived unnoticed and died unremembered:

> Full many a flow'r is born to blush unseen,
> And waste its sweetness on the desert air.
> Some village-Hampden, that with dauntless breast
> The little tyrant of his fields withstood;
> Some mute inglorious Milton here may rest,
> Some Cromwell guiltless of his country's blood.

To extend an analogy used in passing by Cattell (1943, pp. 178–179), the dynamic relationship between fluid and crystallized intelligence can be likened to the formation of a coral reef. The bulk of a coral colony's structure is not alive, but consists of the accumulated skeletal remains of long-dead coral polyps. Only the outermost layer has living polyps, which feed on small organisms in the surrounding waters. The hardened remains of coral polyps create surfaces on which new polyps can grow. Under the right conditions, many coral colonies together form coral reefs, which create sanctuary ecosystems for many organisms—some of which the coral eat, thus contributing to the growth of the reef.

To stretch the analogy just a bit further, fluid intelligence is like the outermost layer of a coral colony. Fluid reasoning creates new knowledge, and via memory, knowledge accumulates; today's fluid insights become tomorrow's crystallized knowledge (Cattell, 1987, p. 139). However, crystallized knowledge is not merely raw data stowed away somewhere in the brain. In the same way that coral skeletons create structures ideally suited for new polyps, crystallized knowledge provides conceptual structures on which new fluid insights are more likely to occur (Beier & Ackerman, 2005; Ericsson & Kintsch, 1995; Goode & Beckmann, 2010). This is one of the reasons why experts absorb new information related to their discipline more quickly than new information unrelated to their expertise (Gobet, 2005; Hambrick & Engle, 2002). Under the right conditions, complex knowledge structures distributed across individuals and institutions can create sanctuary ecosystems (e.g., universities), in which intellectual insights flourish and expertise develops to the limits of human capacity.

Like living coral polyps, fluid intelligence is fragile, vulnerable to the effects of malnutrition, injury, disease, and aging (Cattell, 1987). Like coral skeletons, crystallized intelligence is more robust. Individuals whose fluid intelligence was once high but now disrupted because of disease or injury will usually retain most of their former knowledge and skills. For this reason, knowledge tests are often used to estimate a person's intelligence before the brain injury. In Cattell's words, "[C]rystallized abilities are, as it were, a dead coral formation revealing by its outlines the limits of growth of the original living tissue" (1987, pp. 178–179).

Fluid Reasoning

When Cattell coined the term *fluid intelligence*, his definition was directly parallel to Spearman's definition of *g*: "Fluid ability has the character of a purely general ability to discriminate and perceive relationships between any fundaments, new or old" (1943, p. 178). In that same paragraph, he gave it the same role as that of *g*: It causes the intercorrelations among ability tests. Thus the difference between Spearman's and Cattell's theories is not so great, once it is understood that $g_f \approx g$.

Although Spearman is now known as a pioneering statistician and researcher, his earliest and most enduring passion was philosophy (Spearman, 1930). The question that burned brightest in his mind was that of how new knowledge was created. He objected strongly to then-prevalent ideas inspired by associationism, which held that new knowledge was created by the co-occurrence of sensations. In what he considered his best work, *The Nature of "Intelligence" and the Principles of Cognition*, Spearman (1923) outlined his philosophical argument for how sensory associations alone where insufficient for the creation of new knowledge. Spearman believed that three processes could account for knowledge creation:

- *Apprehension of experience:* Basic features of an object, the *fundaments* of apprehension, are immediately brought into awareness whenever the object is the focus of attention.
- *Eduction of relations:* When two fundaments are perceived, the relation between them tends to be evoked. For example, the juxtaposition of the words *day* and *night* tends to evoke the relation of *opposite* (see Figure 3.3).
- *Eduction of correlates:* When presented with a relation and a fundament, a correlated fundament is evoked. For example, the relation *opposite* paired with the word *friend* might evoke *enemy* (see Figure 3.3).

At the same time that Spearman was grappling with the philosophical question of how knowledge is created, he was also developing statistical procedures for studying the structure of intelligence (Spearman, 1904). After some time, it struck him that what he called *general intelligence* consists of individual differences in the ability to perform these three mental processes. Hitherto, he had considered his philosophical and scientific concerns to be separate matters. Spearman (1923, 1930) described the realization that his two main scholarly pursuits had converged on one and the same idea as the most satisfying intellectual experience of his lifetime.

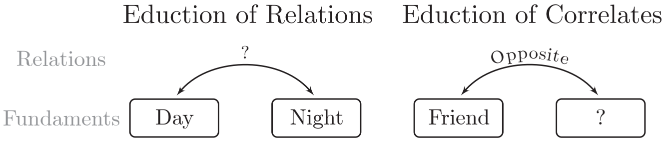

FIGURE 3.3. Illustration of the eduction of relations and correlates.

Definition of Gf

Fluid reasoning (Gf) can be defined as the use of deliberate and controlled procedures (often requiring focused attention) to solve novel, "on-the-spot" problems that cannot be solved by using previously learned habits, schemas, and scripts. Gf is considered a hallmark of intelligence, as it "is essential to learning in school, performance on the job, and life generally" (Kyllonen & Kell, 2017, p. 16). If we can translate Spearman's insights into more modern terms, fluid reasoning is the process by which we extract new knowledge from information we already have. To reason about pieces of information, we need to be able to perceive them, know what they are, and hold them in immediate awareness long enough to perceive their interrelations (Chi, Feltovich, & Glaser, 1981; Fry & Hale, 1996; Kail, 2007; Kane et al., 2004; Krumm et al., 2009). For example, one cannot detect a sequence of colors if one cannot perceive that the colors are different.

One cannot infer the relationship between two fundaments if one does not know what the fundaments are. For example, the analogy "Morning Star is to Evening Star as Venus is to ____________" is a difficult analogy, but not because the relationship between Morning Star and Evening Star is complex. The analogy is difficult because these terms are unfamiliar to most people. Once they are informed that both are alternate names for the planet Venus, the solution is easy: Venus.

Instead of talking about apprehension of experience, we would say that the ability to perceive and hold information in working memory is a precondition of being able to detect previously unnoticed patterns in the information. The question "Who is your mother's sister's husband's daughter's coach's friend's twin's boss?" is difficult not because it contains difficult words or requires complex reasoning to answer, but because it overwhelms the working memory of most listeners. Once this question is split into eight separate questions, anyone familiar with all eight people can answer each question with ease.

In everyday experience, fluid reasoning and prior knowledge are flexibly employed separately, in alternating sequences, or in tandem to meet whatever demands one faces. In contrast, tests of "fluid reasoning" developed for intellectual assessment are designed to minimize the influence of prior knowledge. The tests use simple shapes, simple words, and simple concepts familiar to most people. The difficulty in fluid reasoning tests is in detecting and working with increasingly complex relationships among the stimuli.

Narrow Abilities within Gf[15]

In Carroll's (1993) meta-analysis of over 460 datasets, he identified and classified approximately 240 instances of reasoning factors (Kyllonen & Kell, 2017). Clearly Gf is a well-established broad cognitive ability. Carroll identified several narrow abilities within the fluid reasoning domain, but made no strong claims that his list was comprehensive. It is also important to note that the separate listing of Gf narrow abilities (and narrow abilities in other CHC broad domains) does not indicate that these are highly unique and different abilities. All narrow abilities in a broad domain correlate with each other to some degree. Carroll found that the following three narrow Gf abilities are different, but they are often difficult to distinguish empirically (Kyllonen & Kell, 2017).

1. **Induction: The ability to observe a phenomenon and discover the underlying principles or rules that determine its behavior. This ability is also known as rule inference.* People good at inductive reasoning perceive regularities and patterns in things that otherwise might seem unpredictable. In most inductive reasoning tests, stimuli are arranged according to a principle, and the examinee demonstrates that the principle is understood (e.g., generating a new stimulus that also obeys the principle, identifying stimuli that do not conform to the pattern, or explaining the principle explicitly). For example, complete the next four items in this

sequence: $a^bC_De^fG_H$. Compare these figures: ╔, ╠, ╩, ╣, ╦, ╬, ╝ with these figures: ╒, ╤, ╪, ╫, ╢, ╡. With which group is ╓ most similar? What is the relationship between this group of words (*hope, dread*) and this group (*disappointed, relieved*)?

2. *General sequential reasoning: The ability to reason logically using known premises and principles. This ability is also known as deductive reasoning or rule application.* Whereas induction is the ability to use known facts to discover new principles, general sequential reasoning is the ability to use known principles to discover new facts. For example, if you know that there are no polar bears in Antarctica, and you see a picture of an iceberg with polar bears on it, you can deduce that the iceberg is not in Antarctica.

3. **Quantitative reasoning: The ability to reason with quantities, mathematical relations, and operators.* Tests measuring quantitative reasoning do not require advanced knowledge of mathematics. The computation in such tests is typically quite simple. What makes them difficult is the complexity of reasoning required to solve the problems. For example, choose from among these symbols: +–×÷= and insert them into the boxes to create a valid equation: 8 ☐ 4 ☐ 4 ☐ 8 ☐ 2.

Tentative Narrow Factors

- *Reasoning speed (RE)*: *The ability to reason quickly and correctly.* Carroll (1993) hypothesized that each of the broad factors of ability could be measured with both speed and power tests. The fact that the speed metaphor is often used in synonyms for *smart* (e.g., *quick-witted*) suggests that speed of reasoning has long been noticed as a correlate of intelligence. Unfortunately, clear evidence of a separate reasoning speed factor has not been forthcoming. One of the more rigorous studies designed specifically to distinguish this ability from other aspects of reasoning found reasons to suppose that this is not actually a distinct ability but a complex amalgamation of many influences (Danthiir, Wilhelm, & Schacht, 2005). That is, speed-of-reasoning tasks measure a complex mix of Gf, Gt, Gs, and possibly even aspects of personality such as impulsivity and self-confidence.
- *Piagetian reasoning (RP).* Carroll (1993) advanced the tentative hypothesis that the kinds of tasks used to test Piagetian theories of cognitive development form a distinct narrow factor within Gf. Such tasks are designed to measure seriation (organizing material into an orderly series that facilitates understanding of relations between events), conservation (awareness that physical quantities do not change in amount when altered in appearance), classification (ability to organize materials that possess similar characteristics into categories), and so forth. For now, the hypothesis that there is something distinctive about Piagetian reasoning does not have strong support (Carroll, Kohlberg, & DeVries, 1984; Inman & Secrest, 1981). Given that inductive and deductive reasoning can likely be sub-divided into several extremely narrow abilities, such as analogical, anomalous, antinomous, and antithetical reasoning (Alexander, Dumas, Grossnickle, List, & Firetto, 2016), it is possible that tests of Piagetian reasoning measure a diverse collection of additional narrow reasoning factors as well. Furthermore, Piaget's approach has been criticized based on research that has questioned the idea of qualitative stage transitions; suggested that his theory seriously underestimates the cognitive capabilities of infants and young children; and suggested that more detailed specifications of the mechanisms of change, beyond equilibration, are needed (Newcombe, 2013).[16]

Assessment Recommendations for Gf

Certain narrow abilities are more central to the broad factors than are others. Induction is probably the core aspect of Gf. No measurement of Gf is complete, or even adequate, without a measure of induction. If two Gf tests are given, the second should typically be a test of general sequential (deductive) reasoning. A quantitative reasoning test would be a lower priority unless there is a specific referral concern about mathematics difficulties or other clinical factors warranting such a focus. We also believe it is important that if more than one measure of Gf is administered, attempts should be made to use one measure of "Gf in the wild" (i.e., a test that is not a miniature controlled learning task with structured feedback and examiner scaffolding; Wechsler Matrix Reasoning, WJ IV Number Series) and the other should be a miniature controlled learning task (e.g., WJ IV Concept Formation or Analysis–Synthesis).

Comments and Unresolved Issues Related to Gf

- *How distinct is Gf from the g factor?* As previously noted, hierarchical factor analyses often show that Gf and *g* are perfectly correlated (Undheim & Gustafsson, 1987; Weiss, Keith, Zhu, & Chen, 2013), but not always (Carroll, 2003; Matzke, Dolan, & Molenaar, 2010). In a particularly powerful demonstration, Kvist and Gustafsson (2008) found that Gf and *g* were nearly identical when analyses considered three homogenous groups separately (native-born Swedes, immigrants to Sweden from Europe, and immigrants to Sweden from outside Europe). However, the correlation between *g* and Gf dropped to about .80 when the analyses pooled data from all three groups. The authors interpreted their results as strong support for Cattell's (1987, p. 139) hypothesis that statistical *g* represents the aggregate effect of the investment of Gf in lifelong learning. In populations with similar learning opportunities, Gf and *g* are nearly identical, but the two factors can be distinguished to the degree that learning opportunities are markedly different.

- *Should Gf be divided by content, process, or both?* The distinction between inductive reasoning and general sequential (deductive) reasoning is neat and tidy because they represent distinct kinds of reasoning processes. However, the inclusion of quantitative reasoning as a narrow ability muddies the taxonomy because it spans both inductive and deductive reasoning, but applies only to quantitative content. That is, inductive and deductive reasoning are process factors, and quantitative reasoning is a mixed process and content factor. Oliver Wilhelm (2005) pointed out that most of the tests in Carroll's (1993) induction factor were nonverbal and most of the tests in his general sequential reasoning factor were verbal, thus conflating process with content. Thus, because of this "content confound" (Kyllonen & Kell, 2017), it is not clear what the proper division of Gf should be.

Might there be other content factors in Gf beyond quantitative reasoning? It appears so. CFAs consistently show that fluid reasoning tests can be separated into verbal, spatial/figural, and numerical/quantitative factors (Lakin & Gambrell, 2012; Schroeders, Schipolowski, & Wilhelm, 2015; Schulze, Beauducel, & Brocke, 2005). Evidence from MDS studies suggest that fluid reasoning tests that use similar content, whether it be verbal, spatial, or quantitative, tend to cluster together and that content distinctions matter more in deductive reasoning tests than in inductive reasoning tests (Beauducel et al., 2001; Cohen, Fiorello, & Farley, 2006; Guttman & Levy, 1991; Marshalek, Lohman, & Snow, 1983; Meyer & Reynolds, 2017). These content dimensions are typically referred to as *facets*.[17] In the only study specifically designed to distinguish simultaneously between content (verbal, spatial, and quantitative) and process (inductive vs. deductive reasoning), fluid reasoning tests were distinguished more clearly by content than by process (Wilhelm, 2005). However, a meta-analysis of brain scan research found different patterns of cortical activation for both process (rule inference/induction vs. rule application/deduction) and content (verbal vs. visual–spatial) facets of Gf (Santarnecchi, Emmendorfer, & Pascual-Leone, 2017).

Although Gf tests cluster by content facets, it is not yet clear to us that the separate content clusters represent fundamentally distinct kinds of fluid reasoning. In many of Carroll's (1993) analyses and in more recent studies (Weiss et al., 2013), visual–spatial ability tests often load on the Gf factor, and nonverbal Gf tests often load on the Gv factor. Likewise, verbal analogy tests, markers of verbal Gf, regularly load on Gc, and quantitative reasoning tests often load on the same factor as mathematics achievement tests (McGrew et al., 2014). It seems plausible that the verbal, figural, and numeric content facets in Gf simply represent factor impurities from Gc, Gv, and Gq, respectively. That is, reasoning about words is enhanced if one has background knowledge about them; reasoning about figures is easier if one can manipulate them in the mind's eye; and reasoning about quantity is easier if one has a solid grasp of mathematics. Perhaps the content facets in Gf, and in other domains (e.g., see Gr), reflect an acquired knowledge component of the broad CHC "process" abilities. This distinction between content facet (knowledge) and process would be consistent with Ackerman's theory (see Ackerman, Chapter 8, this volume).

Despite these reservations, the evidence is clear that Gf tests cluster by content, and that the content clusters are not interchangeable in terms of their predictive validity (Gustafsson & Wolff, 2015). Inspired by pioneers who studied intelligence with MDS (Guttman, 1954; Guttman & Levy, 1991; Marshalek et al., 1983), we present both content and process facets of Gf in Figure 3.4.

In Figure 3.4, inductive processes constitute the core of Gf and are relatively independent of stimulus type. Deductive processes (general sequential reasoning and rule application) rely more heavily on content-specific mechanisms—most likely the same collection of content-specific processes that give rise to the broad factors of ability. The three types of content specified in Figure 3.4 have sufficient evidence to support their differentiation,

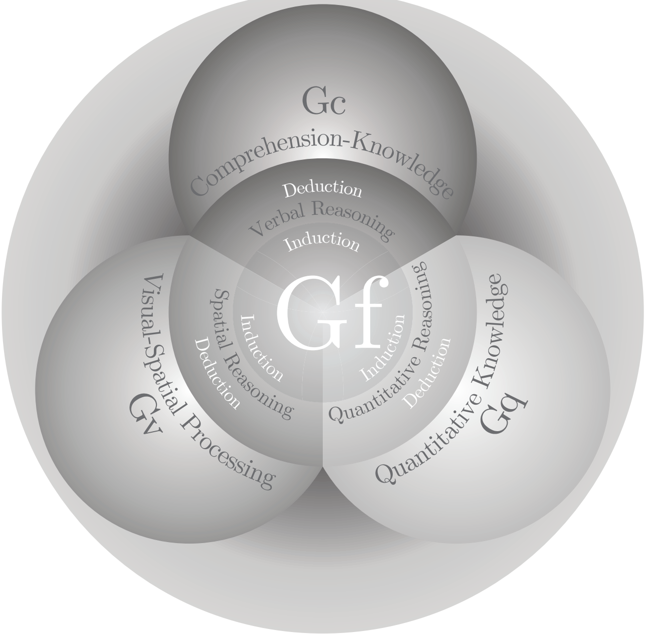

FIGURE 3.4. A conceptual map of fluid reasoning and its overlap with other broad abilities. Fluid reasoning (Gf) probably has both a process facet (inductive vs. deductive reasoning) and a content facet (verbal, spatial, quantitative, and possibly others), each of which overlaps with other broad abilities.

but there may be additional content factors corresponding to each sensory modality (auditory, tactile/kinesthetic, olfactory/gustatory, etc.).

We suspect that this faceted view of fluid reasoning may provide a conceptual bridge for reconciling CHC theory with Johnson and Bouchard's (2005) verbal–perceptual–rotation model. In the latter model, there is no fluid–crystallized distinction, but a verbal–perceptual distinction.

- *What is the relationship among working memory, attentional control, relational complexity of information processing, and Gf?* The past two decades have seen an explosion of research and spirited debate regarding the causal influence of working memory, components of executive functioning, and Gf (e.g., Gwm → Gf). Much of this research is based on the hypothesis that the amount and complexity of information processing made possible by working memory is the foundation of Gf. We touch on this research in our section on Gwm (Kyllonen & Kell, 2017).

- *What is the relation between Gf and complex problem solving and critical thinking?* Educational researchers and policymakers have been driven to embrace constructs believed to be important in the development of essential skills for learners in the 21st century (e.g., complex problem solving and critical thinking; Organization for Economic Co-Operation and Development, 2004). Existing research has indicated that Gf plays a significant role in these aptitude-like amalgams of abilities (Stadler, Becker, Gödker, Leutner, & Greiff, 2015). Research is needed to clarify the importance and role of Gf in these constructs.

- *How can we harness new developments in understanding relational cognitive complexity and cognitive strategy use in Gf test development and research?* Research and theory has indicated a strong link between fluid reasoning and degree of cognitive complexity involved in Gf tasks. Briefly, relational cognitive complexity focuses on the sheer number of interrelated elements (or pieces of information) or element relations in a task that must be processed in parallel, which in turn places a certain amount of relative cognitive load on working memory during reasoning (Birney, Halford, & Andrews, 2006; Halford, Wilson, & Phillips, 1998; Just & Carpenter, 1992). Two approaches to characterizing the cognitive complexity of tests have been employed

(Bertling, 2012). Empirical methods (e.g., MDS) have been used to analyze the relative cognitive complexity of tests after they have been developed. This is a post hoc, data-driven approach to understanding the cognitive complexity demands of Gf and other tests (Marshalek et al., 1983; McGrew et al., 2014). In contrast, theoretical models based on the constraints placed on reasoning by working memory have been used to explain relative cognitive complexity. We believe that test design strategies married with psychometric methods based on item response theory should be used to design, evaluate, and control the relative complexity of Gf items during the test development stage (e.g., see the use of a Latin square design of item types and Rasch analysis by Birney et al., 2006). Such an a priori test design strategy could result in Gf tests with better-known cognitive complexity item characteristics, as well as in the possibility of developing objective "relative cognitive complexity" indexes for comparing Gf tests. Furthermore, studies using experimental psychology methods should be employed to evaluate the amount of cognitive complexity involved in different Gf tests, as well as different cognitive strategies used by individuals as they perform on Gf tests. For example, Hayes, Petrov, and Sederberg (2015) found that eye-tracking technology revealed how cognitive strategy refinement occurred across items and test sessions on matrix reasoning tests.

- *Are we not done "sinking shafts" (Lubinski, 2000) in the domain of Gf (I, RG, RQ)?* During the past decade, there has been an increase in research across multiple domains of inquiry regarding the construct of *relational reasoning.* Relational reasoning is "the ability to recognize or derive meaningful relations between and among pieces of information that would otherwise appear unrelated" (Dumas, Alexander, & Grossnickle, 2013, p. 392). Although often considered synonymous with deductive reasoning (RG), a broader notion of relational reasoning has posited four subtypes of reasoning about relations: *analogy,* or discerning meaningful patterns with otherwise unconnected information; *anomaly,* or identifying structural similarities between two or more objects, concepts, and so on; *antinomy,* or recognizing abnormalities or deviation in an established pattern; and *antithesis,* or identifying directly oppositional relations between two ideas, concepts, or the like (Dumas et al., 2013). In a relatively large sample (*n* = 1,379), albeit limited to undergraduates, Alexander and colleagues (2016) presented structural evidence for a four-factor Test of Relative Reasoning consistent with the four subtypes briefly described above, as well as a single overarching relational reasoning factor. Given that the preponderance of research on relational reasoning has primarily used analogic reasoning tasks (e.g., matrix reasoning; semantic analogies of the form "A:B, then C:D"), this research suggests that the general sequential reasoning (RG) ability may have a substructure, which then begs for similar investigations for inductive and quantitative reasoning. Or perhaps these are just four types of method factors under RG, which could serve the valuable function of generating new test formats for measuring RG.

Memory: General Considerations

Cognitive psychologists have produced a staggeringly complex and impressive body of work on how memory works. Our model of memory draws on this field, but is necessarily much simpler than the cutting-edge models currently available today. Drawing on Unsworth and Engle (2007), we refer to short-term memory at the "trailing edge of consciousness" (Cowan, 2005) as *primary memory,* durable memories that have left consciousness as *secondary memory,* and executive processes that move and manipulate information within and across both systems as *working memory.* Baddeley (2012) calls primary memory *fluid memory systems* and secondary memory *crystallized memory systems,* which for obvious reasons is appealing to us but may well prove confusing in this context.

Primary, secondary, and working memory are not individual-difference variables. They are descriptive terms referring to cognitive structures that everyone has. The most relevant individual-difference variables are working memory capacity (Gwm), learning efficiency (Gl), and retrieval fluency (Gr). *Working memory capacity* refers to how working memory performs its functions. *Learning efficiency* refers to how much time and effort is needed to store new information in secondary memory. *Retrieval fluency* refers to the speed, ease, and accuracy of retrieval of information from secondary memory.

Working Memory Capacity (Gwm)

Definition of Gwm

Working memory capacity (Gwm) can be defined as the ability to maintain and manipulate information in active attention. In the beginning, every animal species went to the computer store to buy a brain. Different species opted for different capacities to meet their needs—dogs got extra olfactory processing, pigeons got GPS, bats got echolocation, and so forth. When it came time to select a memory system, the salesperson laid out these options:

> "Well, I can sell you two different kinds of memory. One is lavishly expensive, ridiculously fragile, achingly slow, and laughably error-prone. It holds only three or four items at a time, and is continuously overwritten every time your attention wanders, which happens pretty much all the time. The other is quick, cheap, reliable, and robust; lasts forever; and offers unlimited storage space."

Only humans were intrigued by the first option.

Compared to long-term memory, what good is a small, fragile, easily overwhelmed, temporary memory system that requires huge swaths of calorically expensive cortex? Whatever flaws working memory may have, most of what makes human thought distinctive would be impossible without it. Working memory sits at the nexus of attention, learning, language, and reasoning (Baddeley, 2002, 2003, 2012). How? Working memory is a mental workspace in which the mind can combine and reconfigure concepts and percepts.

CHC theory concerns individual differences in how well the various components of working memory function. In Baddeley's (2012) multicomponent model, there are domain-specific temporary storage structures and a domain-general control structure. The *visuospatial sketchpad* is the mind's eye, a workspace in which visual objects can be manipulated to create images never seen before. If you are told to visualize a purple hippopotamus pole-vaulting to victory at the next Olympics, your mind creates a temporary image in the visuospatial sketchpad, which you can then make do anything your creative mind can conceive. The *phonological loop* plays the same role as the visuospatial sketchpad, but for sound.

Both storage structures are severely limited in terms of how many independent pieces of information that can be maintained simultaneously. Most people can maintain about three to five "chunks" of information (Cowan, 2005), but these limitations can be circumvented in two ways. First, information can be transferred to long-term memory and then reloaded into working memory when needed (Unsworth & Engle, 2007). Second, smaller chunks can be bound together into ever more elaborate structures (Gobet, 2005; Gobet et al., 2001). For example, the letter sequence *JPGRMMLJGRHSEWAF* would be hard to remember, unless one is familiar with names of the Beatles, the Gospels, the houses of Hogwarts, and the classical elements.

The *central executive* is a hypothetical structure that, depending on the goal, focuses attention, divides attention, switches attention back and forth between objects, and interfaces with long-term memory (Baddeley, 2012). One of its principal functions, called *binding,* is to find relationships among stimuli features (e.g., remembering that a square was red and a circle was blue binds red to square and blue to circle). The limits of working memory capacity are thought to be limited by the efficiency with which new bindings are created and dissolved as one solves problems (Shipstead, Lindsey, Marshall, & Engle, 2014). If one can maintain many objects in the focus of attention for a long time, one has the possibility of discerning more complex relationships among the objects. For this reason, working memory is thought to be a core component of fluid reasoning (De Alwis, Hale, & Myerson, 2014; Duncan, Chylinski, Mitchell, & Bhandari, 2017; Fry & Hale, 1996; Kail, 2007; Unsworth, Fukuda, Awh, & Vogel, 2014).

Working memory capacity is thought to be an important precursor to all forms of academic achievement, either indirectly through fluid reasoning or directly via multistep problem solving (Bull, Espy, & Wiebe, 2008; Hall, Jarrold, Towse, & Zarandi, 2015; Lee, Ng, & Ng, 2009; St Clair-Thompson & Gathercole, 2006).

We have made several changes in our description of working memory from the 2012 version of this chapter. First, we have done what we should have done much earlier: change the name. As of the publication of the WJ IV (Schrank et al., 2014), short-term memory (Gsm) became short-term working memory (Gwm). We believe that there is no loss of information by simply shortening the term to working memory capacity (Gwm).

The second major change has been hinted at previously: Instead of having a single memory span factor, we have formally distinguished between verbal and visual–spatial short-term storage. The evidence for their dissociation is quite clear in multiple factor analyses from many independent studies (Alloway, Gathercole, & Pickering, 2006; Gilhooly, Wynn, Phillips, Logie, & Sala, 2002; Kane et al., 2004; Shah & Miyake, 1996; Swanson & Sachse-Lee, 2001). Their dissociation is also seen in the differential effects of two genetic disorders, Williams syndrome and Down syndrome (Wang & Bellugi, 1994). Verbal and visual–spatial short-term storage differentially predict verbal and visual–spatial reasoning (Kane et al., 2004; Shah & Miyake, 1996; Tanabe & Osaka, 2009). Visual–spatial measures of working memory predict math achievement in young children, but its predictive validity wanes over time. In contrast, verbal working memory becomes an increasingly powerful predictor of math achievement as children age (Friso-van den Bos, van der Ven, Kroesbergen, & van Luit, 2013; van de Weijer-Bergsma, Kroesbergen, & van Luit, 2015; Zheng, Swanson, & Marcoulides, 2011).

The reason we changed memory span's name is that the term *span* implies a certain length that can be repeated back. The number of items that can be recalled depends on many features, including whether the span test uses digits, words, sentences, nonsense words, pictures, symbols, or faces (Baddeley, 2012). Thus the term *span* is better applied to names of tests than to a psychological construct.

Narrow Abilities within Gwm[18]

1. **Auditory short-term storage (Wa): The ability to encode and maintain verbal information in primary memory.* This ability is usually measured with auditory memory span tasks such as digit span, letter span, word span, or sentence span tests that require immediately repeating back short lists of information verbatim. This ability seems to be particularly important for learning new words and understanding complex sentences (Baddeley, 2003, 2012).

2. **Visual–spatial short-term storage (Wv): The ability to encode and maintain visual information in primary memory.* This ability is usually measured with block-tapping paradigms.

3. **Attentional control (AC): The ability to manipulate the spotlight of attention flexibly to focus on task-relevant stimuli and ignore task-irrelevant stimuli. This is sometimes referred to as spotlight or focal attention, focus, control of attention, executive controlled attention, or executive attention.* It is possible to measure attentional control without a memory load, such as with the antisaccade, flankers, Stroop, and stop-signal paradigms (Miyake et al., 2000; Unsworth, Schrock, & Engle, 2004; Unsworth & Spillers, 2010). Many "processing speed" tests also require attentional control (Miyake et al., 2000).

4. **Working memory capacity (Wc): The ability to manipulate information in primary memory.* This is not technically a narrow ability:

"Working memory capacity" = "Short-term storage" + "Attentional control"

Although there are reasons to measure short-term storage and attentional control separately, working memory capacity is best measured with tests with simultaneous storage and processing demands (see Figure 3.5). After all, this is what working memory was designed to do.

Comments and Unresolved Issues Related to Gwm

- *How does working memory capacity relate to other broad abilities?* Working memory has its fingers in everything. For a while, it was plausible that it was synonymous with the general factor (Kyllonen & Christal, 1990), though that hypothesis has been put to rest (Ackerman, Beier, & Boyle, 2005). Alhough not synonymous with working memory capacity, fluid reasoning seems to depend on it heavily (Shipstead et al., 2014).

Assessment Recommendations for Gwm

For understanding academic problems, working memory capacity tests that require simultaneous storage and processing are most important. We

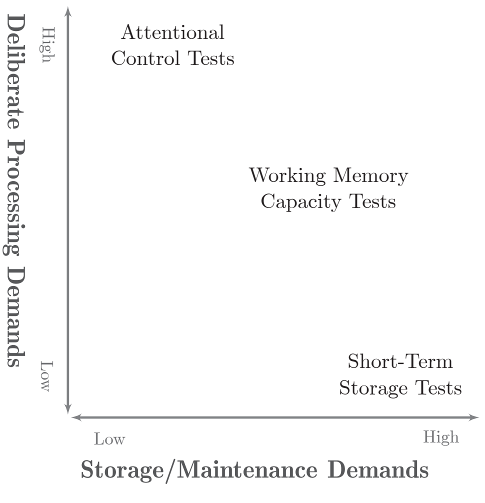

FIGURE 3.5. Working memory capacity tests have simultaneous storage and processing demands.

recommend two types of verbal short-term storage measures: those that minimize the potential for strategy use (e.g., Comprehensive Test of Phonological Processing–Second Edition [CTOPP-2] Memory for Digits), and those with high ecological validity, such as sentence span tests (e.g., WJ IV Memory for Sentences). Visual–spatial short-term storage is less important for most clinical and academic concerns.

Learning Efficiency (Gl)

Definition of Gl

Learning efficiency (Gl) can be defined as the ability to learn, store, and consolidate new information over periods of time measured in minutes, hours, days, and years. As noted previously in this chapter, we believe that long-term learning memory, storage, or learning efficiency (Gl) is distinct from retrieval fluency (Gr) on the one hand and from Gwm on the other. We recognize the risk in using the word *efficiency,* given the conceptual confusion surrounding the term—stemming from its use in a variety of disciplines and even its multiple meanings within educational psychology (Hoffman, 2012; Hoffman & Schraw, 2009, 2010). We do not mean efficiency as conveyed by the Gs + Gwm mental efficiency notion present in certain intelligence composite scores (the WJ III/WJ IV Cognitive Efficiency cluster; the Wechsler batteries' Cognitive Proficiency Index). Our definition is consistent with Hoffman's (2012) conception as related to the efficiency of learning and storing new information: "*Learning efficiency* is primarily based upon individual performance *during* learning when accounting for the incremental costs associated with the learning process. Individual performance means measurable changes in the amount, rate, frequency, or qualitative complexity of knowledge structures. Incremental costs mean factors such as time taken, effort invested, or error rates incurred" (p. 134; original emphasis). For example, to learn and retain a certain amount of information (e.g., a 16-word list), some individuals need to exert more effort than others. To achieve the same outcome, they need more learning inputs (e.g., more learning trials or more time to study).

All tests of learning efficiency must present more information than can be retained in Gwm. This can be accomplished with the repeated supra-span paradigm, where individuals are asked to remember more information than they can learn in a single exposure. Then the information is presented several more times. A paradigm that minimizes the involvement of Gwm is the structured learning task. Such tasks have a teach–test–correct structure. First, a single bit of information is taught. That item is tested, and corrective feedback is offered if required. Another item is taught, and both items are tested with corrective feedback if needed. Then another item is taught, and all three items are tested with corrective feedback if needed. The test becomes longer and longer, but short-term working memory is never overwhelmed with information. The WJ III Visual–Auditory Learning subtest is a good example of a structured learning task.

Narrow Abilities within Gl

1. **Associative memory (MA)*: The ability to form a link between two previously unrelated stimuli, such that the subsequent presentation of one of the stimuli serves to activate the recall of the other stimuli.* Pairs of stimuli (e.g., an abstract visual symbol and a word) are presented together in the teaching phase of the test. In the testing phase, one item of the pair is presented, and the individual recalls its mate. Item pairs must not have any previously established relationships (as in the word pair *table–chair*), or the test is also a measure of meaningful memory.

2. **Meaningful memory (MM)*: The ability to remember narratives and other forms of semantically related information.* Carroll (1993) allowed for tests of meaningful memory to have a variety of formats (e.g., remembering definitions to unfamiliar words), but the core of this ability is the ability to remember the gist of a narrative. After hearing a story just once, most people can retell the gist of it accurately. People who cannot do so are at a severe disadvantage in many domains of functioning. Stories are how we communicate values, transmit advice, and encapsulate especially difficult ideas. Much of the content of our interpersonal relationships consists of the stories we tell each other and the shared narratives we construct. Indeed, much of our sense of identity is the story we tell about ourselves (McAdams, Josselson, & Lieblich, 2006). Many so-called "story recall" tests are barely concealed lists of disconnected information (e.g., "Mrs. Smith and Mr. Garcia met on the corner of Mulberry Street and Vine, where they talked about the weather, their favorite sports teams, and current events. Mr. Garcia left to buy gum, shoelaces, and paper clips. Mrs. Smith left to visit with

her friends Karen, Michael, and Susan. . . ."). A good story recall test has a story that has a true narrative arc. Because story recall tasks require the listener to understand certain conventions of language and culture, many story memory tests have a moderate secondary loading on Gc.

3. *Free-recall memory (M6): The ability to recall lists in any order.* Typically, this ability is measured by having individuals repeatedly recall lists of 10–20 words. What distinguishes this ability from a method factor is that free-recall tests allow the individual to strategically maximize the primacy and recency effect by dumping the contents of primary memory first.

Assessment Recommendations for Gl

We recommend measuring learning efficiency with structured learning tasks to minimize the contaminating effects of Gwm. Structured learning tasks usually measure associative memory. We also recommend measuring meaningful memory because of its diagnostic value. Although differences in performance between tests of associative memory (e.g., WJ IV Visual–Auditory Learning) and meaningful memory (e.g., WJ IV Story Recall) may be related to differences in type of and degree of meaningfulness of the stimuli, score differences may also reflect differences in the complexity of the associative learning capacity between individuals (Cucina, Su, Busciglio, & Peyton, 2015). For example, an associative memory test like WJ IV Visual–Auditory Learning requires learning a series of one-link node pairs, with repeated cumulative study–test phases, while recalling connected discourse (meaningful memory; Story Recall) requires learning a complex network of a larger number of interconnected nodes in a single supraspan trial.

Given that all recent revisions of the major intelligence batteries were published prior to the official split between Gl and Gr, we provide additional guidance for obtaining valid broad Gl norm-based scores (and similar guidance for Gr in the next section). For the WJ IV, the Glr cluster in the cognitive battery is comprised of a measure of meaningful memory (Story Recall) and associative memory (Visual–Auditory Learning). Clinicians should simply drop the r and interpret this norm-based index as a valid proxy of broad Gl. The most recent Wechsler test (the WISC-V) includes associative memory and naming facility tests that can be combined as complementary index scales. As per CHC theory XBA test classifications (Flanagan & Alfonso, 2017), the norm-based Symbol Translation Index should be interpreted as a two-test version of associative memory (MA under Gl), but not broad Gl. The Storage and Retrieval Index score is consistent with the now historical notion of Glr. The SB5, Wechsler Preschool and Primary Scale of Intelligence–Fifth Edition (WPPSI-V), and WAIS-IV do not include Gl or Gr measures. The DAS-II includes two measures of free recall memory (Recall of Objects–Immediate; Recall of Objects–Delayed), but not enough test indicators to form a norm-based broad Gl score. The KABC-II Atlantis and Rebus tests (both first administration and delayed) are both considered measures of associative memory, and the resulting Learning/Glr composite score is best interpreted as a two-test version of associative memory under Gl, but not broad Gl. Where necessary, XBA procedures and guidelines (Flanagan et al., 2013) can be used to create a broad Gl composite by combining two or more indicators of associative memory, meaningful memory, or free-recall memory from other intelligence, neuropsychological, or memory batteries.

Comments and Unresolved Issues Related to Gl

- *Do scores on associative memory tests reflect natural variation in this ability or represent significant differences in "how" different people form associations, or both? Can scoring and interpretation procedures be developed to tease out the "how" differences between individuals?*

- *To what extent does attentional control (AC) influence performance on associative memory tests, and can scoring and interpretation systems be developed to parse out the AC component?* Some forms of associative memory learning appear influenced by attentional control—specifically, the distinction between selectively focusing on the most relevant elements of the stimuli (narrow focus) versus the entire gestalt (broad or global focus) of the stimuli (e.g., focusing on the entire visual rebus symbols vs. a focus on particularly salient parts of the visual rebus symbol, in the WJ IV Visual–Auditory Learning test) (Byrom & Murphy, 2016).

- *Can innovations in network science (e.g., latent semantic analysis) and the development of expert knowledge structure networks or concept maps (Beier, Campbell, & Crook, 2010; Day, Arthur, & Gettman, 2001) be used to develop age-based normative* *associative network maps of narratives in story recall tests, against which an individual's performance could be compared to provide a more rich and complete picture of a person's meaningful memory performance?* The use of tablets and portable computers for test administration, coupled with the high-speed computing embedded in online test scoring platforms, makes this feasible.

Retrieval Fluency (Gr)

Definition of Gr

Retrieval fluency (Gr) can be defined as the rate and fluency at which individuals can produce and selectively and strategically retrieve verbal and nonverbal information or ideas stored in long-term memory. Gr is important. "Throughout the day we are constantly being asked to retrieve facts, events from our life, names of acquaintances, and other important information. The ability to retrieve this information, generally in the absence of potent external cues, is vital for the success of many everyday tasks. As such, strategic retrieval processes are critical aspects of the overall cognitive system" (Unsworth, 2017, p. 135).

People differ in the rates at which they can access information stored in long-term memory, across different type of tasks, along a continuum from very fluent to very dysfluent. People with good Gr are often considered "quick-witted," "quick of mind," or "clever." Although related to cognitive speed (Gs), these characterizations do not reflect fundamental differences in Gs, but rather the "ease" at which mental operations are performed (Alter, 2013; Reber & Greifeneder, 2017). When people are said to be fluent in a second language, it does not mean that they talk rapidly, but that they communicate easily. This aspect of ability has been researched in many fields such as cognition, neuropsychology, and creativity. It is an ability that has become increasingly recognized as important in educational psychology (Reber & Greifeneder, 2017). There is also a long-standing line of research demonstrating that verbal fluency of recall is an important precursor to certain forms of creativity (see Silvia, 2015).[19]

Given the long history of interest in creativity and intelligence, we briefly comment on the role of Gr (and other CHC abilities) in creativity. People who can produce many ideas from memory quickly are in a good position to combine them in creative ways. Individuals high in Gr, together with good Gc and general intelligence (or Gf, depending on the model evaluated), may also be more clever and funny (Beaty et al., 2017). It is important to note that high retrieval fluency is only a facilitator of creativity, not creativity itself. Creativity has also been associated with Gf, Gc, Gs, and Gwm (Avitia & Kaufman, 2014; Silvia, 2015) and a variety of personality and dispositional characteristics. Possessing a large amount of well-organized domain-specific knowledge (Gkn) is also associated with creativity (Weisberg, 2006), although Gkn's importance is dependent to a large extent on Gr and top-down executive control processes (Silvia, 2015). The ability to leverage well-organized knowledge structures requires efficient access, fluent retrieval, management (e.g., manipulation, combination and transformation), and strategic executive control strategies (Silvia, 2015).

Narrow Abilities within Gr

We believe it is useful to categorize fluency factors according to content or stimulus facets—ideas, words, and figures.

Fluency factors in the following group are alike in that they involve the production of *ideas.*

1. **Ideational fluency (FI): The ability to rapidly produce a series of ideas, words, or phrases related to a specific condition or object.* Quantity, not quality or response originality, is emphasized. An example of such a test would be to think of as many uses of a pencil as possible in 1 minute.
2. **Expressional fluency (FE): The ability to rapidly think of different ways of expressing an idea.* For example, how many ways can you say that a person is drunk?
3. *Associational fluency (FA): The ability to rapidly produce a series of original or useful ideas related to a particular concept.* In contrast to ideational fluency (FI), quality rather than quantity of production is emphasized. Thus the same question about generating ideas about uses of pencils could be used, but credit is given for creativity and high-quality answers.
4. *Sensitivity to problems/Alternative solution fluency (SP): The ability to rapidly think of several alternative solutions to a practical problem.* For example, how many ways can you think of to get a reluctant child to go to school?
5. *Originality/creativity (FO): The ability to rapidly produce original, clever, and insightful responses (expressions, interpretations) to a given topic, situa-*

tion, or task. This factor is quite difficult to measure for a variety of reasons. Because originality manifests itself in different ways for different people, such diversity of talent does not lend itself to standardized measurement. This factor is not strictly a "retrieval" factor because it is by definition a creative enterprise. However, much of creativity is the combination of old elements in new ways. When we say that one idea sparks another, we mean that a person has retrieved a succession of related ideas from memory, and that the combination has inspired a new idea.

The next three fluency abilities are related in that they involve the fluent recall of *words*.

6. **Speed of lexical access (LA): The ability to rapidly and fluently retrieve words from an individual's lexicon. LA may also be described as verbal efficiency or automaticity of lexical access.* This is a new narrow ability proposed by the WJ IV authors (McGrew et al., 2014). Although a relatively new suggested addition to the CHC taxonomy, this narrow ability is also based on seminal research regarding the importance of verbal efficiency or automaticity of lexical access for reading that dates to the 1970s and 1980s (LaBerge & Samuels, 1974; Neely, 1977; Perfetti, 1985). See Perfetti (2007) and Perfetti and Hart (2002) for more recent information on what is now frequently referred to as the *lexical quality hypothesis* as it relates to reading. Until appropriate research studies are completed with valid indicators of these related constructs, we believe that the definition of LA is such that it subsumes most aspects of NA and FW. Thus we propose that LA is an intermediate-level ability that subsumes NA and FW.

7. **Naming facility (NA): The ability to rapidly call common objects by their names.* In contemporary reading research, this ability is called *continuous naming speed* or *rapid automatic naming* (RAN). A fair measure of this ability must include objects that are known to all examinees. Otherwise, it is a measure of lexical knowledge. The most commonly used visual stimuli are either alphanumeric (colors, objects) or nonalphanumeric (letters, digits) (Kirby, Georgiou, Martinussen, & Parrila, 2010). Naming facility (NA) and speed of lexical access (LA) are the only fluency factors in which each response is controlled by testing stimulus materials. The other fluency factors are measured by tests in which examinees generate their own answers in any order they wish. In J. P. Guilford's terms, NA is an ability involving convergent production, whereas the other fluency factors involve divergent production of ideas. In this regard, naming facility tests have much in common with Gs tests (Kirby et al., 2010): They are self-paced tests in which an easy task (naming common objects) must be done quickly and fluently in the order determined by the test developer. Deficits in this ability are known to cause reading problems (Araújo, Reis, Petersson, & Faísca, 2015; Kirby et al., 2010). In a sense, reading is the act of fluently and automatically "naming" printed words (Bowers, Sunseth, & Golden, 1999). More recently, RAN (NA) has also been linked to various math achievement skills, especially math fluency (Koponen, Georgiou, Salmi, Leskinen, & Aro, 2017).

8. **Word fluency (FW): The ability to rapidly produce words that share a phonological (e.g., fluency of retrieval of words via a phonological cue) or semantic (e.g., fluency of retrieval of words via a meaning-based representation) feature.* An example of an FW task is the ability to rapidly produce words starting with the letter *T*. This ability has been mentioned as possibly being related to the "tip-of-the-tongue" phenomenon (e.g., word-finding difficulties [WFD]; Carroll, 1993). This ability is likely to be well developed in fans of Scrabble and crossword puzzles.

The next two fluency factors are related to *figures*.

9. *Figural fluency (FF): The ability to rapidly draw or sketch as many things (or elaborations) as possible when presented with a nonmeaningful visual stimulus (e.g., a set of unique visual elements). Quantity is emphasized over quality.* For example, in one part of the Delis–Kaplan Design Fluency test, examinees must connect dots with four straight lines in as many unique ways as they can within a time limit.

10. *Figural flexibility (FX): The ability to rapidly draw different solutions to figural problems.* An example of a test that measures this ability is to draw as many ways as possible to fit several small shapes into a larger one.

Assessment Recommendations for Gr

Of the fluency measures, we recommend measures of ideational fluency and speed of lexical access (or naming facility), as the predictive validity of these factors is better understood than for the others, or research has demonstrated their importance for reading. For broad Gr scores, the following advice is offered.

For the WJ IV, the Speed of Lexical Access cluster in the Oral Language battery can be reinterpreted as a reasonable proxy for broad Gr (one indicator each of ideational fluency and naming facility). As per CHC theory XBA test classifications (Flanagan et al., 2013), the WISC-V Naming Speed Index should be interpreted as a two-test version of naming facility, and not broad Gr. The KABC-II, SB5, WPPSI-V, and WAIS-IV do not include Gr measures. The DAS-II includes a single test of naming facility, which is insufficient to form a norm-based broad Gr score. Where necessary, XBA procedures and guidelines (Flanagan et al., 2013) can be used to create a broad Gr composite by combining two or more indicators of naming facility, speed of lexical access, ideational fluency, word fluency, or figurative fluency from other intelligence, neuropsychological, or memory batteries.

Comments and Unresolved Issues Related to Gr

- *How is the RAN, NA, WFD, and LA jingle–jangle jungle to be dealt with?* Psychology has had an interest in rapid naming tasks since the late 1800s (Carroll, 1993). Despite this long history, considerable overlap and confusion exist across the similar, yet different, definitions derived from factor-analytic research (NA, naming facility; Carroll, 1993); RAN reading research (Norton & Wolf, 2012); speed of lexical access (LA) and lexical quality hypothesis reading research (Perfetti, 2007); and the WFD language research (Messer & Dockrell, 2006). A close inspection of all definitions reveals discussions and controversies regarding the role of multiple and different underlying cognitive processes (e.g., phonological access, lexical access, orthographic processing, processing speed, executive functions). We cannot resolve the similarities and differences among these related terms in this chapter; it would require a separate chapter and possibly even a book. There is a critical need for joint or XBA studies, as well as CHC-based causal modeling research, with the most commonly used and psychometrically sound measures of RAN, NA, WFD, and LA (together with other Gr fluency abilities), to carve a path through this jingle–jangle jungle.

A small step in this direction is illustrated by Decker, Roberts, and Englund's (2013) analysis of the strength of association between the CHC-based WJ III cognitive tests and a single WJ III measure of RAN (Rapid Picture Naming) in ages 5–12 of the WJ III norm sample. Contrary to some theories of RAN and reading, phonology processing (Ga) was not related to the alphanumeric WJ III RAN test (naming common objects). Multiple cognitive abilities (Gc, Gf, Gs, and Gr) were related to RAN, although there were developmental differences. The WJ III Retrieval Fluency test, a test of the narrow ability of ideational fluency (this test is also now considered one marker of LA in the WJ IV), was consistently the strongest predictor of the RAN-designated test. In the absence of definitive structural and causal evidence research, and consistent with our focus on CHC theory, we are standing pat with the separate definitions of naming facility (NA) and speed of lexical access (LA) provided above. Whether LA is a higher-level intermediate ability above NA subsumed by Gr, or whether the alphanumeric RAN tasks share significant common variance with LA (and not much with the nonalphanumeric RAN tasks), or whether LA is a narrow ability as currently listed, is currently an unresolved issue.

- *Is the long-standing hunt for practical measures of the holy grails of creativity (i.e., originality of responses, FO; alternative solution fluency, SP) doomed to failure, or are some current FO and SP measures "good enough" for understanding real-world problem solving?* Should intelligence test developers add FO and SP measures to their batteries? Research has consistently demonstrated that when both quantity and originality indexes are generated from Gr tasks, the originality indexes provide no new information beyond quantity of responses (typical correlations range from .80 to almost .90). "Clearly, there is little unique variance to be found in uniqueness scores—they are basically the same as fluency" (Silvia, 2015, p. 601). This finding is explained by the fact that as people generate more responses, the probability of unique responses increases. Despite this measurement problem, perhaps quantity indexes from FO and SP measures are sufficient and practically important.

- *Is there an option generation ability?* Del Missier, Visentini, and Mäntylä (2015) recently reported that *option generation fluency* in three simulated real-world problems (i.e., parking lot, fund-raising, and energy-saving problems) was not related to traditional verbal or word fluency measures. However, quantity scores from an alternative-uses test (a measure of FO and SP) accounted for approximately 20% of option generation fluency performance in the real-world problems. This study also suggests that a new option generation fluency ability might exist and is ripe for research. Also, in a study that used a method to control for quantity of responses to obtain scores for originality, Benedek, Jauk, Sommer, Arendasy, and Neubauer (2014) reported a latent factor correlation of .45 between divergent thinking originality (as measured by FO/SP-type tests) and Gf. Collectively this research, along with calls from experts in the intelligence–creativity nexus (J. C. Kaufman, 2016), argues for intelligence test developers to continue exploring the development of measures of CHC narrow abilities associated with creativity.

- *How can we tease out and interpret the role of top-down executive control in Gr tasks?* Neurocognitive research has demonstrated that the generation of ideas invokes top-down executive control processes (Silvia, 2015). For example, performance on ideational (verbal) fluency tasks requires the ability to strategically organize words into meaningful groups or "patches," retrieve a single bit of information (while inhibiting the interference of "persistent alternatives"), flexibly make quick shifts or transitions to new clusters or patches, retrieve from the new group, then use the immediately prior retrieved response as a cue to refine the search, and then repeat the cyclical process (Molinari & Leggio, 2015; Unsworth, 2017). It may be impossible to measure Gr in the absence of executive functioning, as it is likely to be a core component of Gr.

- *Given that retrieval tasks typically invoke executive strategies, is it possible to develop reliable and valid posttest "testing-the-limits" structured think-aloud protocols or questionnaires to identify an individual's use of typical global or specific search strategies?* For example, Unsworth (2017) presented a think-aloud system for a semantic fluency retrieval task that identified a number of different retrieval strategies (viz., visualization, link-to-previous, personal importance, general-to-specific, semantic, rhyme, alphabet, no strategy, and other). Also see Schelble, Therriault, and Miller (2012) for an example of a 16-category retrieval strategy questionnaire developed for a categorical retrieval fluency task. Build it . . . validate it . . . and they (practitioners) shall come.

- *Can new scoring methods, based on network science technology and psycholinguistic research, provide new types of information regarding the breadth, depth and organization of an individual's corpus of specific knowledge (e.g., semantic or phonological knowledge); the individual's degree of match to an age-based normative network; and, more importantly, the "how" of an individual's Gr processes?* We believe that the psycholinguistic research regarding semantic network searches via *optimal foraging* strategies (Abbott, Austerweil, & Griffiths, 2015; Hills, Todd, & Jones, 2015) may provide answers to these questions. The use of tablets and portable computers for test administration, coupled with the high-speed computing embedded in online test scoring platforms, provides the possibility of using procedures such as latent semantic analysis to develop a "Gr network retrieval efficient quotient" (and possibly other retrieval efficiency parameters; e.g., patch-to-patch transition time) from an individual's retrieved responses when compared to a normative network model (Bossomaier, Harré, Knittel, & Snyder, 2009).

- *Although a broad Gr ability exits, and most individuals who retrieve fluently from one domain tend to also excel in retrieval in other domains, what are the individual differences in retrieval processes among people and among different content domains (ideas, words, figures) (Unsworth, 2017)?* Although the extant Gr literature does not support distinct domain-specific retrieval processes, neurocognitive research suggests that differential retrieval test performance by facets (e.g., semantic vs. figural fluency; semantic vs. phonetic) may be related to impaired function in different brain networks (Schmidt et al., 2017; Vannorsdall et al., 2012).

General Cognitive Speed: Considerations

The Difference between Gs and Gt

Both processing speed (Gs) and reaction and decision speed (Gt) are general cognitive abilities related to speed. Both require speeded performance on very easy tests, although Gt tests are generally easier than Gs tests. Gt refers to the speed at which a single item can be performed, on average. That is, each item is presented singly, and the examiner or a computer controls the pace at which the next item is presented. Gs refers to the average speed at which a series of simple items is completed in succession, with sustained concentration over all items over a sustained period (e.g., 2–3 minutes). All Gs items are presented at once, and the examinee determines when the next item will be attempted. In Gt tests, the quickness of responding each time, with pauses between items, is critical. In Gs tests, there are no pauses, and the examinee must sustain mental quickness and move swiftly from item to item until told to stop. This seemingly small difference makes a big difference. In Gs tests, the examinee is constantly shifting attention from item to item. Performance can be enhanced (or hindered) by looking ahead to the next several items. In Gt tests, this is not possible because the examiner (or computer) determines when the next item is seen. Thus Gt is more purely about speed of perception or quickness of reactions, whereas Gs is more about the combination of sustained speed, fluency, and the adaptive allocation of attention. For this reason, Gs is more strongly correlated with *g* (and Gf) than is Gt. Gs requires more cognitively complex information processing than Gt (Roberts & Stankov, 1999).

What Does Recent Factor Analysis Tell Us about Gs and Gt?

The continued presentation of neat hierarchical Gs/Gt models of mental speed in the intelligence literature incorrectly suggests that the multidimensional nature of cognitive speed abilities is well known. This is wrong.[20] What is clear is that the extant factor-analytic evidence supports the conceptualization of mental speed as a multifaceted construct with at least two broad types of abilities: Gs and Gt (Carroll, 1993; Danthiir, Roberts, Schulze, & Wilhelm, 2005; Danthiir, Wilhelm, & Roberts, 2012; Danthiir, Wilhelm, et al., 2005; O'Connor & Burns, 2003; Roberts & Stankov, 1999; Stankov, 2000). Beyond that, gaps and ambiguities in the available evidence leave us with many unresolved questions about the number, nature, and structural relations of lower-level abilities (Stankov, 2000). The most recent primary mental speed structural research (Danthiir, Roberts, et al., 2005; Danthiir et al., 2012; Danthiir, Wilhelm, et al., 2005) adds little clarity. In fact, these studies have tended to muddy the waters, as both studies found Gs (defined by perceptual speed tests) and Gt to be statistically isomorphic, and the Gt narrow factors to be primarily method- or task-specific factors. The reported Gs/Gt latent correlations of 1.00 in these two studies most likely reflect shared methodological variance (the respective Gs and Gt tasks within each study were both either paper-and-pencil or computer-administered tests).

Given the current state of affairs in Gs and Gt, we went mining for slivers of gold in speed factor analyses conducted in a handful of small-scale studies of children referred for assessment (Nelson, 2009), children with known clinical disorders (Phillips, 2015), and nondisabled adolescents and adults (Feldmann, Kelly, & Diehl, 2004).[21] We also inspected the exploratory cluster analysis and MDS analysis reported in the WJ IV norm data (McGrew et al., 2014), as well as cluster analysis, MDS, and CFA of the WJ III norm data by McGrew (2010).[22] Why? First, we hoped to solidify or clarify what is currently known about Gs and Gt abilities where possible. Second, and more importantly, we wanted to continue revising a hypothesized *g*-speed hierarchical model originally presented by McGrew and Evans (2004), refined by McGrew (2005), and further refined by Schneider and McGrew (2012), in a continued effort to stimulate and "speed up" thought and research regarding human speed variables (see Figure 3.6).

Only one of these studies (Nelson, 2009) included measures of both Gs and Gt. This study reinforced the Gs and Gt distinction, as the reaction time Gt factor displayed low latent variable correlations (.14 to .20) with three Gs-type narrow abilities (naming facility, perceptual speed, and academic fluency). Combined with the Nelson (2009), Phillips (2015), and McGrew and colleagues (2014) findings, the evidence continues to support the distinct speed or fluency narrow abilities of perceptual speed (Gs-P), writing speed or fluency (Grw-WS), number facility (Gs-N), naming facility (Gr-NA), figural fluency (Gr-FF), and ideational fluency (Gr-FI).

An important conclusion from these studies is that processing speed (Gs) and fluency of retrieval (Gr) represent related but very different aspects of mental speed or fluency, which probably share an underlying speed, fluency, or automaticity dimension. This is evident in the WJ III and WJ IV cluster analysis and MDS results, where the Cognitive and Achievement speeded tests formed a distinct cluster, with subclusters reflecting an academic versus cognitive distinction. When the WJ IV Oral Language fluency tests are also included, the speed (Gs) and fluency (Gr) tests are typically found in the same MDS spatial quadrant distinct from the other three MDS quadrants, which include cognitive process or acquired knowledge tests (McGrew et al., 2014). Across four sources (McGrew, 2010; McGrew et al., 2014; Nelson, 2009; Phillips, 2015), there is consistent evidence for a distinction between cognitive and academic speed or fluency ability. This cognitive–academic distinction may reflect intermediate-stratum abilities or different facets of cognitive speed. Finally, Gs tests may be differentiated by subfactors that

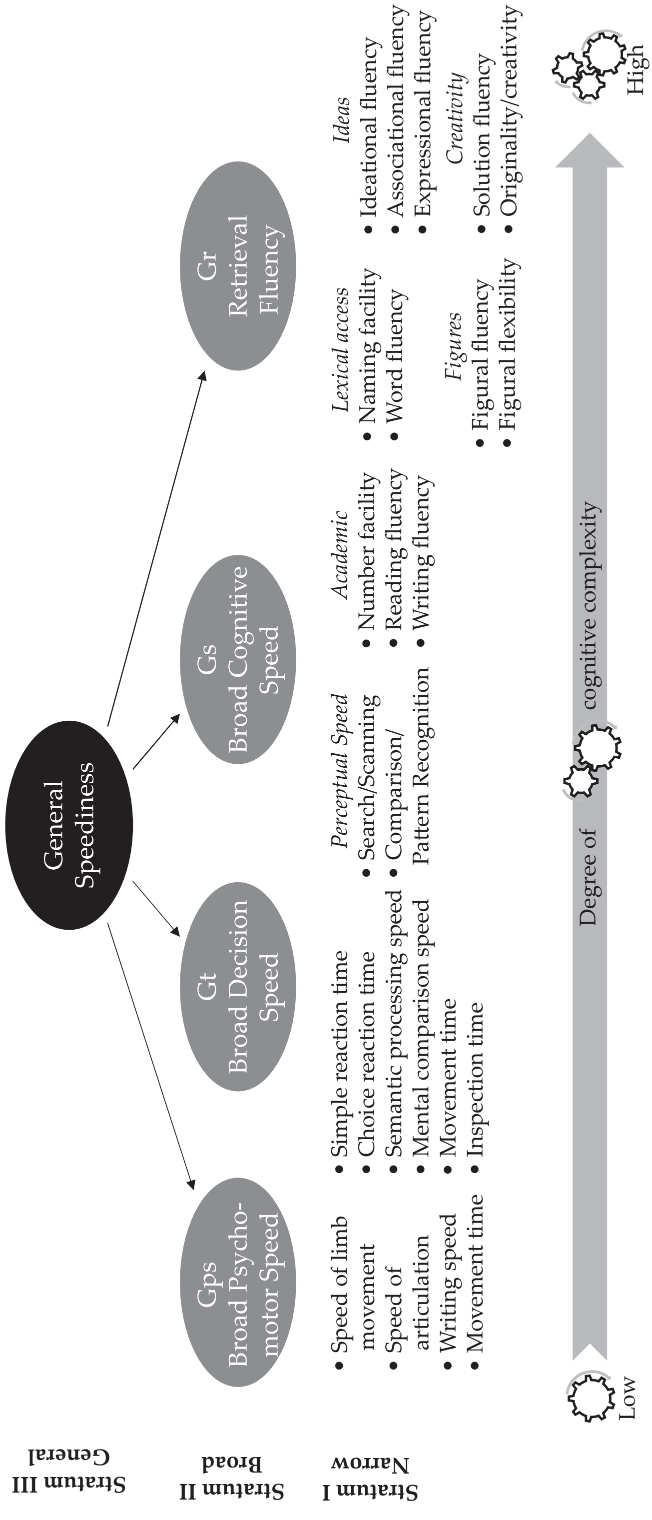

FIGURE 3.6. A hierarchy of speeded abilities.

may represent different content facets—a notion previously suggested by Carroll (1993). McGrew (2010) reported exploratory analyses of the WJ III suggesting that reading and writing (Grw), mathematic (Gq), and visual processing (Gv) stimulus content dimensions might exist under Gs.

A Hypothesized Hierarchy of Speed Abilities

In our search, we discovered that a prior unpublished white paper on structural extensions of CHC theory (McGrew & Evans, 2004), which was the basis for the proposed *g*-speed hierarchical model of human speed abilities (Schneider & McGrew, 2012), did not fully inform (as much as it should have) the most recent elaborations of the speed and fluency domains of CHC theory (McGrew, 2005; Schneider & McGrew, 2012). It is a small gold nugget that we have re-mined and extended. This valuable find was only briefly mentioned in a few sentences in McGrew (2005) and received a single paragraph of treatment in Schneider and McGrew (2012). Both sources focused on the conclusion that the speed domains of Gs and Gt might best be represented within the context of a hierarchically organized speed taxonomy with a *g*-speed factor at the apex. Yet the unpublished McGrew and Evans (2004) paper served as the basis, without the proper context and discussion (unless readers sought out this paper), for the presentation of a hypothesized speed hierarchy model. More importantly, implications for certain narrow-ability definitions and classifications were largely ignored. Where appropriate, we incorporate insights from McGrew and Evans with the factor research summarized above (in the following sections on Gs, Gt, and Gps) to clarify certain narrow speeded abilities and hypothesize possible intermediate factors in the domain of speed and fluency.

Figure 3.6 is the latest iteration of the *g*-speed model. The model is speculative and is based on information from factor studies, theory, and logic. It is not intended to be considered a formal part of the current CHC taxonomy now. It is not a strong statement based on scientific facts. It is meant to "push the edge of the envelope" regarding thinking and research regarding human speed abilities. A hypothesis presented in Figure 3.6 is that speeded and fluency abilities (and tests) might be ordered along a continuum from low to high levels of demands for cognitive complexity processing. The increase in information-processing demands would be associated with abilities and tasks that require increased use of attentional control, working memory, and executive functions.

Processing Speed (Gs)

Definition of Gs

Processing speed (Gs) is the ability to control attention to automatically, quickly, and fluently perform relatively simple repetitive cognitive tasks. Gs may also be described as attentional fluency or attentional speediness. This ability is of secondary importance (compared to Gf and Gc) in predicting performance during the learning phase of skill acquisition. However, it becomes an important predictor of skilled performance once people know how to do a task. Once people learn how to perform a task, they still differ in the speed and fluency (automaticity) with which they perform (Ackerman, 1987). For example, two people may be equally accurate in their addition skills, but one recalls math facts with ease, whereas the other has to think about the answer for an extra half-second and sometimes counts on his or her fingers.

Much as induction is at the core of Gf, perceptual speed is at the core of Gs. Previously (Schneider & McGrew, 2012), we defined perceptual speed (P) as the speed and fluency with which similarities or differences in visual stimuli (e.g., letters, numbers, patterns, etc.) can be compared and distinguished. As noted in our discussion of Gv in this chapter, this ability is also listed under Gv. One way to measure this factor is to present pairs of stimuli side by side, and have the examinees judge them to be the same or different as quickly as possible. Another method of measuring this factor is to present a stimulus to examinees, who must find matching stimuli in an array of heterogeneous figures.

We believe that it is time to acknowledge the white elephant in the perceptual speed (P) room. Does P represent an intermediate factor that includes multiple subfactors? The continued acknowledgment of possible P subfactors in the extant factor structure, test development, and test interpretation literature has been nothing more than that—scholarly recognition of the possibility that there is more to P than P itself. Although mentions are an indication of the authors scholarly awareness of the P research, the use of a single P designation to classify and interpret the wide variety of available P tests has, in our humble opinion, degraded and obscured more accurate interpretation of the factor-analytic literature and, more importantly, the interpretation of scores from P tests on intelligence batteries. It is time to "step up to the plate" and attempt to move the P research and assessment literature forward.

P has been one of the more studied cognitive abilities, starting originally with French (1951). Early factor analysis syntheses (Ekstrom, French, & Harmon, 1979; French, Ekstrom, & Price, 1963) suggested that the P factor may include multiple subfactors. Contemporary research suggests that the structure of P is not well established, but it is likely to be multidimensional (Ackerman et al., 2002; Ackerman & Cianciolo, 2000; Danthiir, Roberts, et al., 2005; French et al., 1963). P tests come in many flavors. Carroll (1993) suggested that the various tests of P consist of two types—those involving *searching* and those involving *comparisons*. Carroll characterized the myriad of possible P factors by means of a mapping statement: speed in [searching for and finding/correctly finding] [one/or more] [literal/digital/figural] stimuli in a visual field arranged [by pairs/by rows/in columns/at random] for [identity/difference/size/etc.]. The combinations and permutations are daunting. Given Carroll's recognition of the various types of P tests and factors, we admit that as the default keepers of the CHC taxonomic scrolls (McGrew, 1997, 2005, 2009; Schneider & McGrew, 2012), we failed to recognize and describe Carroll's two types of P tests and factors in prior attempts to clarify the P factor and assessment landscape.

Based on a review of the extant Gs literature (see "General Cognitive Speed: Considerations," above), we believe that P tasks differ primarily by *content facets* and type and degree of *cognitive complexity* of the cognitive *operations* involved. There is evidence that various Gs and P tests have, in addition to their primary cognitive operations or processing demand, sources of variance (often described as facets in the research) related to different stimulus content. Using the BIS model content facet dimension, which was supported and extended in the WJ IV norm data analysis via MDS, and which is like Ackerman and Cianciolo's (2000) perceptual speed content categorization, we propose that speeded tests and variables be furthered differentiated as visual-figural (Gv), numeric-quantitative (Gq), auditory (Ga), verbal or language (Gc), reading/writing (Grw), or mixed.

More important, based on our rediscovery of the McGrew and Evans (2004) paper, and our review of its original Gs and Gt source research together with newer contemporary research, we believe that Ackerman and colleagues' four-factor P substructure model (Ackerman et al., 2002; Ackerman & Cianciolo, 2000; see McGrew & Evans, 2004) is the best research-based framework that can be used in an initial attempt to further differentiate P variables and tests. Greater confidence is placed in Carroll's speculation regarding the perceptual speed distinction of *searching* and *comparison*, based on the first two subfactors identified by Ackerman and colleagues (pattern recognition and scanning).[23] We have modified the pattern recognition and scanning definitions from McGrew and Evans to be consistent with the essential features of Carroll's two types of perceptual speed abilities (Carroll, 1993). Below, we provide definitions for two types of perceptual speed narrow abilities that lie below the intermediate stratum P.

Narrow Abilities within Gs

The factors listed first are related to the ability to rapidly perform simple *cognitive* tasks (see Figure 3.6).

1. **Perceptual speed (P): An intermediate-stratum ability that can be defined as the speed and fluency with which similarities or differences in visual stimuli (e.g., letters, numbers, patterns, etc.) can be searched and compared in an extended visual field.*

2. **Perceptual speed–search (Ps): The speed and fluency of searching or scanning an extended visual field to locate one or more simple visual patterns.*

3. **Perceptual speed–compare (Pc): The speed and fluency of looking up and comparing visual stimuli that are side by side or more widely separated in an extended visual field.*

The factors listed next are related to the ability to rapidly perform basic *academic* skills or tasks (see Figure 3.6).

4. **Number facility (N): The speed, fluency, and accuracy in manipulating numbers, comparing number patterns, or completing basic arithmetic operations.* Although this factor includes recall of math facts, number facility includes speeded performance of any simple calculation (e.g., subtracting 3 from a column of two-digit numbers). Number facility does not involve understanding or organizing mathematical problems and is not a major component of mathematical/quantitative reasoning (under Gf) or higher mathematical skills. People with slow recall of math facts may be

more likely to make computational errors because the recall of math facts is more effortful (i.e., consumes attentional resources) and is thus a source of distraction.

5. *Reading speed (fluency) (RS): The speed and fluency of reading text with full comprehension.* Also listed under Grw.

6. *Writing speed (fluency) (WS): The speed and fluency of generating or copying words or sentences.* Also listed under Grw and Gps.

Assessment Recommendations for Gs

We recommend that the assessment of Gs primarily focus on perceptual speed. We suggest that examiners use both a test of perceptual speed–search (Ps) and perceptual speed–compare (Pc). Examples of Ps tests, according to Carroll (1993), have names such as "Cancellation, Finding *A's*, First Digit Cancellation, Identical Numbers, Identical Patterns, Inspection, Letter Cancellation, and Scattered *X's*. For example, in Finding *A's* the task is to look through columns of words and cross out all words that contain the letter *a*" (p. 350). Examples of Ps tests from the Ackerman research group include (1) Finding a and t: Scan for instances of "a" and "t" in text passages; (2) Finding € and ¥: Scan for instances of € and ¥ in text made up of random symbols; (3) Canceling Symbols: Scan a page for a single target figure among other simple target figures; (4) Summing to 10: Circle pairs of numbers if they sum to 10.

Examples of Pc tests, according to Carroll (1993), have names such as "Clerical Checking, Faces, Identical Forms, Name Comparisons, Number Checking, and Object Inspection. In some of these, a stimulus is presented at the left of a row of stimuli, and the task can be to find which other stimulus in the row is either identical to, or different from, the first stimulus. Sometimes the task is to find which stimulus, in a row, is different from the others" (p. 350). Examples of Pc tests from the Ackerman research group include (1) Name Comparison: Identify identical or mismatched name pairs; (2) Number Sorting: Find the largest of five large numbers; (3) Number Comparison: Identify identical or mismatched number pairs; and (4) Clerical Abilities—2: Looking up names and numbers in tables (scanning).

We also suggest that examiners classify the primary content facet of Ps and Pc tests. Thus a Ps test involving numbers would be classified as Ps-Gq. A Pc test involving visual–spatial figures would be classified as Pc-Gv. This secondary content specification might provide clues to differences in scores between various tests of Ps and Pc. The three academic fluency factors should be assessed if they are relevant to the referral concern. These abilities sometimes act as predictors of more complex aspects of academic achievement (e.g., reading comprehension and math problem solving) and sometimes are considered academic outcomes themselves, depending on the referral concern.

To facilitate an understanding of this proposed finer differentiation of P abilities, we offer a few examples from two intelligence batteries. As per our proposed scheme, we logically classify the following two WJ IV tests as Ps tests, followed by their content facet designation: Letter–Pattern Matching (Ps-Grw) and Number–Pattern Matching (Ps-Gq). We logically classify both the Wechsler Cancellation test and the old WJ III Cross Out test as Pc-Gv.

Comments and Unresolved Issues Related to Gs

The prior extensive discussion of the literature on cognitive speed and the nature and measurement of perceptual speed covers a wealth of issues. At least four issues remain.

- *Should the rate-of-test-taking (R9) ability be retired?* Yes! This "ability" has been defined as the speed and fluency with which simple cognitive tests are completed. As we noted in our 2012 chapter, Carroll (1993) indicated that these miscellaneous factors were made up of a heterogeneous group of variables (different contents, task formats, and degrees of difficulty) across 12 different studies. A careful review of the results from the 12 studies and Carroll's own statements suggest that this factor never should have been accorded serious status in the CHC framework. Carroll "provisionally" interpreted these factors and stated that "in most cases, they are contrasted with accuracy factors [based on the same speeded variables] that are also found in the same datasets" (p. 475). Carroll characterized two of the factors (from HORN01 and HORN02) as those that normally occur as a second-order speed factor (i.e., Gs). He similarly described the two factors from three studies (VERS01, VERS02, VERS03) as a general cognitive speed factor (i.e., Gs) and a general motor speed factor (i.e., Gps). Carroll further indicated that the various R9 factors he identified may be associated with the major nonspeeded or level abilities, and that their intercorrelations may be linked to a broad speediness (Gs) factor at stratum II. Carroll stated that two factors from the UNDH11 study "might well have been classified under either P (Perceptual Speed) or N (Number Facility); it was classified here [Rate-of-test-taking] because the author (Undheim, 1978) labeled it 'general speed'" (p. 475). Given the obsessive–compulsive quality of Carroll's treatise, this deference to the original source's factor label is odd. The remaining study factors are an eclectic hodgepodge of judgment tasks; verbal analogy or grammatical fluency tasks; tests using manipulatives, such as the Sequin, Manikin, and Cub Construction tests; and various other miscellaneous tasks. Furthermore, we have observed that if scholars cannot easily classify a Gs test in terms of other narrow Gs abilities (e.g., P, N), they typically assign an R9 designation. R9 has become an "I don't know" or "Other" classification. Conversely, all Gs tasks could be classified as R9. The R9 classification, as currently used, has little convergent or divergent validity.

An additional reason for removing R9 is the proverbial jingle–jangle jungle fallacy. In an important Gs structural evidence study, Roberts and Stankov (1999) differentiated cognitive speed abilities as "(a) the rate at which an individual performs complex psychometric tests, and (b) the speed of performance in which complex cognitive capabilities are only minimally involved. The terms *speed of test-taking* and *speed of information processing* are reserved (respectively) to differentiate between these constructs where necessary" (p. 13; original emphasis). Speed of test taking, in this context, is analogous to Gs and not a narrow ability such as R9, while speed of information processing is analogous to Gt. Jingle. Jangle. Jungle. Fallacy.

Furthermore, it is our conclusion that R9 was indeed a miscellaneous Gs factor bin where loosely related speeded factors were placed. The lack of common content, formats, or demands for the variables does not suggest a robust narrow factor. We have not seen any post-Carroll research that would argue for a stand-alone R9 factor. We therefore recommend that it be "voted off the CHC island." If a researcher (or author of a test or test interpretation system) is unable to classify a narrow factor (test) in terms of the remaining Gs narrow-ability factors, or as a new narrow ability with additional supporting evidence, we recommend it be labeled as "Gs-unspecified." We believe that a significant number of otherwise R9 test classifications in the literature might be classifiable with the two perceptual speed subfactors described above. Much additional work is needed to explicate narrow abilities in the Gs domain.

- *Do auditory processing speed abilities exist?* It is logical that the auditory processing channel should have a speed analogue to the visual processing channel. Preliminary evidence for the convergent, discriminant, and incremental validity of newly developed measures of auditory processing speed is emerging (Cameron, Glyde, Dillon, & Whitfield, 2014; Zajac & Nettelbeck, 2016), but it is not yet conclusive that it is distinct from traditional visual processing speed factors (Zajac, Burns, & Nettelbeck, 2012).
- *Will we ever be able to accurately measure the "speed–accuracy tradeoff" dimension on speeded tests?* The cognitive speed literature has had a lengthy and robust debate regarding the importance of the speed and level (accuracy) characteristics of performance. These two primary characteristics have produced a long-standing interest in different strategies used by individuals on speeded tests. Does an individual focus more on speed at the expense of accuracy, or vice versa? Are there validated different speed–accuracy tradeoff strategies, and if so, how do they relate to general intelligence, specific cognitive abilities, cognitive tempo styles, clinical disorders, aging patterns, and so on? The long-standing interest in measuring the speed–accuracy tradeoff has not been matched by the development of suitable measurement approaches and metrics. It is a complicated phenomenon to study (Ackerman & Ellingsen, 2016).
- *Is task switching a new potential narrow ability?* Jewsbury and colleagues' (2016) series of studies suggests that task switching might be an as-yet-unrecognized narrow ability. Task switching is one hallmark of executive control and has a demonstrated relation with working memory (Draheim, Hicks, & Engle, 2016). Typical tasks require individuals to alternate between making one of two (or more) single judgments in successive trials. The metric is the amount of slowing that occurs on trials that require switching (latency switch cost).

Reaction and Decision Speed (Gt)

Definition of Gt

Reaction and decision speed (Gt) can be defined as the speed of making very simple decisions or judgments when items are presented one at a time. Tests of Gt differ from tests of Gs in that they are not self-paced. Each item is presented singly, and there is a short period between items in which no response from the examinee is required. To date, the primary use of Gt measures has been in research settings. Researchers are interested in Gt because it may provide some insight into the nature of *g* and very basic properties of the brain (e.g., neural efficiency). One of the interesting aspects of Gt is that not only is faster reaction time (RT) in these very simple tasks associated with complex reasoning, but so is greater consistency of RT (less variability). People with more variable RTs have lower overall cognitive performance (Jensen, 2006).

Narrow Abilities within Gt[24]

1. *Simple RT (R1): RT to the onset of a single visual or auditory stimulus.* R1 is frequently divided into the phases of decision time (DT; the time to decide to make a response and the finger leaves a home button) and movement time (MT; the time to move the finger from the home button to another button where the response is physically made and recorded). MT is listed under Gps.

2. *Choice RT (R2): RT when a very simple choice must be made.* For example, examinees see two buttons and must hit the one that lights up.

3. *Inspection time (IT): The speed at which differences in visual stimuli can be perceived.* For example, two lines are shown for a few milliseconds and then are covered up. The examinee must indicate which of the two lines is longer. If given sufficient time, all examinees can indicate which is the longer line. The difficulty of the task is determined by how much time the examinees take to perceive the lines. The inspection time paradigm is noteworthy because it does not require a rapid motor response and thus has no confounds with Gps. Measures of inspection time correlate with the *g* factor at approximately .40 (Jensen, 2006). As noted by McGrew and Evans (2004), but overlooked until now, IT tasks have their origin in perceptual and psychophysical aspects of visual perception (Deary & Stough, 1996) and have consistently demonstrated stronger correlations with visual-spatial tests (e.g., Wechsler visual-perceptual organization tests; O'Connor & Burns, 2003) than its reaction/decision time (Gt-RT/DT) and movement time cousins (Gps-MT) (Burns & Nettelbeck, 2003; Luciano et al., 2004). Is this an unrecognized source of Gv variance? These findings suggest that IT may be more "cognitive" than the other Gt abilities.

4. *Semantic processing speed (R4): Reaction time when a decision requires some very simple encoding and mental manipulation of the stimulus content.*

5. *Mental comparison speed (R7): Reaction time where stimuli must be compared for a particular characteristic or attribute.*

Assessment Recommendations for Gt

Tasks measuring Gt are not typically used in clinical settings (except perhaps in CPTs). With the increasing use of low-cost mobile computing devices (i.e., smartphones and iPads/other slate notebook computers), we predict that practical measures of Gt will soon be available for clinical use. Some potential clinical applications are already apparent. We present three examples.

Gregory, Nettelbeck, and Wilson (2009) demonstrated that initial level of and rate of changes in inspection time might serve as an important biomarker of aging. Briefly, a *biomarker* for the aging process "is a biological parameter, like blood pressure or visual acuity that measures a basic biological process of ageing and predicts later functional capabilities more effectively than can chronological age . . . a valid biomarker should predict a range of important age-related outcomes including cognitive functioning, everyday independence and mortality, in that order of salience" (p. 999). In a small sample of elderly individuals, initial inspection time level and rate of slowing (over repeated testing) was related to cognitive functioning and everyday competence. Repeated, relatively low-cost assessment of adults' inspection times might serve a useful function in cognitive aging research and serve as a routine measure (much like blood pressure) to detect possible early signs of cognitive decline.

Researchers have demonstrated how to harness the typical non-normal distributions of RT as a potential aid in diagnosis of certain clinical disorders. Most RT response distributions are not normally distributed in the classic sense. They are virtually always positively skewed, with most RTs falling at the faster end of the distribution. These distributions are called *ex-Gaussian,* which is a mathematical combination of Gaussian and exponential distributions. It can be characterized by the mean (μ), the standard deviation σ, and an exponential function (τ) that reflects the mean and standard deviation exponential component (Balota & Yap, 2011). (Don't worry; one does not need to understand this statistics-as-a-second-language brief description to appreciate the potential application.) The important finding is that "individuals carry with them their own characteristic RT distributions that are relatively stable over time" (p. 162). Thus, given the ease and efficiency with which RT tests could be repeatedly administered to individuals (via smart devices and portable computers), it would be possible to readily obtain each person's RT distribution signature. Of most importance is the finding that all three RT distribution parameters are relatively stable, and τ is very stable (e.g., test–retest correlations in the high .80s to low .90s). Furthermore, there is a robust relation between τ and working memory performance that is consistent with the worst-performance rule (WPR) discovered in the intelligence literature. The WPR states that on repeated trial testing on cognitive tasks, the trials where a person does poorest (worst) are better predictors of intelligence than the best-performance trials (Coyle, 2003). It has been demonstrated, in keeping with the WPR, that the portion of each person's RT distribution representing the slowest RTs is strongly related to fluid intelligence and working memory.

In the not-too-distant future, assessment personal armed with portable smart devices or computers could test an individual repeatedly over time with RT paradigms. Then, via magical software or app algorithms, a person's RT distribution signature could be obtained (and compared against the normative distribution) to gain insights into the person's general intelligence, Gf, or working memory over time. This could have important applications in monitoring of age-related cognitive changes, responses to medication for attention-deficit/hyperactivity disorder (ADHD) or other disorders, the effectiveness of brain fitness programs, and so forth.

Finally, using the same general RT paradigms and metrics, research has indicated that it may be possible to differentiate children with ADHD from typically developing children (Kofler et al., 2013) and children with ADHD from those with dyslexia (Gooch, Snowling, & Hulme, 2012), based on the RT variability—not the mean level of performance. It is also possible that RT variability might simply be a general marker for a number of underlying neurocognitive disorders.

We have the technology.[25] We have the capability to build portable, low-cost assessment technology based on Gt assessment paradigms. With more efficient and better assessments than before, build it . . . and they (assessment professionals) will come.

Psychomotor Speed (Gps)

Definition of Gps

Psychomotor speed (Gps) can be defined as the ability to perform skilled physical body motor movements (e.g., movement of fingers, hands, legs) with precision, coordination, fluidity, or strength. The Gps domain is likely to contain more narrow abilities than are currently listed in the CHC model. In Ackerman's (1987) model of skill acquisition, Gps is the ability that determines performance differences after a comparable population (e.g., manual laborers in the same factory) has practiced a simple skill for a very long time.

Narrow Abilities within Gps[26]

1. *Speed of limb movement (R3): The speed of arm and leg movement.* This speed is measured after the movement is initiated. Accuracy is not important.
2. *Writing speed (fluency) (WS): The speed at which written words can be copied.* Also listed under Grw and Gps.
3. *Speed of articulation (PT): The ability to rapidly perform successive articulations with the speech musculature.*
4. *Movement time (MT): The time taken to physically move a body part (e.g., a finger) to make the required response, after a decision or choice has been made, in an elementary cognitive task.* MT also may measure the speed of finger, limb, or multiple-limb movements or vocal articulation (*diadochokinesis*; Greek for "successive movements"). MT is no longer listed under Gt or considered an intermediate-stratum ability (under Gt), as previously outlined in McGrew and Evans (2004) and Schneider and McGrew (2012). The cognitive complexity demands of MT are minimal to none, and are far below the simple reaction required in DT tasks, which in turn is below the demands of perceptual speed (Gs-P) tasks (Roberts & Stankov, 1999). MT is simply the quickness of initiating and producing a simple motor response after the basic and simple cognitive decision has been made.

Assessment Recommendations for Gps

Psychomotor speed is not generally used in clinical settings except for finger-tapping tests in neuropsychological settings. Although the speed of finger tapping is of some interest to neuropsychologists, they are more concerned with performance that is dramatically uneven on the right and left hands, as this may indicate in which hemisphere a brain injury may have occurred.

Acquired Knowledge

In Cattell's (1941, 1943) earliest formulation of g_f-g_c theory, some aspects of intelligence are directly shaped by cultural, familial, and personal investments in learning, whereas others are more independent of learning. In Ackerman's (1996a) terms, it is useful to distinguish between *intelligence-as-process* and *intelligence-as-knowledge*. That is, we can describe intelligence in terms of how well people processes information (e.g., perceiving, learning, remembering, reasoning, solving problems), or we can describe intelligence in terms of the breadth and depth of useful knowledge people possess. These two aspects of intelligence are a coherent system designed to work together flexibly.

Everyone has had the experience of a perplexing task's being much easier the second time it is completed. Rather than having to undergo the costly process of discovery each time the same task is encountered, humans can retrieve from memory a solution that worked well the last time. If we communicate our knowledge to others, we contribute to the advance of civilization. The human capacity to transmit knowledge permits ordinary high school students to see further than Newton and all his giants combined. Education will not make everyone a genius, but it makes everyone every genius's heir.

In CHC theory, we divide intelligence-as-knowledge into four categories: comprehension–knowledge (Gc), domain-specific knowledge (Gkn), reading and writing (Grw), and quantitative knowledge (Gq). As will be seen, the boundaries between these constructs are blurry, and their nature is such that they cannot be modeled simply as four separate latent variables.

Comprehension–Knowledge (Gc)

Definition of Gc

Comprehension–knowledge (Gc) can be defined as the ability to comprehend and communicate culturally valued knowledge. Gc includes the depth and breadth of both declarative and procedural knowledge, and skills such as language, words, and general knowledge developed through experience, learning and acculturation. Certain cultural skills such as dancing, fencing, sewing, and woodworking can be taught without words, but language allows such skills to be taught more efficiently. Those with strong language skills are better able to learn that which is transmitted via language. For this reason, it is unsurprising that individual differences in language development are closely related to individual differences in factual knowledge (Schipolowski, Wilhelm, & Schroeders, 2014). The two domains are so interconnected that it is useful to think of them as part of an integrated system for learning and transmitting knowledge. In CHC theory, this nexus of language ability and general knowledge is known as the comprehension–knowledge factor (Gc).

Narrow Abilities within Gc

1. **Language development (LD): Ability to comprehend language and use it to communicate; the general understanding of spoken language at the level of words, idioms, and sentences.* Although language development is listed as a distinct narrow ability in Carroll's model, he used the term as an intermediate category between Gc and more specific language-related abilities. It is the general term for how multiple narrow language abilities work together in concert. In its most general conceptualization, language development spans receptive and expressive aspects of both oral and written language (Carroll, 1993, p. 147). The oral–written language distinction is conceptually obvious, and has several lines of evidence supporting it. Factor-analytic evidence clearly shows that oral language and written language are distinct capacities.

In CHC theory, oral language usually refers to Gc and written language to Grw. The distinction is not of the same kind as, for example, the distinction between visual–spatial processing and auditory processing. All developmentally normal humans learn to speak. Literacy, on the other hand, only occurs with explicit instruction, usually in formal education. Specific regions of the brain evolved specifically to process oral language, but literacy has not been prevalent long enough for natural selection to optimize the brain for reading. Instead, learning to read is a painstaking process that requires repurposing capabilities evolved for other functions.

Support for these distinctions (receptive vs. expressive and oral vs. written) can be found using multidimensional scaling. Using the psych package in R (Revelle, 2015), we created distances from the correlation matrix of oral and written language-related subtests from the WJ IV (Schrank et al., 2014) standardization sample (ages 6 and higher). In Figure 3.7, the tests largely fall into the correct quadrants. On the left side of the figure,

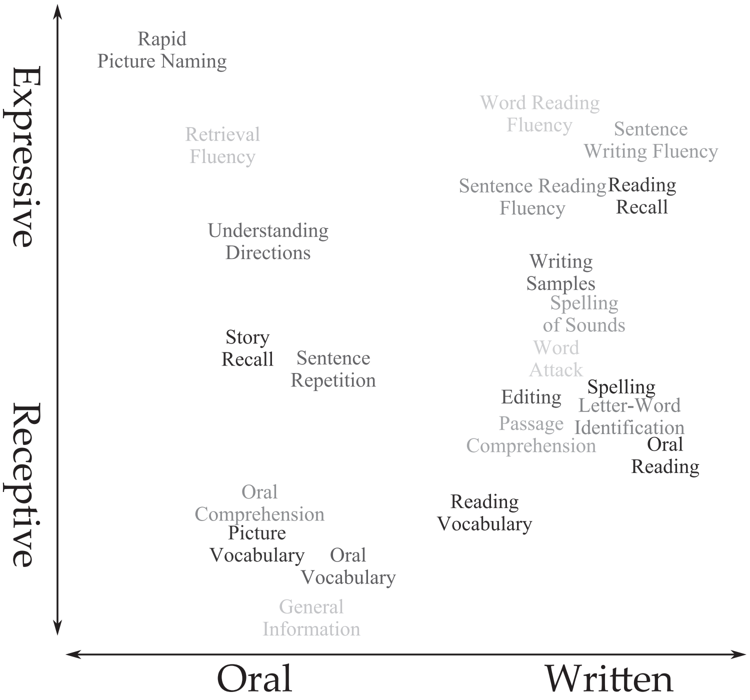

FIGURE 3.7. A multidimensional scaling (MDS) of language tests from the WJ IV standardization sample (ages 6 and higher).

the tests span a wide range of oral abilities, and the tests on the right are written (i.e., measures of Grw). Not every test is purely receptive or purely expressive. For example, Story Recall requires oral comprehension (respective) and oral production (expressive). The exceptions are the tests measuring reading speed. Adding a third dimension to the model (degree to which a test is speeded) resolves this inconsistency with Carroll's prediction. Unfortunately, the complexity of the results and the two-dimensional limitations of the page make a clear presentation of the three-dimensional results impossible to present here.

2. **Lexical knowledge (VL): Knowledge of the definitions of words and the concepts that underlie them; vocabulary knowledge.* For people with deep lexical knowledge, each word in the dictionary is a cognitive aid or tool to help them understand and talk about the world. Lexical knowledge is also an obvious precursor skill for reading decoding and reading comprehension (Storch & Whitehurst, 2002). As with language development, people who read more acquire vocabulary words that are more likely to appear in print than in speech.

3. **General knowledge (K0): The breadth and depth of knowledge considered essential, practical, or worthwhile for everyone in a culture to know.* Shared knowledge allows members of a community to communicate efficiently and come to agreements more peacefully. Deep knowledge of local culture can make the difference between success and catastrophe. For example, Sirolli (1999, p. 9) tells the sad/amusing tale of what happened when Italian aid workers tried to show Zambians how to farm a fertile river valley. Uncurious about why locals had never farmed the valley before, the aid workers invested considerable time, effort, and technical know-how to grow amazingly big tomatoes. Just before the prized tomatoes could ripen, ravenous, unstoppable hippos came out of the river and ate every last one of them.

Much of what we are calling *general knowledge* is common knowledge—familiar to most members of a society. Most adults know enough about local weather patterns to prepare for seasonal changes. They know how to find and prepare food, if needed. They may not know the finer points of etiquette or the technical aspects of law, but they have a general sense of what is polite and what is prohibited.

Beyond common knowledge, general knowledge also includes information that most adults would have been exposed to but might not necessarily remember—such as the plot of the *Iliad,* what the Pythagorean theorem is for, the difference between a monarchy and a dictatorship, the location of Tokyo, the legacy of apartheid, how supply and demand affect prices, how a combustion engine works, and the difference between bacteria and viruses. Although familiarity with these topics is not vital for day-to-day survival for any one individual, a complex society needs a large cohort of people who have a provisional understanding of what is in the world, the processes that govern its functioning, and the diverse people who inhabit it.

General knowledge is contrasted with domain-specific knowledge (Gkn), information that is valuable for members of a specific profession or prized only by enthusiasts with particular interests or hobbies. The distinction between general knowledge and domain-specific knowledge is necessarily blurry at the edges, but clear enough most of the time. If it is taught in general education, it is likely to be general knowledge. If it is taught only in specialized training programs, it is likely to be domain-specific knowledge. Some domain-specific knowledge is so narrow that it is useful for only a few people, such as knowing how to use the complex filing system at a specific branch in a midsized firm.

We have no reason to suppose that learning general knowledge and learning domain-specific knowledge require distinct neurological processes, or that specialized parts of the brain handle the two kinds of knowledge differently. Indeed, any item in a general knowledge test could be transplanted into a domain-specific knowledge test, but not all domain-specific knowledge test items should appear in general knowledge tests. What distinguishes a good general knowledge test item from a domain-specific test item is whether the knowledge is considered important enough such that most adults have been exposed to it. Examining published curricula and introductory textbooks in general education courses can give a good sense of what would be considered general knowledge in a society. An empirical index of the generality of a knowledge item would be its correlation with items in diverse domains, which would manifest as a high item discrimination parameter in an item response theory analysis, a high factor loading in an ordinal factor analysis, or high centrality in MDS.

4. *Listening ability (LS): The ability to understand speech. This ability starts with comprehending single words and increases to long complex verbal statements.* This ability is a receptive oral language ability—a particularly important precursor to reading comprehension, a receptive written language ability (Bishop & Adams, 1990; Catts, Adlof, & Weismer, 2006; Nation, Cocksey, Taylor, & Bishop, 2010; Storch & Whitehurst, 2002). Listening comprehension is also an important predictor of written expression, most likely via oral communication ability (Re & Carretti, 2016). Tests of listening ability typically have simple vocabulary, but increasingly complex syntax or increasingly long speech samples to listen to and answer questions about. As noted later in this chapter, listening ability is not to be confused with narrow abilities listed under auditory processing (Ga).

5. *Communication ability (CM): The ability to use speech to communicate effectively.* This ability is comparable to listening ability, except that it is expressive rather than receptive. Oral communication ability is an important precursor to written expression (Carretti, Motta, & Re, 2016). Carroll's factor came from studies in which people had to communicate their thoughts in nontesting situations (e.g., giving a speech). Although there are many tests in which people are asked to compose essays, we are not aware of language tests in which people are asked to communicate orally in a comparable fashion.

6. *Grammatical sensitivity (MY): Awareness of the formal rules of grammar and morphology of words in speech.* This factor is distinguished from the English usage factor (discussed in the section on Grw) in that it is manifested in oral language instead of written language, and that it measures more the *awareness* of grammar rules than correct usage. Although less is known about this factor's relationship to academic outcomes, it appears that it is an important precursor to reading comprehension (Muter, Hulme, Snowling, & Stevenson, 2004).

Assessment Recommendations for Gc

Adequate measurement of Gc should include a measure of general information and a test of either language development or lexical knowledge (which is a facet of language development). If there is time to give three Gc tests, a test of listening ability is a good choice. A measure of lexical knowledge (vocabulary) is particularly important in the assessment of young children (pre-K and kindergarten), given that a meta-analysis of vocabulary intervention studies has shown strong effects (effect size = 0.88) during this developmental period (Marulis & Neuman, 2010). That is, lexical knowledge is malleable during this formative time period.

Domain-Specific Knowledge (Gkn)

Definition of Gkn

Domain-specific knowledge (Gkn) can be defined as the depth, breadth, and mastery of specialized declarative and procedural knowledge (knowledge not all members of a society are expected to have). Specialized knowledge is typically acquired via one's career, hobby, or other passionate interests (e.g., religion, sports). Knowledge has been featured in several definitions of intelligence, particularly during adulthood. It has been described as a "central ingredient of adult intellect" (Ackerman, 1996b, p. 241). Schank and Birnbaum (1994) stated, "The bottom line is that intelligence is a function of knowledge. One may have the potentiality of intelligence, but without knowledge, nothing will become of that intelligence" (p. 102).

The G in Gkn is somewhat paradoxical. There is no general ability called Gkn because all the abilities within the Gkn domain are specific by definition. Yet when all possible specific Gkn domains are considered collectively, it is broader than Gc (Hambrick, Pink, Meinz, Pettibone, & Oswald, 2008). Ackerman and colleagues (Ackerman, 1987, 1996a, 1996b, 2000; Ackerman & Heggestad, 1997; Ackerman & Rolfhus, 1999; Beier & Ackerman, 2005; Rolfhus & Ackerman, 1996, 1999) have conducted the most systematic study of the domain of Gkn in adults. In addition to the importance of Gc and prior domain knowledge as predictors, these researchers have demonstrated that learning new domain-specific knowledge (particularly declarative knowledge) is also influenced by several non-ability-related (conative) variables. These conative variables include situational and individual interests, as well as the Big Five personality characteristics of openness to experience and typical intellectual engagement. The personality trait of need for cognition has also been implicated as a causal factor. The Ackerman intelligence-as-process, personality, interest, and intelligence-as-knowledge (PPIK) theory is the best available empirically based comprehensive explanation of the development of Gkn abilities (see Ackerman, Chapter 8, this volume). The PPIK theory has its conceptual roots in Cattell's investment hypothesis.

Gkn is unusual in that the proper reference group is not a person's same-age peers in the general population. Rather, the basis of comparison for Gkn is a group of people expected to have the same kinds of specialized knowledge. For example, when measuring an oncologist's Gkn in oncology, it only makes sense to compare the oncologist's knowledge with the average score of other oncologists. Gkn is also unusual in that there are an infinite number of possible narrow factors of specialized knowledge (i.e., one for each potential specialization).

The accumulation of specialized knowledge is often called *expertise. Passive* expertise is a type of knowledge-based specialization that arises from experiences in life and one's position in a society or culture. *Formal* expertise is the result of a self-selection of a domain of knowledge that is mastered deliberately and for which there are clear benchmarks of success (Fisher & Keil, 2016). Interestingly, there is a phenomenon known as the "curse of expertise." Briefly, as expertise develops, it is possible for experts to become overconfident and miscalibrate their ability to solve a problem; in other words, a knowledge "blind spot" may occur (Fisher & Keil, 2016).

In Gc tests, there is a sense in which people are expected to know the answers to all the test questions. In Gkn tests, there is no such expectation unless the person is a member of a certain profession or is considered an expert in a certain domain. The fact that a nurse does not know how to tune a guitar has no bearing on the evaluation of the nurse's abilities. However, if the nurse does not know how to administer a shot, the nurse would be considered incompetent, as would a guitarist who is unable to tune a guitar.

Another noteworthy distinction between Gc and Gkn is their differing relationships with working memory. When solving problems outside their expertise, most experts are unable to perform extraordinary feats of working memory. However, in a phenomenon called *expertise wide-span memory* (Horn & Blankson, 2005) or *long-term working memory* (Ericsson & Kintsch, 1995), experts seem to be able to access large amounts of specialized knowledge very quickly in long-term memory. They can hold it in immediate awareness as if it were stored in working memory, so it can be used to solve complex problems efficiently. But this phenomenon is only true of experts who are working within their areas of specialization.

In the previous version of this chapter (Schneider & McGrew, 2012), we speculated that the structure of domain-specific knowledge would be similar to Holland's (1997) theory of career choice, also known as "Holland's hexagon" and the RIASEC model of vocational interests. According to the RIASEC model, there are six broad, partially overlapping vocational interest domains: Realistic (interest in technical, mechanical, and hands-on activities), Investigative (interest in furthering knowledge), Artistic (interest in the humanities and arts), Social (interest in working with and helping people), Enterprising (interest in getting ahead in terms of profit, power, and influence), and Conventional (interest in order, structure, and business processes). The six domains have a circumplex structure, meaning that interest in adjacent domains are more correlated than interests in nonadjacent domains (e.g., people with investigative interests are most likely also to have realistic and artistic interests, less likely to have conventional and social interests, and least likely to have enterprising interests).

The prediction that knowledge domains and interest domains would have a similar structure was rooted in the straightforward finding that people learn more about things they are interested in than about things they find less interesting (Ackerman, 2000; Ackerman & Rolfhus, 1999; Hambrick, Meinz, & Oswald, 2007; Rolfhus & Ackerman, 1996, 1999; Schmidt, 2014). For this chapter, we identified two studies that would allow us to test this hypothesis. In Reeve (2004) and Rolfhus and Ackerman (1999), participants completed a diverse battery of knowledge tests from many disciplines. We used the psych package (Revelle, 2015) in the R programing environment to convert the correlation matrices published in the two articles into Euclidian distance matrices. These distances were converted into two-dimensional maps via MDS. As seen in Figures 3.8 and 3.9, the results were broadly consistent with our hypotheses. The RIASEC labels were placed by us to summarize our interpretation of the plots.

FIGURE 3.8. An MDS of a knowledge test battery correlation matrix, from Rolfhus and Ackerman (1999). Note: Overlapping labels were manually adjusted to allow for easy interpretation.

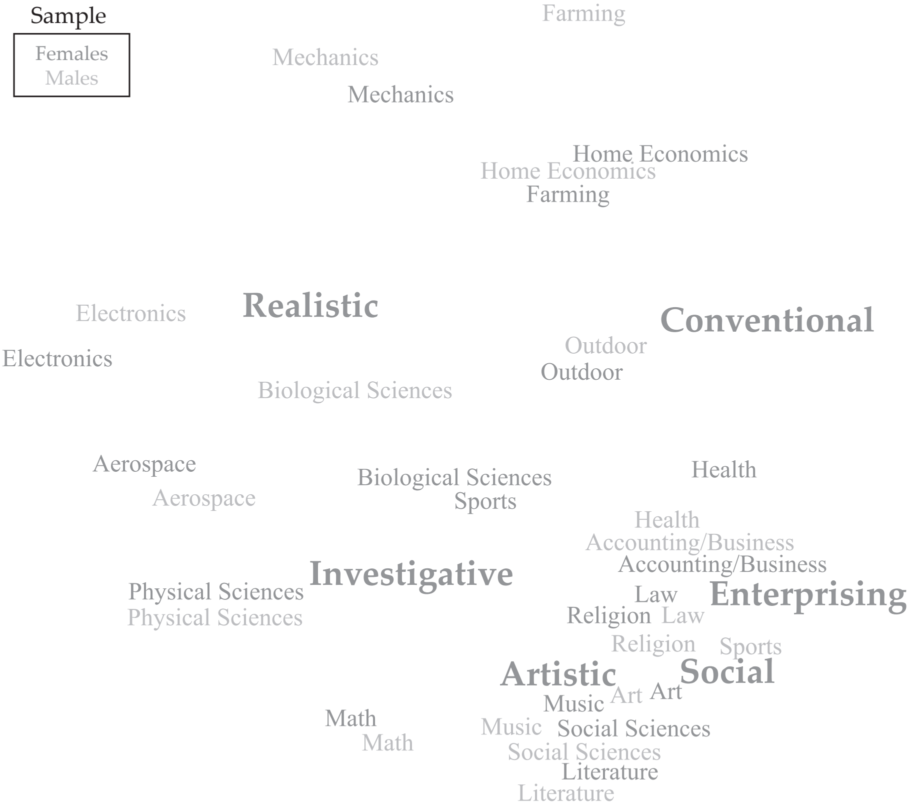

FIGURE 3.9. An MDS of a knowledge test battery correlation matrix for a sample of adults, from Reeve (2004). Results for males (light gray type) and females (darker type) are largely the same. Note: Overlapping labels were manually adjusted to allow for easy interpretation.

Our simplified conceptual structure of knowledge abilities is presented in Figure 3.10. At the center of overlapping knowledge domains is general knowledge—knowledge and skills considered important for any member of the population to know (e.g., literacy, numeracy, self-care, budgeting, civics, etiquette, and much more). The bulk of each knowledge domain is the province of specialists, but some portion is considered important for all members of society to know. Drawing inspiration from F. L. Schmidt (2011, 2014), we posit that interests and experience drive acquisition of domain-specific knowledge.

In Schmidt's model, individual differences in general knowledge are driven largely by individual differences in fluid intelligence and general interest in learning, also known as *typical intellectual engagement* (Goff & Ackerman, 1992). In contrast, individual differences in domain-specific knowledge are more driven by domain-specific interests, and also by the "tilt" of one's specific abilities (Coyle, Purcell, Snyder, & Richmond, 2014; Pässler, Beinicke, & Hell, 2015). In Figure 3.11, we present a simplified hypothetical synthesis of several ability models in which abilities, interests, and personality traits predict general and specific knowledge (Ackerman, 1996a, 1996b, 2000; Ackerman, Bowen, Beier, & Kanfer, 2001; Ackerman & Heggestad, 1997; Ackerman & Rolfhus, 1999; Fry & Hale, 1996; Goff & Ackerman, 1992; Kail, 2007; Kane et al., 2004; Rolfhus & Ackerman, 1999; Schmidt, 2011, 2014; Schneider et al., 2016; Schneider & Newman, 2015; Woodcock, 1993; Ziegler, Danay, Heene, Asendorpf, & Bühner, 2012).

Narrow Abilities within Gkn

1. *General science information (K1): Range of scientific knowledge.* This factor is quite broad, since it encompasses all disciplines within science. It is likely that this factor has many subfactors,

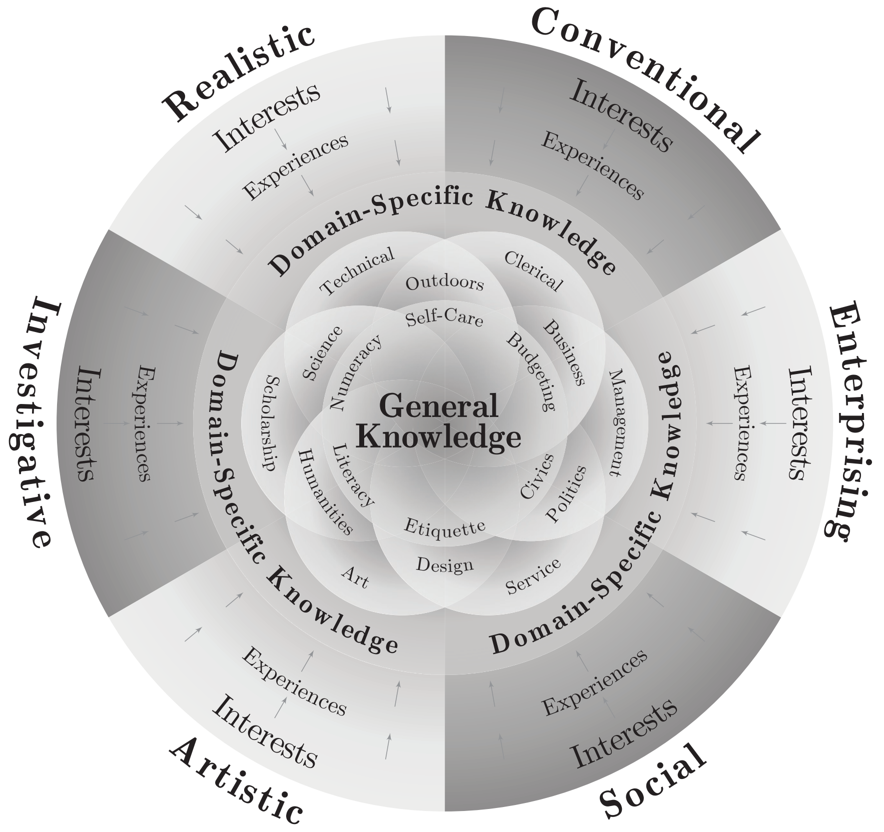

FIGURE 3.10. Conceptual structure of general and domain-specific knowledge.

which may be divided into ever-narrower areas of specialization. It is common to distinguish among the physical sciences (e.g., physics, chemistry, geology, astronomy), the life sciences (e.g., biology, ecology, medicine), and the social sciences (e.g., psychology, sociology, anthropology, archeology, political science, geography, and economics). Of course, there are many fields of study that span these artificial academic boundaries (e.g., evolutionary genetics).

2. **Knowledge of culture (K2): Range of knowledge about the humanities.* As with general science information, this factor is also quite broad and has many subfactors, which may be divided into ever-narrower areas of specialization. It is common to distinguish between artistic/aesthetic domains (e.g., art, literature, and music), and sociohistorical domains (e.g., history, law, politics, religion, language, communication studies). As with the sciences, there are many fields that deliberately cross boundaries within the humanities (e.g., cultural studies, communication). Indeed, there are many disciplines that stand astride the humanities and the sciences (e.g., philosophy, linguistics, and geography). Ultimately, scholars are working toward what E. O. Wilson (1999) calls *consilience:* one interconnected and coherent body of knowledge for all humans.

3. *Mechanical knowledge (MK): Knowledge about the function, terminology, and operation of ordinary tools, machines, and equipment.* There are many tests of mechanical knowledge and reasoning used for personnel selection (e.g., the Armed Services Vocational Aptitude Battery, the Wiesen Test of Mechanical Aptitude).

4. *Foreign-language proficiency (KL): Similar to language development, but in another language besides one's native language.* This ability is distinguished from foreign-language aptitude in that it represents achieved proficiency instead of poten-

tial proficiency. Note that this factor is unusual because it is not a single factor: There is a different foreign-language proficiency factor for every language.

5. *Knowledge of signing (KF): Knowledge of finger spelling and signing (e.g., American Sign Language).*

6. *Skill in lip reading (LP): Competence in the ability to understand communication from others by watching the movements of their mouths and expressions.*

Assessment Recommendations for Gkn

In most situations, Gkn is measured informally by peer reputation, but there are many educational tests that can serve as reasonable markers of specific Gkn domains (e.g., the WJ IV Sciences, Social Sciences, and Humanities tests). Other methods have included cataloguing the productivity and accomplishments of experts (e.g., number of patents, number of creative works, number of prestigious awards).

Unresolved Issues and Comments about Gkn

The theoretical and empirical research regarding domain-specific knowledge expertise is vast. It is so large that we provide no comments regarding issues, as this would require that we be experts in the expertise literature. Interested readers can consult a number of recent summaries and debates regarding expertise to learn more about the status and issues in the field (Ackerman, 2014; Anders Ericsson & Towne, 2010; Detterman, 2014; A. Ericsson & Pool, 2016; S. B. Kaufman & Duckworth, 2017; Sternberg, 1999a; Weiss & Shanteau, 2014).

Reading and Writing (Grw)

Definition of Grw

Reading and writing (Grw) can be defined as the depth and breadth of declarative and procedural knowledge and skills related to written language. What CHC theory calls Grw has traditionally been called *literacy*. Not long ago, literacy was a province of scribes and elites, and thus would have been considered an aspect of domain-specific knowledge (Gkn). In recent centuries, literacy has become so essential to industrialized societies that it is now a core desired skill for every citizen.

In CHC theory, Grw is not technically a separate broad ability distinct from Gc. It is best conceptualized as a facet of language development so important to modern life that it requires special

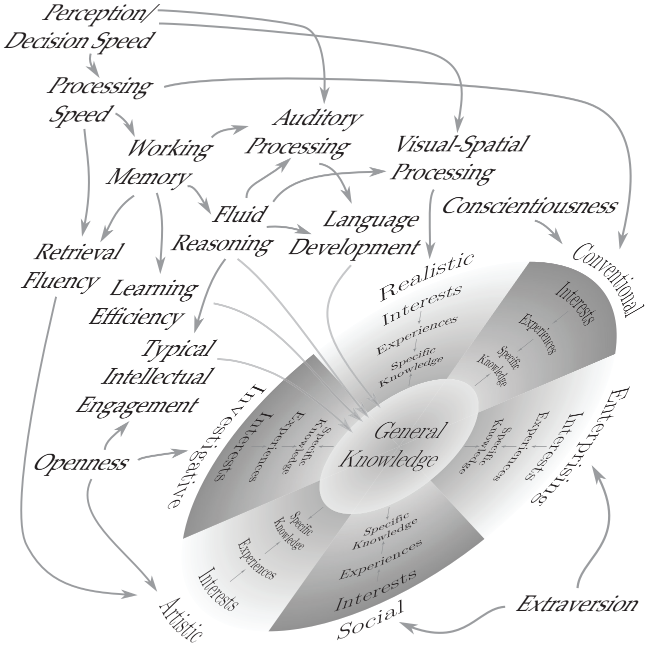

FIGURE 3.11. Ability, interest, and personality precursors of knowledge.

emphasis apart from oral language. Although oral language and Grw are clearly related, to some degree they have different antecedents and predict different outcomes.

It is important to note that when we administer tests of Grw, we are measuring much more than just literacy. Often reading comprehension tests require not just literacy skills, but verbal comprehension, general knowledge, and sometimes auditory processing, working memory, processing speed, and retrieval fluency.

Narrow Abilities within Grw

1. **Reading comprehension (RC): The ability to understand written discourse.* Reading comprehension is measured in a variety of ways. One common method is to have examinees read a short passage and then have them answer questions that they can only answer if they understood the text. A direct method of measuring Grw reading comprehension with reduced contamination from Gc (or Gf) is to ask questions about information that was stated directly in the text. However, we also wish to measure more complex aspects of reading comprehension, such as inference and sensitivity to the author's intent. Such skills draw deeply on Gc. A second method of measuring reading comprehension is the cloze technique, in which a key word has been omitted from a sentence or a paragraph. Examinees who understand what they are reading can supply the missing word.

2. **Reading decoding (RD): The ability to identify words from text.* Typically, this ability is assessed by oral reading tests with words arranged in ascending order of difficulty. Tests can consist of phonetically regular words (words that are spelled how they sound, such as *bathtub* or *hanger*), phonetically irregular words (words that do not sound how they are spelled, such as *sugar* or *colonel*), or phonetically regular pseudowords (fake words that conform to regular spelling rules, such as *gobbish* or *choggy*).

3. *Reading speed (RS): The rate at which a person can read connected discourse with full comprehension.* There are various methods of measuring reading speed, and there is no clear consensus about which method is best for which purposes. Should reading speed be measured by oral reading speed or silent reading speed? Should examinees be told to read as quickly as they can to measure maximal ability, or should they be told to read at their normal pace to measure their typical reading rate? How should the speed–accuracy (of comprehension) tradeoff be handled? Should the format be single words (to measure the efficiency of reading decoding) or full sentences or paragraphs (to measure the efficiency of reading comprehension)? We are certain that different kinds of reading speed tests measure different things that are important, but we are not sure exactly what is different about them. Clinicians are encouraged to think carefully about what exactly the test requires of examinees and to check to see whether there is a logical connection between the apparent task demands and the referral concern. Reading speed is classified as a mixed measure of Gs (broad cognitive speed) and Grw in the hierarchical speed model, although the amount of Gs and Grw measured most likely reflects the degree of difficulty of the reading involved in the task (e.g., reading lists of simple isolated words vs. reading short statements and indicating whether they are true or false).

4. *Writing speed (WS): The ability to copy or generate text quickly.* Writing speed tasks are considered to measure both Grw and Gps (broad psychomotor speed). Like measures of reading speed, the relative importance of Grw or Gps probably varies, depending on the format and level of writing skills involved.

5. *English usage (EU): Knowledge of the mechanics of writing (e.g., capitalization, punctuation, and word usage).*

Assessment Recommendations for Grw

Much more is known about reading assessment than writing assessment. For reading, it is recommended that assessments focus on the point of reading: comprehension. If a person comprehends text well, minor weaknesses in decoding and reading speed are of secondary concern (unless the assessment concerns are reading efficiency problems rather than reading comprehension problems). If there are comprehension deficits, the assessment should focus on the proximal causes of reading comprehension problems (decoding problems, slow reading speed) and then explaining the proximal causes with more distal causes (e.g., slow naming facility → slow reading speed → slow, labored, inefficient reading → comprehension problems). We recommend measuring reading decoding with both real words and pseudowords. Reading comprehension is probably best measured with a variety of methods, including the cloze method and having examinees answer both factual and inferential questions about longer passages.

Spelling ability is an important skill (especially in a phonetically irregular language like English) and is easily measured with a traditional spelling test. It is generally a good idea to select a test that allows the clinician to be able to understand the nature of spelling problems (e.g., phonetically regular misspellings?).

Writing tests are extremely varied and probably measure a wide variety of abilities other than just specific writing abilities. Observing a child's pattern of grammar, usage, and mechanics in responses to writing tests allow clinicians to distinguish between specific writing problems and more complex problems (e.g., general language difficulties). However, it is generally a good idea to examine a wide variety of samples of the examinee's writing, both from formal tests and from school writing assignments.

Quantitative Knowledge (Gq)

Definition of Gq

Quantitative knowledge (Gq) can be defined as the depth and breadth of declarative and procedural knowledge related to mathematics. Gq consists of acquired knowledge about mathematics, such as knowledge of mathematical symbols (e.g., $\int$, π, Σ, ∞, $\neq$, $\leq$, $+$, $-$, $\times$, $\div$, $\surd$, and many others), operations (e.g., addition–subtraction, multiplication–division, exponentiation–*n*th rooting, factorials, negation, and many others), computational procedures (e.g., long division, reducing fractions, the quadratic formula, and many others), and other math-related skills (e.g., using a calculator, math software, and other math aids).

At this time in history, being numerate is almost as important as being literate. Modern economies shower money on those who can use the abstract tools of mathematics to solve concrete problems (Ayres, 2007). For a complex society to function, most adults must have mastered core numeracy skills such as counting and arithmetic. To provide public services and to guide public policy, a sizeable proportion of the population must also understand the basics of algebra, geometry, and statistics. Beyond that, complex societies require many specialists who understand advanced subfields of mathematics. Thus, as with Grw, Gq is not strictly separate from Gc. It is probably best conceptualized as a construct that straddles general and domain-specific knowledge.

Generally, measures of Gq are selected as academic achievement tests and thus must be aligned with a student's curriculum for the score to be diagnostic of math difficulties. This is not the case when measures of Gq are used as aptitude tests (e.g., on the SAT, GRE, or ACT). Gq is unusual in that it consists of many subskills that are fairly well defined by curriculum guides and instructional taxonomies. Thus, metrics of Gq tests can be specified in relative terms (e.g., index scores) and in terms of absolute standards (e.g., an examinee can multiply two-digit numbers or can use the quadratic equation). We believe that both forms of description are necessary to paint a vivid picture of a person's Gq abilities.

Narrow Abilities within Gq

1. **Mathematical knowledge (KM): Range of general knowledge about mathematics, not the performance of mathematical operations or the solving of math problems.* This factor involves "what" rather than "how" knowledge (e.g., "What does π mean?" "What is the Pythagorean theorem?")

2. **Mathematical achievement (A3): Measured (tested) mathematics achievement.* This ability is measured in two ways. The first method is to administer decontexualized math calculation problems (e.g., 67 + 45 = ____). This method gets at the heart of the factor: calculation with the demands of quantitative reasoning minimized. The second method is messier, but focuses on the primary goal of mathematics: solving problems. Examinees are given a scenario and a problem, and they must use reasoning to translate the word problem into a mathematically tractable solution. Examinees then use their calculation skills to arrive at a solution. For example, how many square meters of flooring are needed to cover a 6-meter by 8-meter rectangular room? The examinee has to intuit (or use KM) that this problem is solved by setting up the equation 6 × 8 = ____. Such tests clearly draw upon quantitative reasoning, a facet of Gf.

Assessment Recommendations for Gq

As with Grw, the selection of Gq tests for assessment will depend on the question being asked. Most assessments concentrate first on calculation skills and then on math problem solving. Calculation fluency is typically of secondary concern, but can yield important information regarding the proximal causes of calculation and problem-solving difficulties (e.g., a person who must think about the answer to basic math facts can easily be distracted and make careless errors in the midst of an algebra problem). Math knowledge tests that have no calculation demands can distinguish between people who do not know how to answer the question and people who do not know what the question is.

Comments and Unresolved Issues Related to Gq

- *Are there narrower Gq abilities?* Yes. Carroll (1993) only reported the narrow KM and A3 factors, given their emergence in datasets that included mathematics measures in addition to the cognitive variables that were the primary target of Carroll's review. Carroll did not go out of his way to identify all possible datasets that included tests of mathematics. Essentially, the Gq factors he identified were "bycatch"[27] found when he cast his wide net to capture cognitive ability datasets. Thus other Gq narrow abilities most likely exist, but have yet to be validated within the context of CHC theory.
- *What is the relationship between Gq and number sense? Number sense* refers to core systems of numerical representation present in infants and other animals (Dehaene, 1997; Feigenson, Dehaene, & Spelke, 2004). It does not refer to the verbal counting systems in human language, but to nonverbal capacities for basic quantification. Feigenson and colleagues (2004) presented evidence for two core systems: the *parallel individuation system* for tracking and distinguishing among three to four individual objects at a time as they move over time, and the *approximate number system* for rapid nonverbal estimates of quantity. These primitive systems serve as the foundation for early mathematics skills in children as they learn to map nonverbal estimates of quantity to explicit verbal number systems (Geary, 2004, 2007, 2013; Geary, Hoard, Nugent, & Bailey, 2012). In theory, the division between number sense and Gq is clear: Number sense is fluid (inborn, not taught), and Gq is crystallized (acquired via formal instruction). In practice, however, there is no clean division between inborn number sense and developed capacities at the lower developmental end of the Gq narrow abilities of KM or A3 (or RQ in Gf). Not all measures of number sense distinguish between nonverbal/inborn and verbal/acquired quantitative abilities (e.g., Jordan & Glutting, 2012). Given the importance of number sense in understanding math development and disabilities (Geary, 2007, 2013) and predicting both future reading and math performance (Jordan, Kaplan, Nabors Oláh, & Locuniak, 2006), we expect that number sense assessment will become increasingly common. A recent example is the Number Sense test in the WJ IV Tests of Early Cognitive and Academic Development (ECAD; Schrank et al., 2015).

Sensory- and Motor-Linked Abilities

Cattell, Horn, and Carroll all noted something different about abilities directly associated with sensory modalities. Despite the G in their abbreviation, they are not as general as Gf, Gwm, Gl, Gr, Gs, and Gt; yet they are still broad. What distinguishes these broad abilities from other broad CHC abilities is that they are linked to well-defined regions and functions of the cerebral cortex (i.e., primary regions of the cerebral cortex and their associated secondary regions).

A common theme in the discussion that follows is that these abilities are hard to define. We are not used to talking about sensory-related abilities without talking about the senses and sensory acuity. The distinction between sensation and perception is relevant here, but it is not fully adequate to describe these abilities. *Sensation* refers to the detection of a stimulus. *Perception* refers to complex processing of sensory information to extract relevant information from it (i.e., to literally to make sense of it). These abilities do encompass perception, but also refer to higher-order and goal-directed processing of sensory information (e.g., imagining how a room might look different if it were painted a darker color).

The difficulty in defining and differentiating sensory abilities is captured in a statement regarding the Gv domain, which is likely shared by each of these sensory-based domains. According to Eliot and Czarnolewski (2007),

> One difficulty with defining spatial intelligence is that it is a dimension that is so fundamental and pervasive in people's everyday lives that they take it for granted. It is fundamental and pervasive in the sense that it may operate at any given moment at several levels of human consciousness and, in combination with other cognitive functions, may contribute to the solution process in different ways for many different types of problems. (p. 362)

Well stated!

Visual Processing (Gv)

Definition of Gv

Visual processing (Gv) can be defined as the ability to make use of simulated mental imagery to solve problems—perceiving, discriminating, manipulating, and recalling nonlinguistic images in the "mind's eye." Humans do more than "act" in space; they "cognize" about space (Tommasi & Laeng, 2012). Once the eyes have transmitted visual information, the visual system of the brain automatically performs several low-level computations (e.g., edge detection, light–dark perception, color differentiation, motion detection). The results of these low-level computations are used by various higher-order processors to infer more complex aspects of the visual image (e.g., object recognition, constructing models of spatial configuration, motion prediction). Traditionally, tests measuring Gv are designed to measure individual differences in these higher-order processes as they work in tandem to perceive relevant information (e.g., a truck is approaching!) and solve problems of a visual-–spatial nature (e.g., arranging suitcases in a car trunk).

Among the CHC domains, Gv has been one of the most studied (Carroll, 1993). Yet it has long been considered a second-class citizen in psychometric models of intelligence, due in large part to its relatively weak or inconsistent prediction of important outcomes in comparison to powerhouse abilities like Gf and Gc (Lohman, 1996). But "the times they are a-changing." Carroll (1993), citing Eliot and Smith (1983), summarized three phases of research on spatial abilities, ending in large part in the late 1970s to early 1980s (Lohman, 1979). A reading of Carroll's survey conveys the impression that his synthesis reflects nothing more than what was largely known already in the 1980s. We believe that the Gv domain is entering a fourth period and undergoing a new renaissance, which will result in its increased status in CHC theory and eventually in cognitive assessment. Carroll, the oracle, provided a few hints in his 1993 Gv chapter.

Carroll (1993) was prophetic regarding two of the targets of the resurgent interest in Gv and Gv-related constellations (often broadly referred to as *spatial thinking, spatial cognition, spatial intelligence,* or *spatial expertise*; Hegarty, 2010; National Research Council, 2006).[28] In Carroll's discussion of "other possible visual perception factors" (which he did not accord formal status in his model), he mentioned "ecological" abilities (e.g., abilities reflecting a person's ability to orient the self in real-world space and maintain a sense of direction) and dynamic (vs. static) spatial reasoning factors (e.g., predicting where a moving object is moving and when it will arrive at a predicted location).

Carroll's ecological abilities are reflected in a growing body of research regarding large-scale spatial navigation. *Large-scale spatial navigation* is concerned with finding one's way, or the ability to represent and maintain a sense of direction and location, and move through the environment (Allen, 2003; Hegarty, 2010; Newcombe, Uttal, & Sauter, 2013; Wolbers & Hegarty, 2010; Yilmaz, 2009). Using a map or smartphone GPS system to find one's way to a restaurant, and then to return to one's hotel room, in an unfamiliar large city requires large-scale spatial navigation. A primary distinction between small- and large-scale spatial abilities is the use of different perspectives or frames of reference. *Small-scale spatial ability,* as represented by traditional psychometric tests on available cognitive or neuropsychological batteries, involves allocentric or object-based transformation.

Large-scale spatial ability typically involves an egocentric spatial transformation, in which the viewer's internal perspective or frame of reference changes regarding the environment, while the person's relationship with the objects do not change (Hegarty & Waller, 2004; Newcombe et al., 2013; Wang, Cohen, & Carr, 2014). Recent meta-analyses indicate that large-scale spatial abilities are clearly distinct from small-scale spatial abilities, with an overall correlation of approximately .27. In practical terms, this means that the ability to easily solve the 3D Rubik's cube may not predict the probability of getting lost in a large, unfamiliar city. Also supporting a clear distinction between the two types of spatial abilities is developmental evidence suggesting that large-scale spatial abilities show a much faster rate of age-related decline, and that the two types are most likely related to different brain networks (Newcombe et al., 2013; Wang et al., 2014).

The distinction between *static* and *dynamic* spatial abilities is typically traced to work by Pellegrino and colleagues (Hunt, Pellegrino, Frick, Farr, & Alderton, 1988; Pellegrino, Hunt, Abate, & Farr, 1987) and is now considered one of the two primary organizational facets of spatial thinking (Uttal, Meadow, et al., 2013). Static spatial abilities are well represented by standard tests of Gv (e.g., block design tests). Dynamic and static spatial tasks differ primarily by the presence or absence of movement. "Dynamic spatial ability is one's ability to estimate when a moving object will reach a destination, or one's skill in making time-to-contact (TTC) judgments" (Kyllonen & Chaiken, 2003, p. 233). The ability to catch a football, play a video game, or perform as an air traffic controller requires dynamic spatial abilities, as "one must note the position of the moving object, judge the velocity of the object, anticipate when the object will reach another point (e.g., one's hand, car, or ship), and take some motor action in response to that judgment. In the perception literature, the research surrounding this everyday human information-processing activity has been known as 'time to collision'" (Kyllonen & Chaiken, 2003, p. 233). Although the dynamic–static distinction has gained considerable traction and support (Allen, 2003; Buckley, Seery, & Canty, 2017; Contreras, Colom, Hernandez, & Santacreu, 2003), some research has questioned whether the underlying difference reflects an actual spatial ability distinction. Kyllonen and Chaiken (2003) reported research suggesting that the underlying cognitive process involved in performing dynamic spatial tasks may be a nonspatial, counting-like clock mechanism—temporal processing, not spatial.

The driving forces behind the increased interest and new conceptual developments regarding spatial thinking are threefold. First, rapid technological changes in the past decade have now made access to relatively cheap and accessible visual-graphic-based technology available to large portions of the population. Individuals can immerse themselves in 3D virtual-reality environments for pleasure or learning. Computer visualizations, often available on smartphones and computer tablets, can be used to teach medical students human anatomy and surgery. The complexities and nuances underling "big data" can now be unearthed with complex visual network models than can be rotated at will. Anyone can learn geography by zooming over the world via Google Earth to explore locations and cities. Individuals rely on car- or phone-based GPS visual navigation systems to move from point A to point B. Clearly, developing Gv abilities (or spatial thinking) is becoming simultaneously easier via technology, but also more demanding as humans must learn how to use and understand Gv graphic interface tools that present complex visual displays of multidimensional information.

Second, ever-increasing calls have been made to embed spatial thinking throughout the educational curriculum—"spatializing" the curriculum (Newcombe, 2013)—to raise the collective spatial intelligence of our children and youth (Hegarty, 2010; National Research Council, 2006). The extant research has demonstrated a significant link between spatial abilities and educational performance in the fields of science, technology, engineering, and mathematics (STEM; Buckley et al., 2017; Hegarty, 2010; Lubinski, 2010; Newcombe et al., 2013). Gv abilities and individuals with spatially oriented cognitive "tilts" (Lubinksi, 2010) are becoming increasingly valued by technologically advanced societies. More important, research has demonstrated that spatial abilities or strategies are malleable (National Research Council, 2006; Tzuriel & Egozi, 2010; Uttal, Meadow, et al., 2013; Uttal, Miller, & Newcombe, 2013).

Although many psychologists are important drivers of the renewed interest in an expanded notion of the conceptualization and measurement of Gv (e.g., Allen, 2003; Hegarty, 2010; Kyllonen & Chaiken, 2003; Kyllonen & Gluck, 2003; Lubinski, 2010; Uttal, Miller, et al., 2013; Wang et al., 2014), some of the more active research and conceptualizing are being driven by researchers in education (e.g., National Research Council, 2006; Yilmaz, 2009), cognitive neuroscience (e.g., Thompson, Slotnick, Burrage, & Kosslyn, 2009; Wolbers & Hegarty, 2010), and the STEM disciplines (Harle & Towns, 2010; Seery, Buckley, & Delahunty, 2015). Clearly the CHC model's "mind's eye" (Gv) is achieving more prominence, which needs to be supported with renewed research on yet to be identified well-supported additional narrow abilities and innovative measurement methods, particularly regarding large-scale and dynamic spatial abilities.[29]

Narrow Abilities within Gv

1. **Visualization (Vz): The ability to perceive complex patterns and mentally simulate how they might look when transformed (e.g., rotated, twisted, inverted, changed in size, partially obscured).* In the same way that induction (I) is central to Gf and language development (LD) is central to Gc, this is the core ability of Gv. It is also the Gv narrow ability that demonstrates the strongest relation with a general intelligence factor and typically the strongest loading on a well-defined broad Gv factor. These empirical characteristics of Vz most likely represent its greater degree of demand for relative cognitive complexity (compared to other Gv narrow abilities), as Vz tasks require more complicated, multistep mental transformations of the

stimuli (Lohman, 1988; Yilmaz, 2009). Almost all studies showing that Gv has predictive validity in forecasting important outcomes use measures of visualization as a proxy for broad Gv.

2. **Speeded rotation (SR): The ability to solve problems quickly by using mental rotation of simple images.* Whereas visualization is more about the difficulty of visualizing and rotating an image, speeded rotation is distinct because has more to do with the speed at which mental rotation tasks can be completed. Speeded rotation tasks typically involve simple images that can be rotated. For example, a speeded rotation test might consist of an array of letters rotated from 1 to 360 degrees. After mentally rotating the letters to an upright position, the examinee would discover that half of the letters are backward. The test measures the speed at which the correctly oriented letters can be distinguished from the backward letters.

3. **Imagery (IM):*[30] *The ability to voluntarily mentally produce very vivid images of objects, people, or events that are not actually present.* Factor evidence has indicated that visual imagery is a factor separate from visualization and other narrow Gv constructs (Burton & Fogarty, 2003). Research has suggested that mental imagery is likely to be important for a variety of skilled professions, such as surgery, the study of human anatomy, and piloting an airplane (Thompson et al., 2009). In our 2012 chapter, we proclaimed our belief "that imagery is a promising CHC ability warranting more theoretical and psychometric research attention. We would not be surprised to see multiple imagery abilities validated. More importantly, if psychometrically well-developed practical imagery measures can be constructed, there is a good chance that they will be found to have diagnostic or predictive importance in select educational and occupational domains" (Schneider & McGrew, 2012, p. 130). Although interest in imagery as a mental ability has spanned thousands of years, serious empirical work has not been done until the last 30–40 years (Pearson, 2014). Our positive assessment of the imagery ability has not been matched by significant structural evidence studies that have produced a better understanding of imagery and its place in CHC theory.

However, we remain steadfast in our belief in the eventual emergence of the importance of visual imagery ability and new measures based on promising substantive and methodological neurocognitive research (Ganis & Schendan, 2011; Pearson, 2014). Brain imaging studies have suggested that visual–spatial imagery may not be a single faculty; rather, "visualizing spatial location and mentally transforming locating rely on distinct neural networks" (Thompson et al., 2009, p. 1245). This research suggests a distinction between transformational process versus processing and memory for location substructure. An objective versus spatial imagery dichotomy has also been suggested (see Thompson et al., 2009), as well as the possibility of quality versus speed of imagery abilities (Burton & Fogarty, 2003).

4. *Flexibility of closure (CF): The ability to identify a visual figure or pattern embedded in a complex distracting or disguised visual pattern or array, when one knows in advance what the pattern is.* This factor is primarily defined by hidden-figures tests (e.g., examinees find simple figures embedded in complex backgrounds). This ability is often called *field independence* or *disembedding* by other researchers (Velez, Silver, & Tremaine, 2005). Horn (1980) considered this type of test to be the best marker of Gv, probably because it correlates less with Gf than do many visualization tests. We were unable to locate any well-designed validity studies demonstrating any outcome that flexibility of closure could predict beyond *g* or Gv. Although Carroll (1993) included CF in his model, he admitted that "the psychometric evidence for the factor is somewhat ambiguous" (p. 338).

5. *Closure speed (CS): The ability to quickly identify and access a familiar, meaningful visual object stored in long-term memory from incomplete or obscured (e.g., vague, partially obscured, disguised, disconnected) visual cues of the object, without knowing in advance what the object is.* This ability is sometimes called *gestalt perception* because it requires people to "fill in" unseen or missing parts of an image to visualize a single percept. The term *speed* does not mean speed in the classic psychometric sense, but more the mental ease or fluency of completing these tasks.[31] It is not clear that this measure specifically predicts any important life outcomes, once its associations with Gv and *g* are accounted for (Campbell & Catano, 2004). We speculate that the recall of a stored object may suggest that CS may in part represent a store of acquired Gv knowledge.

6. *Visual memory (MV): The ability to remember complex images over short periods of time (less than 30 seconds).* The tasks that define this factor involve being shown complex images and then identifying them soon after the stimulus is removed. MV is not to be confused with visual working

memory. When the stimuli in a task are simple, are numerous, and must be remembered in sequence, it becomes more of a Gwm test than a Gv test. The extent to which verbal mediation (Gc) can be employed on a specific visual memory test is important, as Carroll (1993) noted that "there is good though not abundant evidence for a visual memory factor controlling performance on tasks in which the subject must form and retain a mental image or representation of a visual configuration that is not readily encodable in some other modality" (p. 284). Also, Carroll noted that he was not aware of "any research on the usefulness of visual memory tasks in predicting educational or occupational success" (p. 284). We also have not uncovered any new convincing evidence that contradicts Carroll's judgment.

7. *Spatial scanning (SS): The ability to quickly and accurately survey (visually explore) a wide or complicated spatial field or pattern with multiple obstacles, and identify a target configuration or identify a path through the field to a target endpoint.* This factor is defined by performance on paper-and-pencil maze tasks. It is not clear whether this ability is related to complex, large-scale, real-world navigation skills.

8. *Serial perceptual integration (PI): The ability to recognize an object after only parts of it are shown in rapid succession.* Imagine that a deer is walking behind some trees, and that only a part of the deer can be seen at one time. Recognizing that this is a deer is an example of what this ability allows people to do. It is certain that this ability exists, but it is not yet certain whether individual differences in this specific ability confer any special advantages or disadvantages.

9. *Length estimation (LE): The ability to visually estimate the length of objects (without using measuring instruments).* Intuitively, this ability seems rather useful, but we could not locate any well-designed studies that have demonstrated an association of this ability with any important outcome.

10. *Perceptual illusions (IL): The ability not to be fooled by visual illusions.* It is unclear why this ability might be useful to a clinician. We could not locate any well-designed studies showing that this distinct ability is associated with any important outcome.

11. *Perceptual alternations (PN): Consistency in the rate of alternating between different visual perceptions.* It is also unclear why this ability might be useful. We could not locate any well-designed studies showing that this distinct ability is associated with any important outcome.

12. *Perceptual speed (P): The speed and fluency with which similarities or differences in visual stimuli can be distinguished.* This intermediate-stratum ability is primarily considered a Gs ability (see our discussion of Gs, above) and has not been included under Gv in all contemporary CHC definitions with a genetic heritage in McGrew (1997). However, Carroll (1993) listed and discussed P under both Gs and Gv.[32] We believe that P (and Ps and Pc) needs to be resurrected under Gs (as defined by Carroll), as various perceptual speed tests (which vary in type of visual stimulus content and required mental process—e.g., search, comparisons, matching) may include small but significant portions of Gv variance that have been ignored in contemporary CHC test classifications because of this omission.[33]

Assessment Recommendations for Gv

Adequate measurement of Gv should always include measures of visualization. If a visualization test utilizes manipulatives, it is important for it to minimize motor requirements (Gp, Gps). The physical manipulation of objects is not required to measure "in the mind's eye" visualization (see, e.g., the WJ IV Visualization test). If speeded tasks are used, they should be balanced by the inclusion of unspeeded tasks. The narrow abilities associated with Gv tend to have very low correlations, and thus one should expect uneven Gv test score profiles.

We are unaware of any psychometrically sound commercially available tests of visual mental imagery. Most measures of imagery (visual as well as other modalities) have been in the form of rather dated self-report questionnaires (Ernest, 1977), such as the Vividness of Visual Imagery Questionnaire (Marks, 1973) and the Questionnaire upon Mental Imagery (Betts, 1909). Research that has compared mental visual imagery self-reports to tests of Gv and experimental cognitive measures of quality and efficiency of image generation have found no significant relations (Poltrock & Brown, 1984).

Comments and Unresolved Issues Related to Gv

- *Is visualization part of Gf?* This question remains unanswered since our 2012 chapter. In many factor-analytic studies, Gf is defined in part by tests considered to measure visualization (e.g., Woodcock, 1990). In Carroll's (1993) analyses, visualization tests often loaded on both Gf and Gv, and about a third of the time the loadings were higher on Gf. What might be happening? Studies of visualization tests suggest that people use a variety of strategies on spatial tests (Gluck & Fitting, 2003; Hegarty, 2010; Kyllonen, Lohman, & Woltz, 1984). Hegarty (2010) has classified these strategies broadly as either using mental imagery (e.g., on the Paper Folding Test, "I imagined folding the paper, punching the hole, and unfolding the paper in my mind") or analytic strategies (e.g., "I used the number of holes/folds to eliminate some of the answer choices"). We believe that the Gv loadings for visualization tests occur because many people use imagery to complete the tests some of the time, and that the Gf loadings occur because logical/analytic strategies are also employed by some people. Furthermore, Kyllonen and colleagues (1984) found that the best performers on visualization tests were flexible in their strategy use, adapting to the task demands of a particular item. This kind of judgment is invariably associated with Gf.

- *Do large-scale spatial navigation abilities belong with Gv?* Based on our brief review above of the emerging Gv literature, we offer a tentative "yes" to this question. Large-scale spatial abilities and navigation are becoming increasingly important. This set of abilities is clearly distinct from traditional small-scale spatial abilities and measures. Tests of large-scale spatial abilities are not readily available, largely due to the historical use of paper-and-pencil or intelligence-test-like tests in the Gv research literature. With continued rapid developments in computer graphics, virtual-reality software, and hand-held technology, it is time for researchers and test developers to focus on developing new practical and clinically useful measures of large-scale spatial navigation abilities. Concurrently, the possible inclusion of these abilities in the CHC taxonomy, and their relationship to the currently identified Gv abilities (which are all static measures), need to be established through a series of CHC-designed factor-analytic studies.

- *Do dynamic spatial abilities belong with Gv?* Possibly. Like large-scale spatial abilities, the ability to comprehend visual movements is becoming more important in an increasingly complex world immersed in visual-graphic-based technology. But first research is needed to determine if what are labeled dynamic spatial abilities represent true spatial competencies, or, alternatively, if they represent a nonspatial (temporal) processing ability.

- *Do other Gv narrow abilities exist?* Of course. As with all CHC domains, the validated narrow abilities in the current taxonomy are largely the result of bottom-up programs of research predicated on developing tests for practical purposes (e.g., prediction, diagnosis). Recent conceptualizations of Gv as a broader spatial thinking construct; the dynamic versus spatial and large-scale versus small-scale conceptualizations; and other functional family conceptualizations of Gv abilities are opening a potential Pandora's box of hypothesized new Gv narrow abilities. For example, Buckley and colleagues (2017) have proposed a comprehensive Gv taxonomy that includes the current Gv abilities and posits 16 potential new narrow abilities based on either theory or research, some previously reviewed by Carroll (1993). These possible new narrow abilities are related to classic spatial tasks (spatial orientation); imagery (quality and speed); illusions (shape and direction, size contrast, overestimation and underestimation, frame of reference); judgments (direction, speed, movement); and dynamic versions of current Gv abilities (visual memory, serial perceptual integration, spatial scanning, perceptual alternations).

These new Gv conceptualizations are welcomed, but they must be studied with serious caution. All new candidates for Gv abilities will need to be validated with well-conceptualized structural validity research (see "Criteria for Updating CHC Theory," above). Also, if new Gv abilities are identified, it is important to determine whether they have any practical use or validity. An instructive example is a recent CFA CHC-designed study that provided preliminary support for a narrow ability of face recognition (called *face identification recognition* by the researchers), distinct from other Gv and CHC abilities (Gignac, Shankaralingam, Walker, & Kilpatrick, 2016). The face recognition ability may have practical usefulness, as it could facilitate measurement and research regarding the phenomenon of *prosopagnosia* (in which a cognitively capable individual is completely unable to recognize familiar faces). Although it is important to guard against premature hardening of the CHC categories (McGrew, 2005; Schneider & McGrew, 2012), we believe that even greater due diligence is necessary to prevent premature proliferation of new entries in the Gv domain in the CHC model. We don't want to be at a place soon where formal START negotiations (STrategic Ability Reduction Talks) are necessary to halt unsupported speculation about and proliferation of Gv abilities.

Is it possible to solve the "Gv mystery"? In their review of the extant CHC–achievement relations research, McGrew and Wendling (2010) found a lack of consistent relations between Gv tests on the major intelligence batteries and math achievement, while other bodies of research have consistently linked visual–spatial ability with math performance. This situation constitutes the "Gv mystery." Aside from several research methodology issues, McGrew and Wendling suggested that the specific Gv abilities measured by most intelligence tests may be "threshold" abilities (after a certain minimum level of competency, the Gv ability no longer contributes to math achievement). Given the above-referenced research that has demonstrated a consistent relation between Gv abilities (or broader notions of Gv such as spatial thinking or spatial intelligence) and performance in STEM fields, we believe that most of the mystery lies in the limitations of traditional Gv test formats. The Gv or spatial thinking discussed in the context of the STEM disciplines is, in our opinion, "Gv on steroids" compared to the abilities measured by current spatial tests in intelligence batteries. The Gv required for high math (or STEM) performance is likely to be that associated with more complex visual thought systems employed by the likes of Einstein. Perhaps Hegarty's (2010) exploration of spatial abilities "in the wild"—via the analysis of the performance of experts in different spatially based knowledge domains, to better understand their cognitive struggles and the processes they use—can produce enhanced Gv measures. Other innovative approaches to measuring Gv abilities should be incorporated in the design of the next generation of Gv tests (Jelínek, Kveton, & Voboril, 2015; Lee & Bednarz, 2012; Thissen, Koch, Becker, & Spinath, 2016). With readily available hand-held technology and portable computers for delivering test content, we believe it is now possible for researchers and test developers to harness this technology to develop measures of the elements of, and totality of, more complex Gv abilities required from success in the STEM disciplines.

- *What about spatial language (Gkn or Gc-spatial)?* As individuals explore their environments, "they build up spatial knowledge based on visual, idiothetic, and other sensory information" (Warren, Rothman, Schnapp, & Ericson, 2017, p. 152). Considerable research has revealed a relation between children's production of, and the number of, spatial words in their lexicons (e.g., *left, right, middle, on top*) and spatial ability. This has been interpreted as suggesting that children verbally encode relevant spatial information that supports performance on spatial tasks (Miller, Vlach, & Simmering, 2017). The direction of this relationship (high verbal or Gc/Gkn affects Gv performance; high Gv ability increases spatial Gc/Gkn; spatial Gc/Gkn and Gv are influenced by other variables) is unknown. Research is needed to explore these relationships and, if appropriate, to develop measures of acquired Gv knowledge, which could include spatial knowledge or vocabulary as well as learned spatial strategies. The distinction between Gv processes and Gv knowledge is consistent with the intelligence-as-process and intelligence-as-knowledge components of Ackerman's PPIK theory of intelligence.

- *Is our courtship of the imagery ability (IM) nothing more than a teenage crush, or will it eventually represent a new, mature Gv relationship?* Clearly, given our past and current treatments of this narrow ability, we believe that imagery is next in line to receive a promotion in the Gv hierarchy. Our IM crush stems in part from the encouraging neurocognitive research on mental imagery. Our IM romance is fed in large part by new interdisciplinary research on human imagination that is integrating research regarding CHC-like abilities (perceptual and motor-related mental imagery—visual imagery, mental rotation, auditory imagery, musical imagery, motor imagery), intentionality or recollective processing, novel combinatorial or generative processing, and emotion within a cognitive neuroscience brain network context (Abraham, 2016).[34] New psychometric research is necessary to better understand the nature of the IM ability in the CHC taxonomy.

Auditory Processing (Ga)

Definition of Ga

Auditory processing (Ga) is the "ability to discriminate, remember, reason, and work creatively (on) auditory stimuli, which may consist of tones, environmental sounds, and speech units" (Conzelmann & Süß, 2015, p. 28). Yes, we have borrowed and directly quoted a contemporary source for a revised definition of Ga. We previously defined auditory processing "as the ability to detect and process meaningful nonverbal information in sound" (Schneider & McGrew, 2012, p. 131). As we noted at the time, "this definition is bound to cause confusion because we do not have a well-developed vocabulary for talking about sound unless we are talking about speech sounds or music" (p. 131). We were correct, but the source of confusion was unanticipated. The previous definition seemed to confuse many assessment professionals because of the negative transfer of the historical traditional meaning of *nonverbal,* which many associate with nonverbally assessed abilities such as Gv and Gf on the Wechslers. Conzelmann and Suß (2015), after a review of the major definitions of auditory abilities and auditory intelligence (including the primary-source Ga studies of Horn and Stankov), have a much better handle on a more understandable definition of Ga, which we now use here.

There are multiple misconceptions regarding Ga. First, although Ga depends on sensory input via the momentary perturbations of air pressure in our ears, it is not sensory input itself. Ga is what the brain does with sensory information from the ear, sometimes long after a sound has been heard (e.g., after he became deaf, Beethoven composed some of his best work by imagining how sounds would blend). The second common misconception, even among professionals, is that Ga is oral or verbal language comprehension. It is true that one aspect of Ga (parsing speech sounds, or phonetic coding) is related to oral language comprehension—but this is simply a precursor to comprehension, not comprehension itself (in the same way that adequate vision is a prerequisite for playing tennis, but vision is not normally thought of as a tennis skill). This distinction was made by Carroll (1993) and recently reinforced by Conzelmann and Suß (2015), who noted that in oral or verbal comprehension tasks the entirety of the comprehension process is relevant, not just the processing of tones or speech units. Third, as also articulated by Carroll, musical comprehension, ability, aptitude, or expertise is not included in Ga, as in musical abilities the whole sequence (melody) is considered and needs to be comprehended. Certain Ga narrow abilities are important to the development of musical abilities or aptitude (e.g., maintaining and judging rhythm)—but just as mathematical aptitude (which probably requires certain Gf, Gv, and Gwm abilities and certain noncognitive characteristics) is not considered a CHC factor-based ability, musical ability, aptitude, or expertise is an amalgam of cognitive and noncognitive characteristics and should not be listed as a CHC narrow ability.

Ga has long been the Rodney Dangerfield ("I don't get no respect")[35] of CHC abilities and is often considered the "secondary" sense behind Gv (Lotto & Holt, 2011). Its second-class status is reflected in Ga's not being included in many models of intelligence and in its absence from all major individually administered intelligence batteries (save the Woodcock–Johnson series; Conzelmann & Suß, 2015). This Ga neglect is partially understandable, given that the construct has historically received much less attention than Gv abilities, in part due to the lack of reliable and valid technology for measuring Ga abilities. Ga was the least studied factor in Carroll's (1993) treatise.

This neglect is no longer scientifically sustainable. Ga serves the important function of providing perceptual and cognitive scaffolding ("auditory scaffolding") for many temporally based higher-order cognitive functions such as language (Conway, Pisoni, & Kronenberger, 2009). Ga abilities play important roles in such diverse activities as conversations, performance bottlenecks (e.g., driving a car), navigating in the dark, musical performance, foreign-language acquisition, and understanding of reading and language disorders (Conzelmann & Süß, 2015). Ga requires considerable complex perceptual–cognitive processing (e.g., attention, localization, memory, segmentation, categorization, and pattern recognition) of multiple competing, transient, and temporally ordered brief sound waves (Lotto & Holt, 2011). Clearly, Ga-related abilities are critically involved in many important human functions. Ga requires multiple cognitive processing mechanisms that are equal to, and in many cases more complex than, those involved in many Gv abilities.

These conclusions have been reinforced by a systematic program of research by Rammsayer and colleagues (Haldemann, Stauffer, Troche, & Rammsayer, 2012; Helmbold, Troche, & Rammsayer, 2006, 2007; Pahud, 2017; Rammsayer & Brandler, 2004, 2007; Rammsayer & Troche, 2016), which has demonstrated that a temporal *g*-factor demonstrates higher correlations with a psychometric *g* factor than does a classic Jensen RT *g* factor. These researchers have consistently demonstrated that temporal *g* (which they refer to as the *temporal resolution power* [TRP] hypothesis of the central nervous system) may be a causal factor for speed of information processing (reaction time *g*), which in turn affects general intelligence. Given that sound is inherently a temporal and sequential signal (Conway et al., 2009; Conzelmann & Süß, 2015; Kraus & Slater, 2016; Lotto & Holt, 2011; Pahud, 2017; Slevc, 2012; Tallal, 2004), the impressive TRP findings demand that intelligence scholars and test developers recognize the importance of Ga. This position is also supported by analysis of the only major intelligence test battery that adequately represents Ga. In the WJ III and WJ IV Cognitive batteries, the Ga cluster loaded higher than the Gv cluster on a single *g* factor extracted from the seven CHC broad cluster scores across the entire age range of the two norm samples (Ga = .72/.78; Gv = .66/.68).[36] Ga abilities should be integral to theories of intelligence and cognitive assessment, as "the ability of the auditory system to segregate, locate, and categorize events in the environment is a *remarkable accomplishment* given the complexity and transient nature of sound waves" (Lotto & Holt, 2011, p. 479; emphasis added).

The importance of Ga is now recognized by an ever-widening range of research in psychology, psychometric studies of intelligence, neuropsychology, and cognitive neuroscience (Conway et al., 2009; Conzelmann & Süß, 2015; Kraus & Slater, 2016; Lotto & Holt, 2011; Pahud, 2017; Rammsayer & Brandler, 2007; Slevc, 2012; Wolff & Gustafsson, 2015). Unfortunately, this embarrassment of riches has yet to be organized into a coherent interdisciplinary framework (or frameworks). One of the most important factor-based studies (since our 2012 chapter, which informs the current chapter) has been the Conzelmann and Suß (2015) study, which suggests that the description of Ga abilities could benefit from an auditory-*nonverbal* (e.g., tones, environmental sounds) and auditory-*speech* (e.g., language-related sound units) content facet distinction.

Narrow Abilities within Ga

The following Ga abilities are classified as auditory-*speech* abilities:

1. **Phonetic coding (PC): The ability to distinctly hear phonemes, blend sounds into words, and segment words into parts, sounds, or phonemes.*[37] This ability is also referred to as *phonological processing*, *phonological awareness*, and *phonemic awareness*.[38] People with poor phonetic coding have difficulty hearing the internal structure of sound in words. This makes sounding out unfamiliar words while reading difficult. Poor phonetic coding is one of the major risk factors in reading disorders, specifically phonological dyslexia. Most people, even with very low Ga, can understand speech and speak perfectly well without awareness of the distinct phonemes they are hearing and saying. What they lack is the ability to mentally separate phonemes and hear them in isolation.

Research continues to reinforce the prior conclusion (McGrew, 2005) that PC is a single dimension and is not multidimensional (Anthony, Lonigan, Driscoll, Phillips, & Burgess, 2003; Nelson, Lindstrom, Lindstrom, & Denis, 2012; Wolff & Gustafsson, 2015). Of interest is the recent finding that, aside from different PC measures' being differentiated primarily along a single developmental psychological sensitivity dimension (Pufpaff, 2009), PC tasks can probably be differentiated in terms of two facets—*linguistic* (phoneme/syllable vs. morpheme) and *cognitive complexity* (blending/segmentation vs. manipulation) (Wolff & Gustafsson, 2015).

2. *Speech sound discrimination (US): The ability to detect and discriminate differences in speech sounds (other than phonemes) under conditions of little or no distraction or distortion.* The definition of this factor has been narrowed to nonphonemic aspects of speech sounds, to make it more distinct from phonetic coding. People who have poor speech sound discrimination are less able to distinguish variations in tone, timbre, and pitch in speech; this might reduce their ability to detect subtle emotional changes, or subtle changes in meaning due to differential emphasis.

3. *Resistance to auditory stimulus distortion (UR): The ability to hear words or extended speech passages correctly under conditions of distortion or background noise.* It is not yet clear to what degree this ability depends on sensory acuity. As people age, they tend to complain that they have greater difficulty understanding speech in noisy public places or on a telephone with background noise. Speaking louder usually helps them understand better.

The following Ga abilities are classified as auditory-*nonverbal* abilities:

4. **Maintaining and judging rhythm (U8): The ability to recognize and maintain a musical beat.* This may be an aspect of memory for sound patterns, as short-term memory is clearly involved. However, it is likely that something different about rhythm warrants a distinction. Important research has occurred regarding this ability since our prior chapter, pieces of which are mentioned later.

5. *Memory for sound patterns (UM): The ability to retain (on a short-term basis) auditory events such as tones, tonal patterns, voices, or speech sounds.*[39] This ability is important for musicians, who need to be able to hold in mind a musical phrase they hear so that they can reproduce it later.

6. *Musical discrimination and judgment (U1 U9): The ability to discriminate and judge tonal patterns in music with respect to melodic, harmonic, and expressive aspects (phrasing, tempo, harmonic complexity, intensity variations).*

7. *Absolute pitch (UP): The ability to perfectly identify the pitch of tones.* As a historical tidbit, John Carroll had perfect pitch.

8. *Sound localization (UL): The ability to localize heard sounds in space.*

Assessment Recommendations for Ga

Ga is unusual in CHC theory, in that psychologists have been more interested in a narrow ability (phonetic coding, PC) than in the broad ability (Ga). We believe that this focus on phonetic coding will be changing shortly. Other Ga abilities are clearly related to musical achievement and are priorities if one is attempting to assess musical aptitude, or assess impairment for a brain-injured musician. Based on the continuing explosion of interdisciplinary Ga research, we believe that several Ga abilities (and emerging abilities) warrant more attention from test developers and eventually from assessment professionals. Measures of maintaining and judging rhythm (U8) and temporal processing (temporal *g*; TRP) need to find their way into test development and assessment practices. These new assessment possibilities are briefly highlighted below.

Comments and Unresolved Issues Related to Ga

- *The CHC home of temporal tracking (UK; Carroll, 1993) is still undetermined. Does it belong under Ga or Gwm?* Previously, this factor was listed as part of Ga. *Temporal tracking* was defined as the ability to mentally track auditory temporal (sequential) events to be able to count, anticipate, or rearrange them (e.g., to reorder a set of musical tones). This factor is measured by tests that require simultaneous storage and processing; thus it appears that such tests are methods of measuring attentional control within working memory capacity (Stankov, 2000).[40]

- *Can the assessment of phonetic coding (PC) be improved?* Yes. We believe that the facets of linguistic and cognitive complexity identified by Wolff and Gustafsson (2015) should be incorporated into the design and interpretation of new and existing measures of PC.

- *Did the removal of Carroll's (1993) hearing speech threshold (UA UT UU), sound-frequency discrimination (U5), sound-intensity/duration discrimination (U6), and general sound discrimination (U3) factors from the CHC model (in our 2012 chapter) make sense?* Based on the absence of anyone's crying "foul" because of our recommendation, we believe this recommendation is solid. These are sensory acuity factors that are outside the scope of CHC theory.

- *Can intelligence researchers and applied test developers catch the beat and develop psychometrically sound measures of maintaining and judging rhythm?* Researchers at the Northwestern Auditory Neuroscience Lab[41] have published a series of studies that demonstrate significant relations between measures of beat synchronization (i.e., the coordination of movement with a pacing sound or metronome) and evoked auditory brainstem response, neural coding of speech, psychometric indicators of reading and language development, and specific reading and language disorders in children (Carr, Fitzroy, Tierney, White-Schwoch, & Kraus, 2017; Carr, White-Schwoch, Tierney, Strait, & Kraus, 2014; Tierney, White-Schwoch, MacLean, & Kraus, 2017). Timing or temporal processing has also been linked to mathematics achievement in children (Tobia, Rinaldi, & Marzocchi, 2016). In adults, a battery of rhythm tests suggested two rhythm factors (sequencing and synchronization) that also showed significant relations with measures of brain function and verbal memory and reading (Tierney et al., 2017). We predict that practical measures of beat or rhythm production and synchronization will be part of a coming wave of new Ga-based psychometric tests.

- *It is "time" that intelligence researchers and applied test developers recognize the importance of brain clock timing mechanisms (temporal g, TPR) and develop practical measures of temporal processing and other abilities related to mental timing—which are typically administered via the auditory modality.* Given today's relatively low-cost and portable technology platforms, and a plethora of existing temporal (auditory-based) test prototypes employed in research settings (e.g., see Conzelmann & Suß, 2015—detection of repeated tones, tonal series, tonal analogies, rhythm production, recognition of familiar environmental sounds; also see Rammsayer & Brandler, 2007—rhythm perception, temporal-order judgment, auditory flutter fusion, duration discrimination, temporal generalization), the stage is set for a long-overdue tsunami of temporal test development.

Olfactory Abilities (Go)

Definition of Go

Olfactory abilities (Go) can be defined as the abilities to detect and process meaningful information in odors. Go refers not to sensitivity of the olfactory system, but to the cognition one does with whatever information the olfactory system sends via its dual-model detection system (i.e., sniffing via the external nostrils, and detecting odors arising from within the mouth via the nasopharynx) (Stevenson, 2013).

Although olfaction is the most ancient of the human senses, it is one of the least studied in relation to the practice of psychological assessment. However, odors are a big-money business. The perfume and fragrance industries invest billions of dollars in the identification of various nuances of pleasant odors. The food and beverage industries pay significant attention to the olfactory characteristics of their products. At a more primitive evolutionary level, invertebrates have evolved Go systems over time to perform three primary functions: (1) learning olfactory cues that signal nutrients or toxins when eating and drinking; (2) detecting environmental hazards, such as predators or chemical cues to diseases; and (3) the transmission of social information (Stevenson, 2013). Many of these functions are no longer evolutionarily critical to humans.

Research suggests an attentional component to olfaction. People can voluntarily selectively attend to odors in the environment, and often are involuntarily and unpleasantly forced to attend to smells in the environment (e.g., detecting the smell of natural gas or rotting food) (Stevenson, 2013). Perhaps a narrow ability of olfactory attention (OA?) will be validated in the future. Also, Engen (1982) has suggested that "Functionally, smell may be to emotion what sight or hearing are to cognition" (p. 3). Consistent with this view is research suggesting that different words have consistently been linked to different odors, with unpleasant terms outnumbering pleasant terms (Stevenson, 2013). Perhaps Gei (broad emotional intelligence) may include a narrow olfactory emotion recognition (OER?) ability. Perhaps not. Researchers willing to sniff around this topic will help answer this question.

Clearly, the Go domain includes more narrow abilities than currently listed in the CHC model. In addition to the possibilities mentioned above, a cursory skim of Go-related literature reveals reference to such abilities as olfactory memory, episodic odor memory, olfactory sensitivity, odor-specific abilities, odor identification and detection, odor naming, and olfactory imagery, to name but a few. Among the reasons why the Minnesota Multiphasic Personality Inventory has items about "peculiar odors" are that distorted and hallucinatory olfaction is a common early symptom of schizophrenia, and that poor olfaction is an associated characteristic of a wide variety of brain injuries, diseases, and disorders (Doty, 2001; Dulay, Gesteland, Shear, Ritchey, & Frank, 2008).

For Go skeptics who dislike the scent of Go's being included in CHC theory, contemporary research is increasingly suggesting that olfactory dysfunction often acts as a "canary in the coal mine" for neurological insult or decline. Olfactory dysfunction has been associated with a wide variety of disorders, including ALS, Alzheimer disease, bipolar disorder, depression, epilepsy, HIV, dementia, Huntington disease, Kallmann syndrome, motor neuron disease, multiple sclerosis, neuromyelitis optica, obsessive–compulsive disorder, Parkinson disease, and schizophrenia (Joseph & DeLuca, 2016; Martzke, Kopala, & Good, 1997; Stevenson, 2013), although some of this research has been contradictory for specific disorders (e.g., bipolar disorder, depression, epilepsy, multiple sclerosis). The most important practical implication is that impaired olfactory functioning (Go) may be a marker of disease progression (Martzke et al., 1997).

Narrow Abilities within Go

1. *Olfactory memory (OM) is the ability to recognize previously encountered distinctive odors.* The oft-noted experience of smelling a distinctive smell and being flooded with vivid memories of the last time this odor was encountered does have some basis in research. Memory for distinctive odors has a much flatter forgetting curve than many other kinds of memory (Danthiir, Roberts, Pallier, & Stankov, 2001).

Assessment Recommendations for Go

Most practical and clinical applications of smell tests are sensory acuity tests. People who work where gas leaks must be tested regularly to make sure that they can make potentially life-saving odor detections. The most common olfactory tasks used in research are olfactory acuity, identification, discrimination, recognition, and memory (Martzke et al., 1997). The University of Pennsylvania Smell Identification Test (UPSIT),[42] originally developed by Doty, Shaman, and Dann (1984), is the most recognized commercially available test of olfactory functioning (Doty, 2001). Another recent entry in the olfactory testing field is the “Sniffin’ Sticks” test, which consists of tests of odor threshold, discrimination, and identification (Hummel, Kobal, Gudziol, & Mackay-Sim, 2007). We are unable to make specific recommendations regarding the use of these tests in psychological assessment, as we are unaware of any well-designed factor-analytic studies of these measures, particularly within the CHC framework.[43] Such research is encouraged.

Comments and Unresolved Issues Related to Go

- *Are there separate short-term and long-term OM abilities, or are they part of a common single memory system?* Research regarding this question is inconclusive (Stevenson, 2013).
- *Is there a working memory for odor?* Jönsson, Møller, and Olsson (2011) demonstrated that olfactory stimuli could be retained in a short-term memory store and that this store could be continuously updated. However, they found it difficult to disentangle the influence of an individual’s odor discrimination and verbalization abilities during the task (Danthiir et al., 2001). Jönsson and colleagues concluded: “Altogether, the present study demonstrates the ability to maintain information about odorants online, updating this information in service of correctly matching odors in a series to previously presented ones. This is true for nameable odors, but also, to a lesser degree, for odors that are notoriously difficult to name. This is in line with the notion of a separate olfactory slave system, but it is premature to draw firm conclusions at this point” (p. 1030).
- *Is odor naming (ON?) a narrow ability?* If so, like face naming, is poor odor naming partially dependent on visual and verbal contextual cues? Is odor naming dependent on a different set of retrieval fluency (Gr) abilities from those associated with naming ability and retrieval fluency? Does the ability to name odors suggest a separate odor knowledge ability (OK?) and odor retrieval fluency ability (OR?)? One of the most robust findings in olfactory research is the finding that people have difficulty naming odors and rarely correctly identify over 50% of familiar odors (Stevenson, 2013).
- *Is there such an ability as odor imagery (OI)?* Although imagery has been documented in both the visual and auditory systems, research regarding whether, in the absence of immediate presence in the environment, odors can be in the “mind’s nose” (Stevenson & Case, 2005) is confusing and inconclusive (Danthiir et al., 2001; Stevenson, 2013).
- *Do the studies indicating that measures of simple olfactory functions might be an “early warning system” for underlying neurocognitive disorders reflect real Go deficits, or are these deficits due to problems with other cognitive abilities required to perform these Go tasks? Is it possible to disentangle common cognitive abilities from measures of Go, or are Go abilities by nature dependent on cognitive abilities?* In a study of olfactory sensitivity, discrimination, and identification, Hedner, Larsson, Arnold, Zucco, and Hummel (2010) found that performance on common Go measures was influenced by the participants’ executive functioning and semantic and episodic memory.
- *Does olfactory sensitivity (OS) belong in CHC theory?* This is the ability to detect and discriminate differences in odors. That is, it is a sensory acuity factor, and we believe it is thus outside the scope of CHC theory.

We await innovations in measurement and well-designed studies that will answer these questions and help determine the taxonomy of Go-related cognitive abilities. Given the Go link to a wide variety of cognitively related disorders, we hope for future psychometric research in this area. Curious noses want to know.

Tactile Abilities (Gh)

Definition of Gh

Tactile abilities (Gh) can be defined as the abilities to detect and process meaningful information in haptic (touch) sensations. This domain includes perceiving, discriminating, and manipulating touch stimuli. Gh refers not to sensitivity of touch, but to the cognition one performs with tactile sensations. Because this domain is not yet well defined and understood, it is hard to describe authoritatively. We speculate that it will include such things as tactile visualization (object identification via palpation), localization (where has one been touched), memory (remembering where one has been touched), texture knowledge (naming surfaces and fabrics by touch), and many others. Tests of Gh have long been used in neuropsychological batteries because of their ability to detect brain injury, especially to the somatosensory cortex. Attempts to develop haptic-based assessment batteries have also been made for individuals who are blind or have severe visual disabilities (e.g., the Blind Learning Aptitude Test).

Much to the disdain of new parents, our initial explorations of the world as infants is filled with touching, grabbing, and sucking almost any object within immediate reach. The human sense of touch, be it with our hands or mouth, provides perceptual information regarding our immediate environment and serves as a primary foundation for the development of many concepts. The importance of touch permeates our discussion of learning, as "we often talk about 'grasping' an idea, 'getting a handle on' a problem, or being 'touched' by a reading" (Minogue & Jones, 2006, p. 317). Driven by recent technological developments—for instance, in robotics, 3D printers (making it possible to develop precise 3D stimuli), prosthetic limbs and hands, touch screen mobile devices, haptic feedback displays, technology to aid the visually impaired, the teleoperation of remote sensing or manipulation devices (e.g., telesurgery, use of remote drones), and virtual-reality-based training and simulation (e.g., training of surgeons)—interest and research in tactile or haptic abilities are increasing (Kappers & Bergmann Tiest, 2013).

Circumscribing the emerging research on haptic perception is beyond the scope of this chapter. Haptic perceptual characteristics include material properties (e.g., roughness, compliance, viscosity, friction, temperature, density, and weight) and spatial properties (e.g., shape, curvature, length, volume, and orientation), as well as quantitative properties such as numerosity (Kappers & Bergmann Tiest, 2013). A complete understanding of haptic perception requires an understanding of the peripheral sensory receptors (in the skin, muscles, tendons, and joints); of research that has identified two channels of haptic perception ("what" and "where"); and of other issues such as vision–touch interactions, affective touch, and neural plasticity (Lederman & Klatzky, 2009). Furthermore, consumer psychologists have learned that some individuals have a "need for touch" (Peck & Childers, 2003) when evaluating products to counter common visual misperceptions (some scientists refer to touch as the "reality sense"; Nuszbaum, Voss, Klauer, & Betsch, 2010). The implications of touch for cognition are recognized by many educators who advocate the use of "hands-on" instruction (see Minogue & Jones, 2006, for emerging educational applications of haptic sensations).

Narrow Abilities within Gh

Despite the recent increase and variety of haptic perception research and applications, the limited structural evidence research does not allow us to articulate a more nuanced version of the fundamental factors of haptic abilities than the one outlined in our 2012 chapter. In other words, there are as yet no well-supported cognitive ability factors within Gh. Although Stankov, Seizova-Cajic, and Roberts (2001) identified a narrow tactile sensitivity (TS) factor, this is a sensory ability (i.e., the ability to make fine discriminations in haptic sensations) and not a cognitive ability. For example, if two caliper points are placed on the skin simultaneously, we perceive them as a single point if they are close together. Some people can make finer discriminations than others. The very narrow TS factor was found to be minimally related to higher-level broad CHC abilities (Gf, Gv, Ga; Stankov et al., 2001). Two new (or previously overlooked) Gh structural evidence studies summarized below were either inconclusive or based on samples too small to suggest revisions to the Gh domain.

In a factor study of the tactile measures from the Dean–Woodcock Sensory Motor Battery and CHC measures with a co-normed cognitive battery of measures representative of the CHC model of intelligence, Decker (2010) found that the Palm Writing and Object Identification tests did not form a distinct Gh factor and either loaded on a processing speed (Gs) factor or were factorially complex (Gs and Gv). Ballesteros, Bardisa, Millar, and Reales (2005) investigated the psychometric characteristics, including factor-analytic structure, of a psychological test battery designed to measure the perceptual and cognitive abilities of children with visual handicaps. The 20-test battery materials consist of raised-dot, raised-surface shapes and displays, and familiar and novel 3D objects requiring active touch. In a small sample, exploratory factor analysis identified six factors—spatial comprehension, short-term memory, object identification, shape identification efficient exploration, material and texture discrimination. Given the small sample size and the lack of other CHC ability indicators, the Ballesteros and colleagues study can only be considered a suggestive first step in the exploration of the structural nature of Gh.

Assessment Recommendations for Gh

Most practical and clinical applications of Gh tests actually use sensory acuity tests. There are currently no available tests of higher-order Gh processes that are clearly distinct from Gv or Gs. The Halstead–Reitan Neuropsychological Test Battery and the Dean–Woodcock Neuropsychological Battery include several Gh tests.

Comments and Unresolved Issues Related to Gh

- *How is Gh to be distinguished from Gv and Gf?* Two well-designed studies (Roberts, Stankov, Pallier, & Dolph, 1997; Stankov et al., 2001) found it difficult to distinguish between complex tests assumed to measure Gh and well-defined markers of Gv and Gf. Why might this be so? If a test involves identifying common objects (coins, keys, books, etc.) by handling them while blindfolded, the examinee is essentially using the hands instead of the eyes to visualize an object in the "mind's eyes."
- *What about "dynamic touch"?* Do abilities from the Gh and kinesthetic (Gk) domains combine to reflect individual differences in dynamic touch (Stankov et al., 2001; Turvey, 1996)?
- *Like the presence of imagery in vision and auditory abilities, does some form of haptic imagery ability exist? If so, what role would it play in Gh abilities?*

Kinesthetic Abilities (Gk)

Definition of Gk

Kinesthetic abilities (Gk) are defined as the abilities to detect and process meaningful information in proprioceptive sensations. The term *proprioception* refers to the ability to detect limb position and movement via proprioceptors (sensory organs in muscles and ligaments that detect stretching). Gk refers not to the sensitivity of proprioception, but to the cognition one does with proprioceptive sensations. Because this ability is not yet well understood, and because we have not located any significant new structural evidence literature related to the nature of this ability domain since our 2012 chapter, we can only continue to speculate that it will include such things as a dancer's ability to move into a certain position and visualize how it looks to another person (which would have Gv components), and knowledge of which body movements will be needed to accomplish a specific goal (e.g., passing through a narrow space). Such abilities are likely to be involved in Gardner's bodily–kinesthetic intelligence (see Chen & Gardner, Chapter 4, this volume). One interesting possibility is that proprioceptive receptors and other receptors in muscles are used in inferring characteristics of objects that are hefted and wielded (Turvey, 1996). That is, when an object is held and waved about (dynamic touch), one can get a sense of its length, weight, and mass distribution.

Higher-order cognition occurs when tactile information informs potential uses (affordances or "action possibilities"; Gibson, 1979) of the object (e.g., a hammer, a lever, a weapon). In our previous chapter, we hypothesized that Gk and Gp are so interconnected that they may form the same broad-ability construct. We noted that although there is a clear physiological distinction between motor abilities and kinesthetic perception, motor performance is constantly informed by sensory feedback, and thus Gk and Gp might be considered an integrated functional unit. Perhaps our speculation regarding a broad-ability Gf + Gp umbrella construct does not reflect a higher-order ability construct, but instead reflects the functional role played by Gk (as well as Gp and Gh) in understanding recent developments in the cognitive science of embodied cognition (Borghi & Cimatti, 2010; Mahon & Caramazza, 2008; Wilson, 2002).

The historical roots of embodied cognition date back to early 20th-century philosophers (Martin Heidegger, Maurice Merleau-Ponty, and John Dewey). In simple terms, *embodied cognition* means that our cognition is not restricted to the gray and white matter computing unit between our ears, and is perhaps determined by our interaction and experiences (e.g., movement and touch) in the physical world. The embodied-cognition literature, although having a relatively short history in comparison to mind-based cognitive sciences, is growing fast. This literature is somewhat construct-dense, filled with unresolved issues, and counterintuitive to the traditional view of "the mind as an abstract information processor, whose connections to the outside world were of little theoretical importance. Perceptual and motor systems, though reasonable objects of inquiry in their own right, were not considered relevant to understanding 'central' cognitive processes" (Wilson, 2002, p. 625).

The embodied-cognition perspective emphasizes the importance of sensory and motor functions for interacting with the environment. As summarized by Wilson (2002),

> there is a growing commitment to the idea that the mind must be understood in the context of its relationship to a physical body that interacts with the world. It is argued that we have evolved from crea-

> tures whose neural resources were devoted primarily to perceptual and motoric processing, and whose cognitive activity consisted largely of immediate, on-line interaction with the environment. Hence human cognition, rather than being centralized, abstract, and sharply distinct from peripheral input and output modules, may instead have deep roots in sensorimotor processing. (p. 625)

We can see the concept of embodied cognition reflected in such everyday sayings as "This is over our heads," "I've warmed up to him," "I'm on top of the situation," "They are at the height of their power," or "I could feel the electricity between us" (McNerney, 2011).[44] Finally, given that recent "learning by acting" strategies derived from generative learning theory have proven effective in enhancing learning in the STEM fields (Fiorella & Mayer, 2016), we believe that intelligence scholars and educational psychologists need to spend more time operationalizing better measures of Gk (and Gp and Gh) and completing structural validity studies to establish the possible cognitive elements that underlie embodied cognition.

Narrow Abilities within Gk

There are no well-supported cognitive ability factors within Gk yet. Kinesthetic sensitivity (KS), a sensory acuity ability, refers to the ability to make fine discriminations in proprioceptive sensations (e.g., whether and how much a limb has been moved).

Assessment Recommendations for Gk

We are unaware of commercially available measures of Gk. Very little is known about the measurement of Gk. Readers are referred to Stankov and colleagues (2001) for ideas about Gk tests.

Comments and Unresolved Issues Related to Gk

- *How separate is Gk from Gp?* We suspect that Gk and Gp (and possibly Gh) are so interconnected that they may form the same broad-ability construct or may be functional components of what is now called embodied cognition.
- *How do the CHC abilities related to immediate environment–body interaction (Gk, Gp, Gh) fit within the embodied-cognition literature? Conversely, how do psychometrically and cognitively trained psychologists wrap their heads around the concept of embodied cognition? Where does the embodied-cognition research literature fit within the CHC taxonomy—if it does at all?*
- *What about "dynamic touch"?* Do abilities from the Gh and kinesthetic (Gk) domains combine to reflect individual differences in dynamic touch (Stankov et al., 2001)?

Psychomotor Abilities (Gp)

Definition of Gp

Psychomotor abilities (Gp) can be defined as the abilities to perform physical body motor movements (e.g., movement of fingers, hands, legs) with precision, coordination, or strength. The Gp domain received little attention in our previous chapter (approximately half a page) or in Carroll's (1993) seminal treatise on the factor structure of cognitive abilities. The reasons for giving Gp the cold shoulder are threefold. First, psychomotor abilities historically have been considered to represent a noncognitive domain independent of intelligence (Chaiken, Kyllonen, & Tirre, 2000). Second, Carroll did not set sail to capture the extant psychomotor research literature—"my survey of cognitive abilities was not intended to cover the domain of physical and psychomotor abilities, but many of the datasets included measures of psychomotor abilities, with the result that a number of interpretable factors in the domain appeared" (Carroll, 1993, p. 532). Essentially, Gp was "bycatch"[45] found when he cast his wide net to capture cognitive ability datasets. Yet, largely due to the origins of the first CHC list of broad and narrow factors, the original incomplete list of Gp narrow abilities in the CHC taxonomy took on a life of its own independent of serious scientific scrutiny. Third, many educational and school psychologists (of our generation) have scars from the early heydays of special education programming, when psychomotor planning or reprogramming intervention was believed to improve academic achievement (e.g., having children relearn to crawl, walk, etc., was believed to help children learn to read). Speaking the phrase "Doman Delecato method" to many educational and school psychologists of our generation might elicit almost posttraumatic reactions.

Aside from Carroll's (1993) self-admitted "duct tape" Gp overview, which was based on Gp bycatch studies integrated with prior structural reviews of the Gp literature, little structural evidence research has been completed in the Gp domain since a relatively active period from the

1950s through the early 1980s (Fleishman, 1964, 1972; Fleishman, Quaintance, & Broedling, 1984; Guilford, 1958; Peterson & Bownas, 1982). Given the assumed disconnect between Gp and intelligence, many psychologists are at peace with this unfinished charting of the Gp landscape. Why bother learning about Gp abilities? Why be concerned with the out-of-date Gp structural evidence literature reviews? Because contemporary cognition research and theory, as well as increasing interests in newly defined motor-based disorders (e.g., developmental coordination disorder, or DCD), require us to pay closer attention to this intelligence stepchild.

As noted in our discussion of Gk, the growing embodied-cognition research is resulting, in some corners of the field of cognitive science, in a growing commitment to the idea that the mind must be understood in the context of its relationship to a physical body that interacts with the world. Hence human cognition, rather than being centralized, abstract, and sharply distinct from peripheral input and output modules, may instead have deep roots in sensory–motor processing (e.g., Gp, Gk, and Gh). For embodied-cognition research to advance and be evaluated, it is important that an empirically based, fully articulated working Gp taxonomy be available.

Structural and causal modeling research (Chaiken et al., 2000), which has confirmed the validity of a broad Gp factor, also suggests that the stereotype of Gp as distinct and independent from cognitive abilities is wrong. Chaiken and colleagues (2000) reported that general cognitive ability is a major component of general psychomotor ability: “Cognitively able individuals tend to do well on psychomotor tasks” (p. 222). These researchers also reported that processing speed (Gs) and temporal processing cognitive abilities are related to Gp abilities. Furthermore, these researchers suggested that the impact of general intelligence on Gp may be due to working memory (Gwm) capacity: “Working memory may be what limits psychomotor performance. Working memory may impact on psychomotor ability in two ways, via complexity and via novelty” (p. 222). Also, preliminary CFA of the CHC-organized Indonesian AJT-CAT (which also includes two indicators of finger dexterity, P1, and one indicator of manual dexterity, P2; see “CHC’s Global Reach,” above) supports the validity of a Gp broad ability that loads in the mid-.40s on a higher-order *g* factor.

Finally, the pseudoscience of diagnosing students with fine and gross motor disabilities to be solved by motor programming or reprogramming has been replaced by theoretically and empirically sound evidence for DCD. DCD is listed under the category of neurodevelopmental disorders in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013). DCD is a recognized as a complex neurodevelopmental disorder characterized primarily by poor Gp abilities that affect a child’s daily learning and living (Cermak & Larkin, 2002; Gillberg & Kadesjö, 2003; Henderson & Hall, 1982). “Children with DCD show (1) acquisition and execution of motor skills below what would be expected at a given chronological age and opportunity for skill learning and use; (2) motor skills deficit[s] significantly interfering with activities of daily living (ADL) appropriate to the chronological age, impacting school productivity, leisure and play; (3) early development onset of symptoms; (4) motor skills deficits that cannot be explained by intellectual disability [or] visual impairment and [are] not attributable to a neurological condition” (Bieber et al., 2016, p. 115). Not unexpectedly, given the relatively soft foundation of the current Gp taxonomy (when compared to the CHC cognitive ability taxonomy), DCD diagnostic, assessment, and intervention research is constrained by a lack of comprehensive measures of the entire range of affected motor abilities (Bieber et al., 2016; Rivilis et al., 2011).

Narrow Abilities within Psychomotor Abilities (Gp)[46]

1. *Manual dexterity (P1). The ability to make precisely coordinated movements of a hand or a hand and the attached arm.*

2. *Finger dexterity (P2): The ability to make precisely coordinated movements of the fingers (with or without the manipulation of objects).*

3. *Static strength (P3): The ability to exert muscular force to move (push, lift, pull) a relatively heavy or immobile object.*

4. *Gross body equilibrium (P4): The ability to maintain the body in an upright position in space or regain balance after balance has been disturbed.*

5. *Multilimb coordination (P6): The ability to make quick specific or discrete motor movements of the arms or legs.*

6. *Arm–hand steadiness (P7): The ability to precisely and skillfully coordinate arm–hand positioning in space.*

7. *Control precision (P8): The ability to exert precise control over muscle movements, typically in response to environmental feedback (e.g., changes in speed or position of object being manipulated).*

8. *Aiming (AI): The ability to precisely and fluently execute a sequence of eye–hand coordination movements for positioning purposes.*

Assessment Recommendations for Gp

Psychologists are not usually interested in Gp for its own sake, although this may change with the increasing interest in DCD. Neuropsychologists use measures of Gp, such as various grip tests and pegboard tests, to measure uneven performance with the right and left hands as an indicator of lateralized brain injury (Strauss, Sherman, & Spreen, 2006). I-O psychologists may use Gp measures for personnel selection in jobs that require manual dexterity. Occupational and physical therapists use measures of motor functioning with consistent regularity. For researchers or practitioners using the *International Classification of Functioning, Disability, and Health—Children and Youth Version* (World Health Organization, 2007), Bieber and colleagues' (2016) review of 19 clinical tests, 3 naturalistic observations, and 6 questionnaires is a good starting point for identifying measures of motor functioning.

It is apparent that a variety of different professionals working in different professional areas use common measures of Gp, as well as profession-specific Gp measures, with little in the way of cross-specialization communication. It is our opinion that the Gp assessment domain needs a program of research analogous to the XBA assessment work leading to the *Intelligence Test Desk Reference* (McGrew & Flanagan, 1998) and the XBA assessment system (Flanagan et al., 2013). That is, an updated empirically based Gp taxonomy needs to be established first, and then joint or XBA Gp assessment factor studies need to occur that will permit the primary Gp assessment instruments to be interpreted with a common nomenclature.

Comments and Unresolved Issues Related to Gp

- *The current Gp taxonomy, within the CHC model, is likely to be incomplete.* Efforts to complete a Carroll-like meta-analytic synthesis of the extant Gp literature are needed to revalidate existing Gp narrow abilities; determine which current Gp narrow-ability definitions should be revised; and, most importantly, identify Gp narrow abilities that have not yet been described.
- *Should psychometrically oriented CHC taxonomists monitor the embodied-cognition literature for potential new insights into the nature of the Gp domain?* We think that the answer should be yes.
- *How do the immediate environment–body interaction CHC abilities (Gk, Gp, Gh) fit within the embodied-cognition literature (Borghi & Cimatti, 2010; Mahon & Caramazza, 2008; McNerney, 2011; Wilson, 2002)?*

Emotional Intelligence (Gei)

Definition of Gei

Emotional intelligence (Gei) can be defined as the ability to perceive emotions expressions, understand emotional behavior, and solve problems using emotions. Below we present the narrow abilities from the Mayer–Salovey–Caruso four-branch model of emotional intelligence, but with the caveat that there have been few other exploratory efforts to uncover the Gei narrow abilities. Most research is focused on overall emotional intelligence and has employed only a few tests, typically from the MSCEIT. Strong tests of the existence of narrow abilities usually requires four or more indicator tests per ability, and the MSCEIT has only two indicators per factor. To explore the narrow-ability space in emotional intelligence, a wide range of new tests with diverse formats will need to be developed and delivered together.

Tentative Narrow Abilities within Gei[47]

1. **Emotion perception (Ep): The ability to accurately recognize emotions in the face, voice, and behavior.* The idea that there are important individual differences in the ability to recognize emotional expressions is probably the least controversial aspect of the emotional intelligence domain: It is a fundamental component of social competence (Chronaki, Hadwin, Garner, Maurage, & Sonuga-Barke, 2015), and may be important in academic functioning as well (Kang, Anthoney, & Mitchell, 2017; Trentacosta & Izard, 2007).

2. **Emotion knowledge (Ek): Knowledge of the antecedents of emotions and the consequences of emotional expression.* Understanding emotions is at the core of emotional intelligence (Denham, 2007) and has the highest correlations with the

"cool" intelligences, particularly with verbal ability (Roberts, Schulze, & MacCann, 2008). Low emotional knowledge is associated with many negative life outcomes, including social incompetence, social withdrawal, internalizing problems, externalizing problems, and academic difficulties (Chronaki, Garner, et al., 2015; Fine, Izard, Mostow, Trentacosta, & Ackerman, 2003; Izard et al., 2001; Schultz et al., 2001; Trentacosta & Fine, 2010; Trentacosta & Izard, 2007). Interventions designed to improve emotional knowledge in children appear to improve social competence and reduce behavioral problems (Giménez-Dasí, Fernández-Sánchez, & Quintanilla, 2015; Grazzani, Ornaghi, Agliati, & Brazzelli, 2016; Ornaghi, Brazzelli, Grazzani, Agliati, & Lucarelli, 2017).

3. *Emotion management (Em): The ability to regulate one's emotions deliberately and adaptively.* People who score higher on performance measures of emotion regulation ability are rated as more interpersonally sensitive and prosocial than people who score lower on such measures, and this effect persists even after researchers control for general intelligence and five-factor personality traits (Lopes, Salovey, Côté, & Beers, 2005).

4. *Emotion utilization (Eu): The ability to make adaptive use of emotion, especially to facilitate reasoning.* In the four-branch model of emotional intelligence (Mayer, Salovey, et al., 2008), utilizing emotion is an ability one uses consciously to facilitate reasoning and problem solving. Factor-analytic studies have not successfully isolated this factor, however. Izard (2001) believes that emotion utilization is better thought as a direct effect of emotion than as a distinct intellectual ability, but concedes that one can maximize the adaptive benefits of emotion if one understands emotions and can manage them first (Trentacosta & Izard, 2007).

Comments and Unresolved Issues Related to Gei

- *What is needed to remove the tentative status of Gei?* The scope of evidence supporting the validity of emotional intelligence is quite impressive. Although results from MacCann and colleagues (2014) are an impressive start, we would like to see more convergent and discriminant validity research showing that in a factor analysis of diverse cognitive abilities, emotional intelligence measures are distinct from other abilities and form a coherent broad ability. A related concern is whether emotional intelligence is distinct from other "hot" intelligences (Mayer et al., 2016), such as social intelligence (perceiving, understanding, and reasoning about interpersonal relationships) and personal intelligence (perceiving, understanding, and reasoning about personality). We suspect that these are not separate broad abilities and likely form their own cluster.

- *What is the structure of emotional intelligence?* We suspect that emotional intelligence is not a higher-order variable that simultaneously influences each narrow ability, but a causal system of variables arranged similarly to cascade models like those of Izard (1991, 2001) and Joseph and Newman (2010). That is, in the lower portion of Figure 3.12, emotional intelligence is not *in* the causal system; it *is* the causal system (Schneider et al., 2016).

Assessment Recommendations for Gei

Although there are many questionnaire measures of emotional intelligence, we recommend using well-normed ability tests like the MSCEIT or the WAIS-IV Advanced Clinical Solutions test. The least controversial aspects of Gei are related to emotion perception and emotion knowledge.

CHC ABILITIES AS PARAMETERS OF INFORMATION PROCESSING

We hypothesize that the various CHC broad abilities refer to parameters of information processing. New information comes into the brain via the senses. *Perception* is the process by which the brain makes sense of sensation. For example, four lines at right angles can be perceived to be a square. Gt refers to the speed at which perceptual elaboration can occur and is considered a "fundamental parameter" of information processing (Kail & Salthouse, 1994). The various perceptual processing factors of ability (Gv, Ga, Go, Gh, and Gk) govern the level of complexity at which a person can process perceptual information. That is, some people can more easily group simple percepts into more complex objects.

Attention refers to the processes that govern which percepts arise in consciousness. Some attention processes are automatic, but many require conscious control. As anyone who has tried to meditate knows, attention is only partly under our control. Attentional control refers to the steadi-

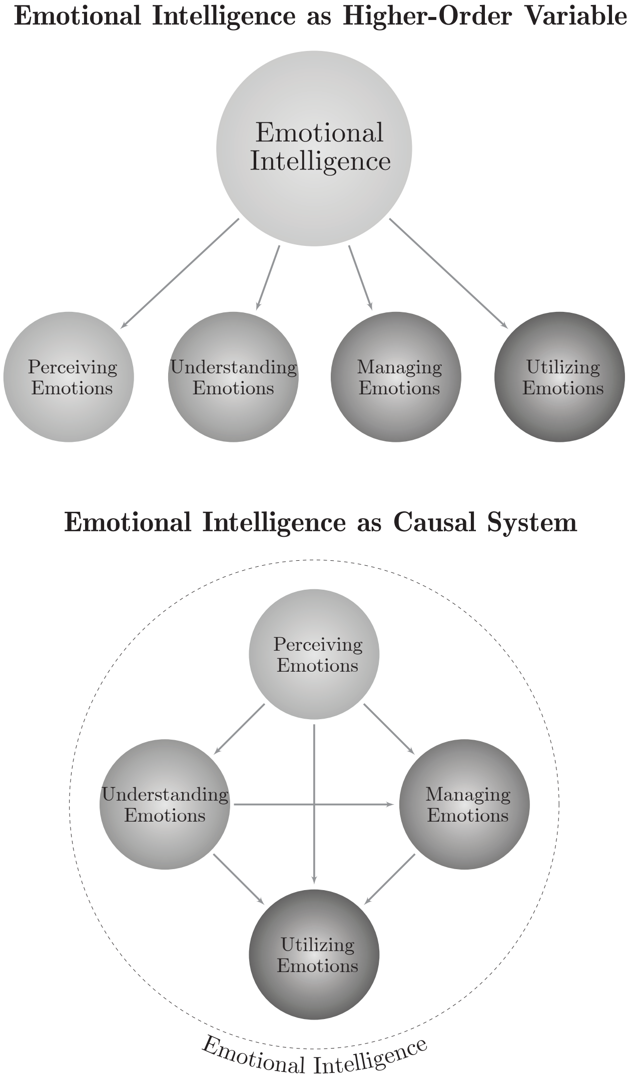

FIGURE 3.12. Two conceptualizations of emotional intelligence.

ness and precision of one's ability to control the focus of attention. Gs refers to how fluently one can shift the focus of attention from one object to the next to make a series of decisions.

Attention interfaces with many other cognitive systems (Hasson, Chen, & Honey, 2015). One can direct the focus of attention to engage in and maintain information in short-term memory, manipulate information in short-term memory, store information in long-term memory, retrieve information from long-term memory, engage in nonautomatic perceptual elaboration, reason through a novel problem, or direct motor movement (Baddeley, 2012; Unsworth, 2017; Unsworth & Engle, 2007). Because attentional control influences many tasks, we suspect that it is a partial explanation for the general factor of intelligence.

We suspect that the maturation of attentional control is the primary reason for the developmental cascade findings in which processing speed predicts working memory, which in turn predicts fluid reasoning (De Alwis et al., 2014; Fry & Hale, 1996; Kail, 2007; Nettelbeck & Burns, 2010). One explanation for the direct influence of processing speed on working memory capacity is that it allows for quicker subvocal rehearsal of information to maintain it in working memory (Bayliss, Jarrold, Baddeley, Gunn, & Leigh, 2005; Kail & Salthouse, 1994). The link between working memory and fluid reasoning is that the operations of reasoning occur within working memory. Greater working memory capacity makes it possible to perceive more complex patterns and to represent more complex relationships among the fundaments of reason (Birney et al., 2006; Halford, Cowan, & Andrews, 2007; Halford et al., 1998). We also predict that the degree to which visualization tasks require attentional control determines their loadings on the fluid reasoning/general factor.

Memory refers to processes that govern the storage and retrieval of information. Gl refers to the efficiency with which information can be stored in long-term memory, and Gr refers to the fluency at which it can be retrieved. We should note that learning efficiency can be supercharged by three related abilities. First, fluid reasoning allows for faster learning via data reduction. That is, if a person can see—via fluid reasoning—that 10 seemingly separate facts are really manifestations of only two phenomena, the learning process is shortened considerably. Second, better language skills (i.e., the language development facet of Gc) allow for more efficient learning because of the conceptual tools embedded in language, especially vocabulary (Perfetti & Stafura, 2014). Third, prior knowledge about a topic allows for more efficient learning of related material (Beier & Ackerman, 2005; Hambrick & Engle, 2002). The breadth and depth of knowledge stored in memory are represented by the general knowledge facet of Gc and domain-specific knowledge (Gkn).

We hope that this presentation stimulates your thoughts and inspires you to contribute to the future development of CHC theory.

9. The Memory for Names test is not included in the WJ IV, but was part of the CFAs. It is included in the WJ IV Tests of Early Cognitive and Academic Development (ECAD; Schrank, McGrew, & Mather, 2015).

10. Kevin McGrew has served as the expert consultant for CHC and applied psychometrics on this project, and helped complete these preliminary structural analyses.

11. In the 2002 *Atkins v. Virginia* decision (see Haydel & Ferber, 2015), the U.S. Supreme Court ruled it unconstitutional to execute individuals with intellectual disabilities. Since *Atkins* cases typically rely on the definitions and guidelines of the American Association of Intellectual and Development Disabilities (2010) and the American Psychiatric Association (2013), IQ scores have become central to life-or-death Atkins decisions.

12. See *https://tinyurl.com/n7ww3zc.*

13. Kevin McGrew served as an external consultant to the SHARP project from 2012 to 2015.

14. This fallacy, which we like to call the jingle–jangle jungle, exists when erroneous assumptions are made that two different things are the same because they have the same name (the jingle fallacy), or that identical or almost identical things are different because they are labeled differently (the jangle fallacy).

15. We believe it is important, when possible, to differentiate narrow abilities within a CHC domain as major and minor. Major factors are those that represent the core characteristics of the domain, typically represent more complex cognitive processing, tend to display higher loadings on the g factor when present in the analysis, and are more predictive and clinically useful. Minor factors typically are less useful, less cognitively complex, and less g-loaded, and tend to "fall near the periphery of scaling representations, or at the bottom of a hierarchical model" (Lohman, 1979, pp. 126–127). Lohman (1979) made this clear distinction in his seminal Gv survey, which Carroll (1993) reinforced. In the discussions that follow, we designate the major abilities within a CHC broad domain with asterisks (*).

We have reordered the narrow abilities under each broad CHC domain ability so that the major abilities come first. Where possible, we have used the average g loadings for narrow factors as reported by Carroll (1993, Table 15.5, p. 597), as well as each narrow ability's average loading on its respective broad factor (e.g., average narrow factor loadings on the Gv factor as per Carroll, 1993, p. 609), to rearrange the list of narrow abilities in a rough major-to-minor continuum. In the absence of clear differences in g or broad factor loadings, we have kept functionally similar abilities adjacent to each other in our narrow-ability listings. Also, when average g loadings and average loadings within broad CHC domains differ between different narrow abilities, we have treated the within-broad-CHC-domain loadings as more important. Also, for many of the narrow abilities, no such information was summarized by Carroll; in the end, we have had to use our combined expert judgment for some of these rough ordering decisions. The reader should consider the order in which we list narrow abilities as relative, approximate, and not without possible error.

16. We would be remiss if we did not mention that a number of neo-Piagetians have advanced Piaget's original theory, especially in research related to education (e.g., mathematical thinking; see Fuson & Li, 2009).

17. Facets are based on facet theory and represent logically based classifications of test materials as per stimulus content characteristics (e.g., verbal, numerical, figures, etc.) and are not to be confused with ability factors. See Humphreys (1962).

18. Tinkering with the CHC taxonomy, and trying to stay consistent with the two-letter coding system that has evolved over time, are challenging endeavors and have required some fluid reasoning and creativity on our part. Historically, almost all narrow memory abilities were coded M__ (MV = memory visual, or visual memory; MA = memory associative, or associative memory; etc.). Using this system would not work here. Auditory short-term store would be MA, a code already used. Using W__, with the W standing for the "working" part of Gwm, might have worked better, but we could not use WA, as that stands for writing ability (WA) under Grw. The only "satisficing" solution was to use W and have the second letter be lowercase—thus eliminating any duplicate two-letter codes.

19. It should be noted that the broader concept of processing fluency in education also includes its influence in the metacognition of learning, belief formation, and affect. Also of interest is research suggesting that despite fluency's possessing a positive value connotation, sometimes cognitive dysfluency (which tends to have a negative connotation) may produce superior learning outcomes, as it results in less automatic responding and may prompt individuals to engage in more controlled, deliberate "deep" processing.

20. The concerns mentioned here apply to more than the domain of speed in the CHC model, with some ability domains more developed (e.g., Gf, Gc) and other less well developed (e.g., Ga, Gs, Gt).

21. The original Feldmann and colleagues (2004) study only presented factor-analytic evidence for a subset of the speeded variables in the study (viz., three number facility measures and three writing speed measures referenced in Carroll, 1993). We extracted the complete correlation matrix, which also included four perceptual speed tests from the DAS, WJ III, and WISC-III, and completed cluster analysis, MDS, and exploratory principal-components analysis (this was necessary due to singular matrix warnings) of all variables. Three distinct factors or dimensions emerged: perceptual speed (P), writing speed (WS), and number facility (N).

22. See *https://tinyurl.com/lyvfo9q.*

23. We believe that the Ackerman and colleagues memory and complex perceptual speed factors are not distinct narrow abilities, but represent factorially complex perceptual speed abilities that include other cognitive abilities (e.g., Gwm).

24. Given the lack of sufficient information in Carroll (1993), it was not possible to order these narrow abilities in this domain according to the major–minor distinction.

25. See King, Ryan, Kantrowitz, Grelle, and Dainis (2015); Sliwinski and colleagues (2016); and Wild, Howieson, Webbe, Seelye, and Kaye (2008).

26. Given the lack of sufficient information in Carroll (1993), it was again not possible to order the narrow abilities in this domain according to the major–minor distinction.

27. Bycatch is a term from the fishing industry for untargeted fish or marine life that are caught in fishing nets. The term also refers to untargeted material gathered in other forms of animal harvesting or collecting.

28. The broad notion of spatial thinking (or cognition, thinking or expertise) is conceptually like Snow's notion of aptitude–trait complexes. Spatial thinking includes not only the factor-analysis-based Gv psychometric abilities that have been identified (both procedural and declarative Gv abilities), but also spatial thinking dispositions (spatial habits of mind) and use of spatial strategies. "Spatial thinking is based on a constructive amalgam of three elements: concepts of space, tools of representation, and processes of reasoning. It depends on understanding the meaning of space and using the properties of space as a vehicle for structuring problems, for finding answers, and for expressing solutions. By visualizing relationships within spatial structures, we can perceive, remember, and analyze the static and, via transformations, the dynamic properties of objects and the relationships between objects" (National Research Council, 2006, p. 3). The reader is referred to the National Research Council (2006) report, which is available from the National Academy of Sciences (www.nap.edu/catalog/11019/learning-to-think-spatially).

29. The dynamic versus static and large- versus small-scale factor or facet distinctions are the two most prominent developments in the Gv domain. That does not mean that there are not other possible conceptual frameworks for organizing Gv abilities. For example, Allen (2003) presents a functional model that divides spatial tasks into "What is it?" and "Where am I?" questions, underneath which follow dynamic versus spatial and environment-based versus movement-based distinctions, respectively. The next level categorizes primarily narrow cognitive abilities.

30. Note that the designation of the imagery (IM) ability as "major" is an exception to our use of Carroll's (1993) average factor loadings and is our designation for the reasons explained in the text.

31. We debated whether to change the name of this narrow ability to closure ability or closure fluency.

Carroll (1993) himself was originally hesitant in calling this a speed factor: "It is with some hesitation that I classify this as a speed factor because some people are seemingly unable to perform very difficult items at all, even when given a very generous time-limit. . . . The factor could perhaps just as well be classified as a level factor" (p. 465). After reviewing some of the classic early sources on factor naming (Ekstrom et al., 1979) in the hopeful search for a different historical term, we decided not to disrupt this small corner of the CHC taxonomy, given the long-standing tradition of using the term closure speed and the general acceptance and understanding of the term in contemporary scholarship.

32. In fact, Carroll's (1993) full description and interpretation of the P factor occurs in his Gv chapter (Chapter 8; approximately 8 pages) and not his Gs chapter (one sentence where it is listed under "Factors in the Domain of Visual Perception [See Chapter 8]" (pp. 464–465). His intended dual Gv and Gs classification is made clear in his grand synthesis chapter (Chapter 15), where P is listed and discussed under both Gv and Gs.

33. Astute (or obsessive–compulsive) CHC literature fans may have already noticed the striking similarity in the fonts and graphic format of the model figures presented in McGrew's (1997) original synthesis of the Carroll and Cattell–Horn models (Figure 9.1, p. 155) and, in the same book, Carroll's three-stratum figure (Figure 7.1, p. 125). They are similar, as McGrew created both figures; the creation of Carroll's figure was a professional favor, to produce a higher-quality version of Carroll's somewhat crude figure in his 1993 publication (Figure 15.1, p. 626). Although created concurrently by McGrew, Carroll's figure includes perceptual speed (P) under both Gv and Gs, but McGrew's figure does not. Why? Because at the time McGrew was influenced by available factor-analytic results and common interpretation schemes. At the time, commonly used factor salience rules of thumb (e.g., considering factor loadings < .25 or .30 nonsignificant and omitting the actual values from the factor summary tables; Kline, 2005, p. 245) were being used by the primary CHC CFA investigators of the CHC-based WJ-R and WJ III, as well as the foundational CHC XBA studies (Flanagan, McGrew, & Ortiz, 2000; McGrew, 1997; McGrew & Flanagan, 1998; McGrew, Werder, & Woodcock; 1991; McGrew & Woodcock, 2001; Woodcock, 1990). In hindsight, we now believe that this practice obscured potentially important insights regarding small, yet meaningful, sources of secondary CHC ability variance present in certain tests in intelligence batteries.

For example, WJ-R and WJ III coauthors Woodcock and McGrew frequently noted (to each other) that the Cross Out test often showed small yet consistent loadings on Gv, which typically were not reported due to the rules of thumb about factor salience. The Cross Out test is not present in the WJ IV, but the Pair Cancellation test is also reported to display consistent significant loadings on Gv (median loading across age groups = .22). We (the current chapter's authors) completed a series of exploratory factor analyses of the WJ-R and WJ III norm data; we confirmed that the Cross Out test consistently displayed a lower loading on Gs (.60 to .65) than Visual Matching (mid-.80s) and displayed consistent Gv loadings (.15 to .30 range), while Visual Matching did not. Task analysis of these three mentioned tests reveals that the WJ-R/WJ III Cross Out and WJ IV Pair Cancellation tests require the processing of much more complex visual symbols than Visual Matching. Thus the Gv variance makes sense. But is this amount of variance important? Yes—and we now believe that the commonly used factor salience rules of thumb may have resulted in less-than-accurate CHC classifications of some tests in the CHC test interpretation literature.

The problem has rested in incorrect assumptions regarding intuitive judgments about smaller factor loadings. For example, let us assume that we have a standardized CFA model with latent Gs and Gv factors that correlate .63 (*g* loadings of .70 [Gs] and .90 [Gv]). We have a speed test that loads .80 on Gs, thus accounting for 64% of the test score variance (36% unexplained). If we now add a secondary Gv cross-loading of .32, the typical intuitive conclusion is that this Gv loading now explains approximately 9% of the test performance ($.32^2 = .09$). But this intuition and its underlying math are wrong. Since the latent factor correlation between Gv and Gs is .63, the model incorrectly explains more than 100% of the test score variance—which is impossible. With a .63 latent correlation, the maximum possible cross-loading for Gv is slightly less than .28. A Gv cross-loading of .20 explains not 4% additional test score variance, but 24% additional variance, leaving just 12% unexplained. A Gv cross-loading of .10 explains not 1% additional variance, but 11% additional variance in the test, with 25% unexplained (specific test variance and error variance). Thus many potentially important sources of meaningful CHC ability variance may have been missed in the extant CHC CFA-driven test interpretation and classification literature. Cattell must have recognized this issue, as he frequently considered loadings as small as .15 as salient. The resulting less-than-accurate CHC classification occurred for Cross Out. In all CHC XBA publications, when the Cross Out test was still part of the WJ-R and WJ III, it was always classified as a "strong" indicator of Gs (e.g., see Flanagan et al., 2000, p. 352)—much like its perceptual speed sister Visual Matching. We now believe that it should have not been considered a strong Gs indicator, but a moderate indicator of Gs, and more accurately a mixed Gs/Gv indicator. We have no idea of the extent to which the number of existing CHC test classifications in the literature may not be more accurate; we believe that it is not an extensive issue. However, we now believe that from this point on, CHC-organized factor studies should report the complete set of factor loadings. Retroactively reviewing the extant CHC cross-battery research data and classifications would be nearly impossible, as it would require access to the original raw output from all analyses.

34. See information regarding the recently founded Imagination Institute (http://imagination-institute.org), which is focused on the application of contemporary psychological and neurocognitive theories and methods to the study of human imagination.

35. For our younger readers, Rodney Dangerfield was a comic who, from the 1950s to the early 2000s, became known for his catchphrase "I don't get no respect."

36. Technically, these are component loadings, as the first principal component was extracted.

37. The limited factor summary data provided by Carroll (1993) made it impossible to use his average g and Ga loadings to help designate Ga narrow abilities as major or minor. Thus we have used our expert judgment and knowledge of research and theory to designate PC as major. The designation of U8 as major is based on the research we have reviewed and reported in this chapter, and is at this point a future predicted indication of the status of this narrow ability.

38. There are so many phon- words used in research in reading, psycholinguistics, psychology, cognitive neuroscience, and language that we have a clear phon- jingle–jangle jungle fallacy. Scarborough and Brady (2002) made a valiant attempt to corral and clarify many of the related terms.

39. The addition of speech sounds to UM was suggested by the authors of the WJ IV (McGrew et al., 2014), based on the analysis of the WJ IV norm data; the WJ IV includes numerous measures of different aspects of Ga. Thus the UM classification as auditory-nonverbal may be inaccurate when the memory is for patterns of sounds.

40. As noted in our 2012 chapter, Lazar Stankov has long maintained (at least from 1989) that he and John Horn (Stankov & Horn, 1980) should receive credit for the first known publication to recognize what is now known as working memory.

42. See *http://sensonics.com/smell-identification-test-international-versions-available.html.*

43. The UPSIT was factor-analyzed together with nine other tests of odor identification, discrimination, detection, memory, suprathershold intensity, and pleasantness perception in a small sample of 97 subjects (Doty, Smith, McKeown, & Raj, 1994). The researchers concluded that the 13 available olfactory variables suggested, "for all practical purposes, measure a common source of variance, perhaps analogous to the 'G' factor observed in intelligence measurement theory" (p. 704). Although the sample was small and there were no other broad CHC factor indicators, this study does provide some support for the broad Go domain.

44. See *https://blogs.scientificamerican.com/guest-blog/a-brief-guide-to-embodied-cognition-why-you-are-not-your-brain.*

45. Only 9+ pages in Carroll's 819-page tome were devoted to discussing the Gp bycatch findings.

46. Given the lack of sufficient information in Carroll (1993), it was not possible to order these narrow abilities in this domain according to the major–minor distinction.

47. See note 18 for a similar rationale to the one we have followed here in proposing two-letter codes for the Gei narrow abilities. EU could not be used, as that is a code already present in Grw. Thus the capital/lowercase abbreviation system is used here also.

CHAPTER 4

Assessment from the Perspective of Multiple-Intelligences Theory

Principles, Practices, and Values

Jie-Qi Chen
Howard Gardner

Howard Gardner of Harvard University introduced the theory of multiple intelligences (MI) in his book *Frames of Mind*, first published in 1983. The theory has touched numerous branches of psychology and education, including counseling psychology, developmental therapy, teacher training, gifted education, programs for at-risk children, and museum education, to name a few. As the book has been translated into more than 20 languages, MI-inspired educational practices have made noticeable impacts in many countries and regions around the world (Chen, Moran, & Gardner, 2009).

A central issue in MI-inspired educational practice is assessment. With MI's focus on individual differences, educators need assessment tools designed to detect these differences. This chapter addresses the questions of what to assess, as well as how to assess individuals' diverse intellectual abilities, from an MI-based perspective. We begin the chapter with an overview of MI theory. Moving from theory to practice, we identify distinctive features of the MI approach to child assessment. We then introduce several instruments that incorporate MI assessment features. Empirical studies based on these instruments are reported as well. We conclude with a discussion of the role that values play in the assessment process—specifically, in determining both what is assessed and how it is measured.

UNDERSTANDING MI THEORY

A significant departure from the traditional view of intelligence as IQ, MI theory (Gardner, 1983, 1993a, 1999, 2006, 2011) fundamentally changes what intelligence is by (1) redefining what constitutes intelligence, (2) redesigning the methods used to study intelligence, and (3) identifying intelligences beyond the verbal and quantitative abilities that IQ measures.

Gardner (1999) defines *intelligence* as "a biopsychological potential to process information that can be activated in a cultural setting to solve problems or create products that are of value in a culture" (p. 33). By considering intelligence a potential, Gardner asserts its emergent and responsive nature, thereby differentiating his theory from traditional ones that view human intelligence as fixed and innate. Whether a potential can be activated depends on the values of the culture in which an individual grows up; the opportunities available in that culture; and personal choices made by individuals, their families, and others in their lives. These activating forces shape the development and expression of a range of intelligences from culture to culture and from individual to individual. Gardner's definition of intelligence also differs from other formulations in that it considers the creation of products, such as musical scores, sculptures, or computer programs, to be as important an expression of intelligence as abstract problem solving. Traditional theories do not recognize created artifacts as manifestations of intelligence and therefore are limited in both conceptualization and measurement.

The methodology Gardner used to develop MI theory represents a major departure from the psychological testing approach that has been used to study intelligence. The distinctive method Gardner used in studying intelligence is inseparable from his groundbreaking view of human intelligence. In the process of developing MI theory, Gardner considered the range of adult end states that are valued in diverse cultures around the world. To identify the abilities supporting these end states, he examined empirical data from disciplines that had not been considered previously for the purpose of defining human intelligence. His examination of these datasets yielded eight criteria for identifying an intelligence. The criteria took into consideration brain function, evolutionary history, special human populations, end-state adult performances, skill training, correlation of intelligence test results, development of symbol system, and core operations of intelligence (Gardner, 1993a). Of principal importance to Gardner in developing the criteria was capturing the range of purposes and processes entailed in human cognitive functioning.

Gardner (1993a, 2006, 2011) has argued that standardized intelligence tests typically probe a limited number of intelligences, such as linguistic, logical–mathematical, and certain forms of spatial intelligences. MI theory has added five more candidates to the list: musical, bodily–kinesthetic, naturalistic, interpersonal, and intrapersonal intelligences (see Table 4.1). According to Gardner, all human beings possess all of the intelligences, but differ in relative strengths and weaknesses—an important source of individual differences. The eight identified intelligences, according to Gardner, cannot be viewed merely as a group of raw computational capacities. They are subject to encoding in varied symbol systems created by various cultures. It is through symbol systems that intelligences are applied in specific domains or bodies of knowledge within a culture, such as mathematics, art, basketball, and medicine (Gardner, 1993a, 1999). As well, the world is wrapped in meanings. Intelligences can be implemented only to the extent that they partake of these meanings and enable individuals to develop into functioning, symbol-using members of their community. An individual's intelligences, to a great extent, are shaped by cultural influences and refined by educational processes. It is through the process of education that "raw" intellectual competencies are

TABLE 4.1. Identified Multiple Intelligences

Intelligence	Sample adult role	Definition
Linguistic intelligence	Writers and poets	The ability to perceive and generate spoken or written language
Logical–mathematical intelligence	Mathematicians and computer programmers	The ability to appreciate and utilize numerical, abstract, and logical reasoning to solve problems
Musical intelligence	Musicians and composers	The ability to create, communicate, and understand meanings made out of sound
Spatial intelligence	Graphic designers and architects	The ability to perceive, modify, transform, and create visual or spatial images
Bodily–kinesthetic intelligence	Dancers and athletes	The ability to use all or part of one's body to solve problems or fashion products
Naturalistic intelligence	Archaeologists and botanists	The ability to distinguish among, classify, and use features of the environment
Interpersonal intelligence	Leaders and teachers	The ability to recognize, appreciate, and contend with the feelings, beliefs, and intentions of other people
Intrapersonal intelligence	Apparent when individuals pursue a particular interest or choose a field of study or work	The ability to understand oneself—including emotions, desires, strengths, and vulnerabilities—and to use such information effectively in regulating one's own life

developed and individuals are prepared to assume mature cultural roles. Rich educational experiences are essential for the development of each individual's particular configuration of interests and abilities (Gardner, 1993b, 2006).

MI-BASED ASSESSMENT PRINCIPLES

Assessment based on MI theory calls for a significant departure from traditional approaches to assessment. From the start, a distinctive hallmark of MI theory has been its spurning of one-shot, decontextualized, paper-and-pencil tests to rank an individual's "smartness" based on a single score (Gardner, 1993b, 2006). MI theory presents several basic principles for the assessment of intelligences: (1) sampling intellectual capacities in a wide range of domains; (2) using media appropriate to each assessed domain; (3) choosing assessment materials that are meaningful to students; (4) attending to the ecological validity of assessment contexts; and (5) portraying complete intellectual profiles to support learning and teaching (Chen, 2004; Krechevsky, 1998) (see Table 4.2).

TABLE 4.2. MI Principles for the Assessment of Intellectual Profiles

- *Sample intellectual capacities in a range of domains* that include both traditionally defined academic areas such as reading, literacy, math, and science, as well as nonacademic areas such as visual arts, performing arts, movement, and understanding of others and self.
- *Use media appropriate to each domain of assessment* to engage in an intelligence-fair assessment process by looking at the problem-solving features and operational mechanisms of particular intelligences; such a process allows one to look directly at the functioning of each intellectual capacity.
- *Choose assessment materials that are meaningful to students* by supporting thinking, inviting questions, stimulating curiosity, facilitating discovery, and encouraging the use of imagination and multiple symbol systems in the students' problem-solving processes.
- *Attend to the ecological validity of assessment contexts* to ensure that the assessment environments are natural, familiar, and ongoing; use multiple samples of a child's performance; and incorporate clinical judgments from those who are knowledgeable about the child being assessed and directly responsible for using the results.
- *Portray complete intellectual profiles* that focus on students' strengths and include concrete, practical suggestions to help educators understand each child as completely as possible, and then mobilize the child's intelligences to achieve specific educational goals.

Sampling Intellectual Capacities in a Wide Range of Domains

Because the fundamental principle of MI is that human intelligence is pluralistic, assessment based on MI theory incorporates a range of domains to tap different facets of each intellectual capacity. In addition to language, literacy, and mathematics—the primary foci of traditional intelligence tests and school achievement tests—MI-based assessment also looks at children's performance in areas often viewed as nonacademic, such as music, arts, movement, and understanding of self as well as others. The MI approach to assessment recognizes students who excel in linguistic and/or logical pursuits, as well as those who have cognitive and personal strengths in other intelligences. By virtue of the wider range they measure, MI types of assessment identify more students who are "smart," albeit in different ways (Gardner, 1993b, 2000).

It has been well documented that students who have trouble with some academic subjects, such as reading or math, are not necessarily inadequate in all areas (Diaz-Lefebvre, 2009; Levin, 2005). The challenge is to provide comparable opportunities for these students to demonstrate their strengths and interests. When students recognize that they are good at something, and their accomplishment is acknowledged by teachers, parents, and peers, they are far more likely to feel valued in the classroom and to experience further school success. In some instances, the sense of success in one area may make students more likely to engage in areas where they feel less comfortable. When that occurs, the systematic use of multiple measures goes beyond its initial purpose of identifying diverse cognitive abilities and becomes a means of bridging students' strengths from one area to other areas of learning (Chen, Krechevsky, & Viens, 1998; Dweck, 2007; Gardner, 1998).

Using Media Appropriate to Each Domain Assessed

On the basis of its contention that each intelligence exhibits particular problem-solving features and operational mechanisms, MI theory argues for *intelligence-fair* instruments to assess the unique capacities of each intelligence. Too often, language is the gatekeeper, forcing individuals to reveal their intelligence through the customary lens of linguistic ability; or logical analysis serves as a route to, or an obstacle thwarting, the measurement of nonscholastic abilities. In contrast, intelligence-fair instruments engage the key abilities of particular intelligences, allowing one to look directly at the functioning of each intellectual capacity.

When intelligence-fair instruments are used, bodily intelligence can be assessed by recording how a person learns a new dance or physical exercise. To consider a person's interpersonal intelligence, it is necessary to observe how he or she interacts with and influences others in different social situations. One situation might be the individual's interacting with a friend to offer extra support when the friend loses an art contest. Another relevant situation is observing an individual giving advice to a friend who is the target of a rumor. It is important to note that what is assessed is never an intelligence in pure form. Intelligences are always expressed in the context of specific tasks, domains, and disciplines. For example, there is no "pure" spatial intelligence; instead, there is spatial intelligence as expressed in a child's puzzle solution, route finding, block building, or basketball passing (Gardner, 1993b).

Choosing Assessment Materials Meaningful to Students

Materials are important in assessment because intelligence is manifested through a wide variety of artifacts. To be meaningful, the assessment materials first need to be familiar to children. Assessment based on MI theory is responsive to the fact that students' prior experience with assessment materials directly affects their performance on tasks. For example, children who have little experience with blocks are less likely to do well on a block design task. Likewise, it would be unfair to assess a child's musical ability by asking the child to play a music instrument that he or she has never experienced. In recognition of the role that experience plays, the MI approach to assessment emphasizes using materials that are familiar to children. If children are not familiar with materials, they are given ample opportunities to explore materials prior to any formal assessment.

The term *meaningful* also signifies the role of assessment materials in supporting a student's problem-solving process. To be fair, materials used in many current intelligence tests, such as pictures, geometric shapes, and blocks, are not unfamiliar to children in industrial societies. Yet such materials provide little intrinsic attraction because they have little meaning in children's daily lives. For assessment to be meaningful for students, the selection of materials must be a careful and deliberate process. Materials ought to be an integral part of students' problem-solving processes, supporting thinking, inviting questions, and stimulating curiosity. Meaningful materials also facilitate students' discovery and encourage the use of imagination and multiple symbol systems (Rinaldi, 2001).

Attending to the Ecological Validity of Assessment Contexts

In the traditional intelligence assessment situation, a psychologist works with one child at a time, preferably in a relatively quiet room away from any distractions, including regular classroom activities. MI theory emphasizes the ecological validity of assessment contexts (Gardner, 1993b); that is, the assessment environments must be natural, familiar, and ongoing. When a child's ability is measured through a one-shot test using decontextualized tasks, the child's profile of abilities is often incomplete and may be distorted. In contrast, when assessment is naturally embedded in learning environments, it allows psychologists and educators to observe children's abilities in various situations over time. Such observations generate multiple samples of a child's ability that can be used to document variations of the child's performances within and across domains, and so to portray the child's intellectual profile more accurately.

Integrating authentic activities and observations over time, assessment based on MI theory does not typically function as a norm-referenced instrument does. Intelligence in the MI framework is defined as a potential, exhibiting various possible forms and subject to continuous changes in expression and strength. MI-based assessment involves performance standards or criterion references that educators can use to guide and evaluate their observations. In contrast to norm-referenced tests, which feature decontextualized and seemingly impartial judgments of students' performance, MI-based assessment is open to incorporating the clinical judgments of classroom teachers. In so doing, MI-based assessment places greater value on the experience and expertise of educators who are knowledgeable about the child being assessed and are directly responsible for using the assessment results (Chen, 2004; Darling-Hammond & Ancess, 1996; Linn, 2000).

Portraying Complete Intellectual Profiles to Support Learning and Teaching

Traditional tests—of achievement, readiness, intelligence, and the like—are often used to rank-order and sort students on the basis of a single quantitative score. Seemingly objective scores on these standardized tests disguise the complex nature of human intelligence. In the process, the scores also limit a child's range of learning potentials and may narrow opportunities for success in school. Instead of ranking and labeling, the purpose of MI types of assessment is to support students on the basis of their complete intellectual profiles. Such an intellectual profile portrays a child's strengths, interests, and weaknesses. It also includes concrete, practical suggestions to the student, such as how to build on the identified strengths, work on areas that need attention or intervention, and develop approaches to learning that are conducive to productive work (Chen & McNamee, 2011; Krechevsky, 1998).

It is important to note that the identification of intellectual strengths and weaknesses of individuals is not the endpoint of MI types of assessment. The purpose of portraying a complete intellectual profile is to help educators understand each child as completely as possible and then mobilize his or her intelligences to achieve specific educational goals. MI-based assessments promote achievement of these goals by assisting educators in selecting appropriate instructional strategies and pedagogical approaches, based on a comprehensive and in-depth understanding of each child.

MI-BASED ASSESSMENT PRACTICES

Since MI theory was introduced, educators have looked for an assessment that could be used to better understand students' diverse intellectual abilities and inform instructional practice. We introduce three tools that are designed for such purposes: the Spectrum battery, the Bridging assessment, and the Multiple Intelligences Developmental Assessment Scales (MIDAS™). Empirical work associated with the three instruments is also reported.

The Spectrum Battery

The Spectrum battery, designed by the staff of Project Spectrum at the Harvard Graduate School of Education, is the only MI-based assessment instrument developed with Gardner's direct involvement. Designed for preschool children, the Spectrum battery is composed of 15 activities in seven domains of knowledge: language, math, music, art, social understanding, sciences, and movement (Chen, 2004; Krechevsky, 1998) (see Table 4.3). The Spectrum's name reflects its mission of recognizing diverse intellectual strengths in children.

TABLE 4.3. Spectrum Assessment Activities

Spectrum areas	Spectrum activities	Measured abilities
Language	1. Storyboard activity	Invented narrative
	2. Reporter activities	Descriptive narrative
Visual Arts	3. Art portfolio	Visual arts skills
Mathematics	4. Dinosaur game	Counting strategies
	5. Bus game	Calculating and notation
Sciences	6. Discovery area	Naturalist observation
	7. Treasure hunt game	Logical inference
	8. Sink and float activity	Hypothesis testing
	9. Assembly activity	Mechanical abilities
Movement	10. Movement with music	Creative movement
	11. Obstacle course	Athletic movement
Social Understanding	12. Classroom model	Social analysis
	13. Peer interaction checklist	Social roles
Music	14. Montessori bells	Music perception
	15. Singing songs	Music production

During the assessment process, an assessor or a teacher works with children either individually or in small groups. Children engage in a range of activities, such as disassembling and assembling several house gadgets in the science domain; playing Montessori bells in the music domain; keeping track of passengers getting on and off a toy bus in the mathematics domain; and manipulating figures in a scaled-down, three-dimensional replica of the children's classroom to assess social understanding. Fun and challenging, these activities invite children to engage in problem-solving tasks. They are intelligence-fair, using materials appropriate to particular domains rather than relying only on language to assess multiple forms of competence and ability. They help to tap key abilities—abilities that are essential to the operation of particular intellectual domains in children's task performance. Each activity is accompanied by written instructions for task administration. These instructions include a score sheet that identifies and describes different levels of the key abilities assessed in the activity, making a child's performance on many activities quantifiable.

Spectrum assessment results are presented in the form of a Profile—a narrative report based on the information obtained from the assessment process (Chen, 2004; Krechevsky, 1998). Using nontechnical language, the report focuses on the range of cognitive abilities examined by the Spectrum battery. It describes each child's relative strengths and weaknesses in terms of that child's own capacities, and only occasionally in relation to peers. Strengths and weaknesses are described in terms of the child's performance in different content areas. For example, a child's unusual sensitivity to different kinds of music may be described in terms of facial expressions, movement, and attentiveness during and after listening to various music pieces. It is important to note that the child's intellectual profile is described not only in terms of capacities, but also in terms of the child's preferences and inclinations. Furthermore, the Profile is not a static image, but a dynamic composition that reflects a child's interests, capabilities, and experiences at a particular point in time. The profile changes as the child's life experience changes. The conclusion of the Profile typically includes specific recommendations to parents and teachers about ways to support identified strengths and improve weak areas (Krechevsky, 1998).

Using the Spectrum battery, Chen studied a group of first graders in four public classrooms (Chen & Gardner, 2005). Among those who had been identified as at risk for school failure, Chen found out that they demonstrated identifiable strengths on the Spectrum assessment. Also noteworthy, these students showed more strengths in nonacademic areas such as mechanical, movement, and visual arts than in academic areas such as language and math. Had the assessment been limited to academic areas, these at-risk children's strengths would have gone undetected and could not have served as bridges for extending the children's interest and learning to other curricular areas.

Bridging

Bridging was developed by Chen and McNamee (2007) to help teachers document and describe intellectual profiles of children between the ages of 3 and 8. It shares certain features with the Spectrum assessment, including the identification of children's diverse cognitive strengths, the use of engaging activities, and a focus on guided observation and careful documentation. It differs from the Spectrum assessment by focusing on the operation of intellectual abilities in school curricular areas, such as language and literacy; number sense and geometry; physical, mechanical, and natural sciences; and performing and visual arts. Bridging is organized in terms of school subject areas rather than intellectual domains, for several reasons: (1) Intelligences never function in abstract form, but rather are used in the context of specific disciplinary tasks; (2) school subject areas reflect intellectual abilities valued in our society; (3) children mobilize their intelligences in the pursuit of studying subject areas; and (4) aligning assessment areas with school subject areas facilitates teachers' incorporation of the assessment results into curriculum planning. The name of the instrument, Bridging, signifies its goal of building a bridge from assessment to teaching (Chen & McNamee, 2008).

Bridging includes a total of 15 regular classroom activities, such as reading a child's favorite book, constructing a model car with recycled materials, and experimenting with light and shadows (see Table 4.4). Children's performance in each of the 15 activities is scored according to a 10-level, criterion-referenced rubric developed specifically for 3- to 8-year-olds. As an example, the rubric used to measure performance on the "reading books" activity was based on the stages of pretend reading developed by Sulzby (1985) and work in guided reading by Fountas and Pinnell (1996). The ru-

TABLE 4.4. Bridging Assessment Areas and Activities

Bridging areas	Bridging activities
Language Arts and Literacy	1. Reading books (child's choice, teacher's choice) 2. Dictating a story 3. Acting out stories
Visual Arts	4. Experimenting crayon technique 5. Drawing a self-portrait 6. Making pattern block pictures
Mathematics	7. Creating pattern block pinwheels 8. Solving pattern block puzzles 9. Exploring number concepts
Sciences	10. Exploring shadows and light 11. Assembling a nature display 12. Building a model car
Performing Arts	13. Moving to music 14. Playing an instrument 15. Singing a song

bric progresses from attending to pictures without forming stories at level 1 to reading for meaning independently at level 10 (Chen & McNamee, 2007).

Empirical data support the Bridging approach—both its conceptualization of children's abilities and the effective design of its assessment activities. In one study using Bridging, Chen, McNamee, and McCray (2011) examined the intellectual profiles of 92 preschool and kindergarten children. Results indicated that *within a child's profile,* levels of competence varied as a function of content area. A child's competence level was higher in some areas and lower in others. *Among children's profiles,* the patterns of their performance levels were distinctive. That is, the pattern in each child's profile differed from the pattern found in other children's profiles. Children's competence is thus domain-specific.

In terms of Bridging's utility, over 400 preservice and inservice teachers from preschool through third grade have integrated it into their classrooms under the direct supervision of the instrument's developers. An implementation study of 75 preservice teachers revealed that the construction of intellectual profiles for individual students using the Bridging assessment process was a key component in these student teachers' understanding of diverse learners in their classrooms (Chen & McNamee, 2006). In addition, teachers' understanding of individual students and content knowledge increased as the result of implementing Bridging in their classrooms. This increased understanding contributed to their ability to be more effective in curriculum planning and teaching (McNamee & Chen, 2005).

The MIDAS Battery

Developed by Branton Shearer, the MIDAS battery (*www.MIResearch.org*) consists of eight main scales that correspond to the eight intelligences defined by Gardner. It is designed to portray the profile of an individual's intellectual dispositions, both quantitatively and qualitatively (Shearer, 2007). Covering ages from preschool through adulthood in six different forms, the MIDAS can be completed online in less than 30 minutes or administered as a structured interview for respondents with reading limitations. Young children complete the assessment process through the help of parents in collaboration with the teacher. Responding to the criticism that the MIDAS results are questionable because they rely primarily on self-report, Shearer (2007) argues that one of the hallmarks of the MIDAS is attention to the intrapersonal intelligence reflected in the self-report process and profile interpretation. For the MIDAS, intrapersonal intelligence is the "royal road to learning, achievement, and personal growth" (Shearer, 2007).

For each respondent, a MIDAS Profile Report is constructed. This report describes the respondent's specific skills, capacities, and enthusiasms in terms of Gardner's eight intelligences. Depending on the level of detail and descriptive information needed about the respondent, the MIDAS can be used for three purposes: as a brief Screening instrument, to generate an Individual Profile with a brief learning summary, or to produce a more comprehensive Personalized Assessment Plan. An ultimate goal for MIDAS interpretation is to build a communicating *bridge* among important stakeholders in a student's education, so that strength-based plans may be effectively conceived and then implemented. The Profile Report provides instructional information to teachers. It also suggests practical activities for each student and parents at home.

The MIDAS has been translated into numerous foreign languages for use in regions and countries such as Taiwan, Korea, the Netherlands, Iran, Singapore, India, and Chile. It has also been tested for its psychometric properties in the United States as well as internationally, including test–retest reliability, interrater reliability, concurrent validity, and level of independence among scales (Shearer, 2007). In an analysis of 23,000 individuals who completed the MIDAS profile, for example, Shearer (2005) found nine factors corresponding with the MIDAS main scales. These factor-analytic results have been replicated with the Chinese, Farsi, and Korean translations, providing additional cross-cultural empirical validity. Shearer thus concluded that the MIDAS provides a reasonable estimate of the respondents' multiple intellectual dispositions.

The MIDAS has been used with diverse populations, including elementary, secondary, and university students; students with attention-deficit/hyperactivity disorder (ADHD) and learning disabilities; and adults seeking career help. In studies of 116 elementary children diagnosed with ADHD, for example, Shearer and colleagues found that, compared to typically developing peers, these students scored lower on the math, linguistic, and intrapersonal scales of the MIDAS, but higher on the naturalistic, spatial, and kinesthetic scales (Proulx-Schirduan, Shearer, & Case, 2009). The MIDAS profiles provided unique descriptions of the students with ADHD, whose interests and strengths included artistic design, craft work, and recognizing different kinds of plants.

ASSESSMENT AS A VALUES-BASED PROCESS

Over the decades since the inception of MI theory, many MI-based assessments have been developed (Chen & McNamee, 2007; Krechevsky, 1998; Lazear, 1998, 1999; Maker, 2005; New City School, 1994; Niccolini, Alessandri, & Bilancioni, 2010; Shearer, 2007), and several dozen schools in the United States and across the world have adopted the MI approach to assessment (Chen et al., 2009; Kornhaber, Fierros, & Veenema, 2004). However, neither the assessment nor the approach has been widely implemented. In critiquing MI's approach to assessment, no one has asserted that individuals do not have distinctive sets of intellectual abilities or argued that individual differences in abilities are not important in providing instruction. It is our contention that the primary reason the MI approach has not been widely used is related to the role that values play in assessment.

Many educators and parents tend to think of assessment as objective and regard assessment measures as accurate indicators of the intellectual abilities they test. There is an untested assumption of agreement about both what is assessed and how it is measured. Measuring intellectual abilities is likened to the process of measuring characteristics like height and weight. MI theory challenges this assumption. Standardized tests are not measuring tools like tape measures and scales. An individual's intelligences are not amounts of ability that can be quantified in numerical terms, the way height and weight can be measured in inches and pounds. There is no established scale of measure or unit of measurement that objectively describes intelligences.

Because MI theory redefines what intelligences are, it requires us to acknowledge that *intelligence* is a construct. We, as psychologists and educators, *decide* what counts as intelligence, what to measure, and how to measure it. Our purpose in discussing this point is to call attention to the fact that assessment *is* a value-laden process and to question the adequacy of traditional standardized tests, including intelligence tests, aptitude tests, and achievement tests. We briefly describe four aspects of assessment that are affected by values.

1. *Values define the purpose of assessment.* Standardized test scores are used to rank-order, label, and categorize individuals. This stands in contrast to the value that underlies MI assessment—namely, to learn about every individual's competencies and interests, and use this knowledge to design educational experiences that maximize each student's opportunities to succeed in school and in life.

2. *Values determine the content of assessment.* Traditional school achievement tests focus largely on math and reading. MI-based approaches to assessment look across a wide range of domains, including art music, dance, science, competencies in relating to others, and understanding of self. Attention to this wide range of intellectual abilities increases the likelihood of identifying each student's strengths and interests, which they can pursue further and use to develop skills in other areas of learning.

3. *Values influence the selection of assessment methods and materials.* Paper-and-pencil tests are used in standardized school testing of math and reading. Assessing abilities and interests in a wide range of domains, MI-based approaches are based on diverse materials specific to the domains being assessed. Furthermore, MI-based approaches rely

on students' use of these materials in contexts that enable them to demonstrate their competencies through applying them to solve problems and create products.

4. *Values shape how assessment results are used.* Students' performance on standardized end-of-year tests are used to make decisions about the students' promotion and to evaluate their schools' effectiveness. Scores also affect federal funding decisions. In contrast, MI approaches focus on directly linking assessment results to teachers' ongoing design and delivery of instruction.

Assessment, as much current literature points out, provides major leverage for affecting educational practice. Many people criticize current educational practices; a significant part of our educational malaise, however, lies in our current methods of assessing student learning and abilities—methods that, not incidentally, signal restricted views of what learning is and what cognitive abilities constitute. The assumption that assessment is an objective process, based on measuring quantifiable intellectual abilities, produces an approach that is inflexible and impervious to review. In contrast, MI theory gives us the basis for a more fluid understanding of what constitutes *intelligence,* a more flexible approach to assessing how it is applied in authentic educational settings, and more attention to the values that underlie educators' decisions about assessment. Recognizing that values affect assessment makes it possible to continually examine what is assessed, including its relevance to preparing students to be the citizens of the 21st century. Whether or not one agrees with its assertions, MI theory calls us to be explicit about the subjective nature of the assessment process and to be objective about the adequacy of the current assessment methods used. Nothing less than the future of students' lives depends on our willingness to question the relevance and usefulness of traditional approaches, rather than simply to continue their use because they are accepted.

CHAPTER 5

The Triarchic Theory of Successful Intelligence

Robert J. Sternberg

Some people seem always to be getting lost, even if they have a map; other people never seem to get lost, even if they don't have a map (or GPS!). In general, some of us seem to do what we do better than others; as a result, various cultures have created roughly comparable psychological constructs to try to explain, or at least to describe, this fact. The construct Western cultures have created is called *intelligence* (in English or French, or *inteligencia* in Spanish, or *Intelligenz* in German). Whatever the language, it is our way of saying that some of us seem to adapt to the environments we both create and confront better than do others.

There have been numerous approaches to understanding the construct of intelligence, based on somewhat different metaphors for understanding the construct (Sternberg, 1985c, 1986, 1990; see also essays in Sternberg, 2000; Sternberg & Kaufman, 2011). For example, some investigators seek to understand intelligence via what I have referred to as a geographic model, in which intelligence is conceived as a map of the mind. Such researchers have used psychometric tests to uncover the latent factors alleged to underlie intellectual functioning (Cooper, 2015; Willis, Dumont, & Kaufman, 2011). Other investigators have used a computational metaphor, viewing intelligence in much the way they view the symbolic processing of a computer (Conway, Getz, Macnamara, & Engel de Abreu, 2011; Nettelbeck, 2011). Still others have followed an anthropological approach, viewing intelligence as a unique cultural creation (Ang, Van Dyne, & Tan, 2011; Saklofske, van de Vijver, Oakland, Mpofu, & Suzuki, 2015). The approach I take in the triarchic theory proposed here can be viewed as a systems approach, in which many different aspects of intelligence are interrelated to each other in an attempt to understand how intelligence functions as a system.

The *triarchic theory of successful intelligence* (Sternberg, 1984, 1985a, 1988, 1997a, 1999, 2004, 2005b, 2005c, 2008, 2012b, 2015; Sternberg, Jarvin, & Grigorenko, 2011) explains in an integrative way the relationship between intelligence and (1) the internal world of the individual, or the mental mechanisms that underlie intelligent behavior; (2) experience, or the mediating role of the individual's passage through life between his or her internal and external worlds; and (3) the external world of the individual, or the use of these mental mechanisms in everyday life in order to attain an intelligent fit to the environment. The theory has three subtheories, one corresponding to each of the three relationships mentioned in the preceding sentence.

A crucial difference between this theory and many others is that the operationalizations (measurements) follow rather than precede the theory. Thus, rather than the theory's being derived from factor or other analyses of tests, the tests are chosen on the basis of the tenets of the theory. My colleagues and I have used many different kinds of tests (see Sternberg, 1985a, 1988, 2003a, 2003b, 2003c for reviews), such as analogies, syllogisms, verbal comprehension, prediction of future outcomes, and decoding of nonverbal cues. In every case, though, the choice of tasks has been dictated by the aspects of the theory that are being investigated, rather than the other way around.

DEFINITION OF SUCCESSFUL INTELLIGENCE

According to the proposed theory, *successful intelligence* is (1) the use of an integrated set of skills needed to attain success in life, however an individual defines it, within his or her sociocultural context. People are successfully intelligent by virtue of (2) recognizing their strengths and making the most of them, at the same time that they recognize their weaknesses and find ways to correct or compensate for them. Successfully intelligent people (3) adapt to, shape, and select environments through (4) finding a balance in their use of analytical, creative, practical, and wisdom-based skills (Sternberg, 1985e, 1997a, 1997b, 1997c, 1999, 2002, 2003c). Let us consider each element of the theory in turn.

According to the first element, there is no one definition of success that works for everyone. For some people, success is brilliance as lawyers; for others, it is originality as novelists; for others, it is caring for their children; for others, it is devoting their lives to God. For many people, it is some combination of things. Because people have different life goals, education needs to move away from single targeted measures of success, such as grade point average (GPA) or standardized test scores. Education should be geared toward the goals of each individual, rather than toward one predefined goal that may be relevant to some students but not to many others.

In considering the nature of intelligence, we need to consider the full range of definitions of success by which children can be intelligent. For example, in research we have done in rural Kenya (Sternberg et al., 2001), we have found that children who may score quite high on tests of an aspect of practical intelligence—knowledge of how to use natural herbal medicines to treat parasitic and other illnesses—may score quite poorly on tests of IQ and academic achievement. Indeed, we found an inverse relationship between the two skill sets, with correlations reaching the –.30 level. For these children, time spent in school takes away from time in which they learn the practical skills that they and their families view as needed for success in life. The same might be said, in the Western world, for many children who want to enter careers in athletics, theater, dance, art, music, carpentry, plumbing, entrepreneurship, and so forth. They may see time spent developing academic skills as time taken away from the time they need to develop practical skills relevant to meeting their goals in life.

The second element asserts that there are different paths to success, no matter what goal one chooses. Some people achieve success in large part through personal charm; others through brilliance of academic intellect; others through stunning originality; and yet others through working extremely hard. For most of us, there are at least a few things we do well, and our successful intelligence is dependent in large part upon making these things “work for us.” At the same time, we need to acknowledge our weaknesses and find ways either to improve upon them or to compensate for them. For example, we may work hard to improve our skills in an area of weakness, or work as part of a team so that other people compensate for the kinds of things we do not do particularly well.

The third element asserts that success in life is achieved through some balance of adapting to existing environments, shaping those environments, and selecting new environments. Often when we go into an environment—as do students and teachers in school—we try to modify ourselves to fit that environment. In other words, we adapt. But sometimes it is not enough to adapt. We are not content merely to change ourselves to fit the environment; rather, we also want to change the environment to fit us. In this case, we shape the environment in order to make it a better one for us, and possibly for others as well. But there may come times when our attempts to adapt and to shape the environment lead us nowhere—when we simply cannot find a way to make the environment work for us. In these cases, we leave the old environment and select a new environment. Sometimes the smart thing is to know when to get out.

Finally, we balance four kinds of skills in order to achieve these ends: analytical skills, creative skills, practical skills, and—in the augmented version of the theory (Sternberg, 2015)—wisdom-based skills. We need creative skills to generate ideas, analytical skills to determine whether they are good ideas, practical skills to implement the ideas and to convince others of the value of our ideas, and wisdom-based skills to help achieve a common good that goes beyond just our own self-interest. Most people who are successfully intelligent are not equally endowed with these diverse skills, but they find ways of making the four skills work harmoniously together.

We have used five kinds of converging operations to test the theory of successful intelligence: cultural studies, factor-analytic studies, information-processing analyses, correlational analyses, and instructional studies (some of which are described below). Much of this work is summarized elsewhere (e.g., Sternberg, 1985a, 1997b, 2003a, 2003c, 2015). Examples of kinds of evidence in this work supporting the theory are the factorial separability of analytical, creative, and practical skills; the substantial incremental validity of measures of practical intelligence over the validity of measures of academic (general) intelligence in predicting school and job performance; the usefulness of instruction based on the theory of successful intelligence, in comparison with other forms of instruction; and differences in the nature of what constitutes practical intelligence across cultures (see Sternberg et al., 2000; Sternberg & Hedlund, 2002; Sternberg & Smith, 1985; Wagner, 2011).

INTELLIGENCE AND THE INTERNAL WORLD OF THE INDIVIDUAL

Psychometricians, Piagetians, and information-processing psychologists have all recognized the importance of understanding the mental states or processes that underlie intelligent thought. In the triarchic theory of successful intelligence, they seek this understanding by identifying and understanding three basic kinds of information-processing components, referred to as *metacomponents*, *performance components*, and *knowledge acquisition components*.

Metacomponents

Metacomponents are higher-order, executive processes used to plan what one is going to do, to monitor it while one is doing it, and evaluate it after it is done. These metacomponents include (1) recognizing the existence of a problem, (2) deciding on the nature of the problem confronting one, (3) selecting a set of lower-order processes to solve the problem, (4) selecting a strategy into which to combine these components, (5) selecting a mental representation on which the components and strategy can act, (6) allocating one's mental resources, (7) monitoring one's problem solving as it is happening, and (8) evaluating one's problem solving after it is done. Let us consider some examples of these higher-order processes (see Sternberg & Smith, 1988, for further details on executive processes).

Deciding on the nature of a problem plays a prominent role in intelligence. For example, the difficulty for young children as well as older adults in problem solving often lies not in actually solving a given problem, but in figuring out just what the problem is that needs to be solved (see, e.g., Flavell, 1977; Sternberg & Rifkin, 1979). A major feature distinguishing people with intellectual disabilities from persons with typical functioning is the need of the former to be instructed explicitly and completely as to the nature of the particular task they are solving and how it should be performed (Butterfield, Wambold, & Belmont, 1973; Campione & Brown, 1979; Hodapp, Griffin, Burke, & Fisher, 2011). The disability is probably partially genetic (Lombroso, Sternberg, & Grigorenko, 1999).

Selection of a strategy for combining lower-order components is also a critical aspect of intelligence. In early information-processing research on intelligence, including my own (e.g., Sternberg, 1977, 1985b; Sternberg & Weil, 1980), the primary emphasis was simply on figuring out what study participants do when confronted with a problem. What components do participants use, and into what strategies do they combine these components?

Soon information-processing researchers began to ask why study participants use the strategies they choose. For example, Siegler (1986) proposed a model of strategy selection in arithmetic computation problems that links strategy choice to both the rules and the mental associations participants have stored in long-term memory (see also Siegler, 2007). MacLeod, Hunt, and Mathews (1978) found that study participants with high spatial abilities tend to use a spatial strategy in solving sentence–picture comparison problems, whereas study participants with high verbal abilities are more likely to use a linguistic strategy.

In my own work, I have found that study participants tend to prefer strategies for analogical reasoning that place fewer demands on working memory (Sternberg & Ketron, 1982). They learn better when taught in ways that fit their preferred strategies (Sternberg, Grigorenko, Ferrari, & Clinkenbeard, 1999). In such strategies, study participants encode as few features as possible of complex stimuli, trying to disconfirm incorrect multiple-choice options on the basis of these few features, and then choosing the remaining answer as the correct one. Similarly, study participants choose different strategies in linear–syllogistic reasoning (spatial, linguistic, mixed spatial–linguistic), but in this task, they do not always capitalize on their ability patterns to choose the strategy most suitable to their respective levels of spatial and verbal abilities (Sternberg & Weil, 1980). In sum, the selection of a strategy seems to be at least as important for understanding intelligent task performance as the efficacy with which the chosen strategy is implemented.

Intimately tied up with the selection of a strategy is the selection of a mental representation for information. Investigators have realized that people are quite flexible in their representations of information. The most appropriate question to ask seems to be not how such information is represented, but which representations are used in what circumstances. For example, I (Sternberg, 1977) found that analogy problems using animal names can draw on either spatial or clustering representations of the animal names. In the studies of strategy choice mentioned earlier, it was found that study participants can use either linguistic or spatial representations in solving sentence–picture comparisons (MacLeod et al., 1978) or linear syllogisms (Sternberg & Weil, 1980). We (Sternberg & Rifkin, 1979) found that the mental representation of certain kinds of analogies can be either more or less holistic, depending on the ages of the study participants. Younger children tend to be more holistic in their representations.

As important as any other metacomponent is the ability to allocate one's mental resources. Different investigators have studied resource allocation in different ways. I have found that better problem solvers tend to spend relatively more time in global strategy planning (Sternberg, 1981b, 1981c). Similarly, in solving analogies, better analogical reasoners seem to spend relatively more time encoding the terms of the problem than do poorer reasoners, but relatively less time in operating on these encodings (Sternberg, 1977; Sternberg & Rifkin, 1979). In reading as well, superior readers are better able than poorer readers to allocate their time across reading passages as a function of the difficulty of the passages to be read and the purpose for which the passages are being read (see Brown, Bransford, Ferrara, & Campione, 1983; Spear-Swerling & Sternberg, 1994; Wagner & Sternberg, 1987).

Finally, monitoring one's thinking and solution processes is a key aspect of intelligence (see also Brown, 1978; Conway et al., 2011; Otero, 2015). Consider, for example, the "missionaries and cannibals" problem, in which the study participants must "transport" a set of missionaries and cannibals across a river in a small boat without allowing the cannibals an opportunity to eat the missionaries—an event that can transpire only if the cannibals are allowed to outnumber the missionaries on either side of the river bank. The main kinds of errors that can be made are either to return to an earlier state in the problem space for solution (i.e., the problem solver goes back to where he or she was earlier in the solution process) or to make an impermissible move (i.e., the problem solver violates the rules, as in allowing the number of cannibals on one side to exceed the number of missionaries on that side) (Simon & Reed, 1976; see also Sternberg, 1982). Neither of these errors will result if a given participant closely monitors his or her solution processes. For young children, learning to count, a major source of errors in counting objects is to count a given object twice; again, such errors can result from failures in solution monitoring (Gelman & Gallistel, 1978). The effects of solution monitoring are not limited, of course, to any one kind of problem. One's ability to use the strategy of means–ends analysis (Newell & Simon, 1972)—that is, reduction of differences between where one is solving a problem and where one wishes to get in solving that problem—depends on one's ability to monitor just where one is in problem solution.

Performance Components

Performance components are lower-order processes that execute the instructions of the metacomponents. These lower-order components solve the problems according to the plans laid out by the metacomponents. Whereas the number of metacomponents used in the performance of various tasks is relatively limited, the number of performance components is probably quite large. Many of these performance components are relatively specific to narrow ranges of tasks (Sternberg, 1979, 1983, 1985a).

One of the most interesting classes of performance components is that found in inductive reasoning of the kind measured by tests such as matrices, analogies, series completions, and classifications. These components are important because of the importance of the tasks into which they enter: Induction problems of these kinds show the highest loading on the so-called *g*, or general intelligence factor (Jensen, 1980, 1998; Ortiz, 2015; Snow & Lohman, 1984; Sternberg & Gardner, 1982; see essays in Sternberg & Grigorenko, 2002). Thus identifying these performance components can give us some insight into the nature of the general factor. I am not arguing for any one factorial model of intelligence (i.e., one with a general factor) over others; on the contrary, I believe that most factor models are mutually compatible, differing only in the form of rotation that has been applied to a given factor space (Sternberg, 1977). The rotation one uses is a matter of theoretical or practical convenience, not of truth or falsity.

Knowledge Acquisition Components

Knowledge acquisition components are used to learn how to do what the metacomponents and performance components eventually do. Three knowledge acquisition components appear to be central in intellectual functioning: (1) selective encoding, (2) selective combination, and (3) selective comparison.

Selective encoding involves sifting out relevant from irrelevant information. When new information is presented in natural contexts, relevant information for one's given purpose is embedded in the midst of large amounts of purpose-irrelevant information. A critical task for the learner is that of "sifting the wheat from the chaff," or recognizing just what among all the pieces of information is relevant for one's purposes (see Schank, 1980).

Selective combination involves combining selectively encoded information in such a way as to form an integrated, plausible whole. Simply sifting out relevant from irrelevant information is not enough to generate a new knowledge structure. One must know how to combine the pieces of information into an internally connected whole (see Lohman & Lakin, 2011; Mayer & Greeno, 1972).

Selective comparison involves discovering a nonobvious relationship between new information and already acquired information. For example, analogies, metaphors, and models often help individuals solve problems. The solver suddenly realizes that new information is similar to old information in certain ways, and then uses this information to form a mental representation based on the similarities. Teachers may discover how to relate new classroom material to information that students have already learned. Relating the new to the old can help students learn the material more quickly and understand it more deeply.

My emphasis on components of knowledge acquisition differs somewhat from the focus of some theorists in cognitive psychology, who emphasize what is already known and the structure of this knowledge (e.g., Chase & Simon, 1973; Chi, 1978; Keil, 1984). These various emphases are complementary. If one is interested in understanding, for example, differences in performance between experts and novices, clearly one would wish to look at the amount and structure of their respective knowledge bases. But if one wishes to understand how these differences come to be, merely looking at developed knowledge would not be enough. Rather, one would have to look as well at differences in the ways in which the knowledge bases were acquired. It is here that understanding of knowledge acquisition components will prove to be most relevant.

We have studied knowledge acquisition components in the domain of vocabulary acquisition (e.g., Sternberg, 1987; Sternberg & Powell, 1983). Difficulty in learning new words can be traced, at least in part, to the application of components of knowledge acquisition to context cues stored in long-term memory. Individuals with higher vocabularies tend to be those who are better able to apply the knowledge acquisition components to vocabulary-learning situations. Given the importance of vocabulary for overall intelligence, almost without respect to the theory or test one uses, utilization of knowledge acquisition components in vocabulary-learning situations would appear to be critically important for the development of intelligence.

Effective use of knowledge acquisition components is trainable. I have found, for example, that just 45 minutes of training in the use of these components in vocabulary learning can significantly and fairly substantially improve the ability of adults to learn vocabulary from natural language contexts (Sternberg, 1987). This training involves teaching individuals how to learn meanings of words presented in context. The training consists of three elements. The first is teaching individuals to search out certain kinds of contextual cues, such as synonyms, antonyms, functions, and category memberships. The second is teaching mediating variables. For example, cues to the meaning of a word are more likely to be found close to the word than at a distance from it. The third is teaching process skills—encoding relevant cues, combining them, and relating them to knowledge one already has.

To summarize, then, the components of intelligence are important parts of an individual's intelligence. The various kinds of components work together. Metacomponents activate performance and knowledge acquisition components. These latter kinds of components in turn provide feedback to the metacomponents. Although one can isolate various kinds of information-processing components from task performance through experimental means, in practice the components function together in highly interactive, and not easily isolable, ways. Thus diagnoses as well as instructional interventions need to consider all three types of components in interaction, rather than any one kind of component in isolation. But understanding the nature of the components of intelligence is not in itself sufficient to understand the nature of intelligence because there is more to intelligence than a set of information-processing components. One could scarcely understand all of what it is that makes one person more intelligent than another by understanding the components of processing on, say, an intelligence test. The other aspects of the triarchic theory address some of the other aspects of intelligence that contribute to individual differences in observed performance, outside testing situations as well as within them.

INTELLIGENCE AND EXPERIENCE

Components of information processing are always applied to tasks and situations with which one has some level of prior experience (even if it is minimal experience). Hence these internal mechanisms are closely tied to one's experience. According to the experiential subtheory, the components are not equally good measures of intelligence at all levels of experience. Assessing intelligence requires one to consider not only components, but the level of experience at which they are applied.

According to the experiential subtheory, intelligence is best measured at those regions of the experiential continuum involving tasks or situations that are either relatively novel on the one hand, or in the process of becoming automatized on the other. Totally novel tasks and situations provide poor measures of intelligence: One would not want to administer, say, trigonometry problems to a first grader roughly 6 years old. But one might wish to administer problems that are just at the limits of the child's understanding, in order to test how far this understanding extends. Related is Vygotsky's (1978) concept of the *zone of proximal development,* in which one examines a child's ability to profit from instruction to facilitate his or her solutions of novel problems. To measure automatization skill, one might wish to present a series of problems—mathematical or otherwise—to see how long it takes for their solution to become automatic, and to see how automatized performance becomes. Thus both the slope and the asymptote (if any) of automatization are of interest.

Ability to Deal with Novelty

Several sources of evidence converge on the notion that the ability to deal with relative novelty is a good way of measuring intelligence. Consider three such sources of evidence. First, we have conducted several studies on the nature of insight, both in children and in adults (Davidson & Sternberg, 1984; Sternberg & Davidson, 1982). In the studies with children (Davidson & Sternberg, 1984), we separated three kinds of insights: insights of selective encoding, insights of selective combination, and insights of selective comparison. Use of these knowledge acquisition components is referred to as *insightful* when they are applied in the absence of existing scripts, plans, or frames. In other words, one must decide what information is relevant, how to put the information together, or how new information relates to old, in the absence of any obvious cues on the basis of which to make these judgments. A problem is insightfully solved at the individual level when a given individual lacks such cues (Sternberg & Zhang, 1995). A problem is insightfully solved at the societal level when no one else has these cues, either. In our studies, we found that children who are intellectually gifted are so in part by virtue of their insight abilities, which represent an important part of the ability to deal with novelty (Sternberg, 1981a; Sternberg et al., 2011).

The critical finding was that providing insights to the children significantly benefited the nongifted, but not the gifted, children. (None of the children performed anywhere near ceiling level, so that the interaction was not due to ceiling effects.) In other words, the gifted children spontaneously had the insights and hence did not benefit from being given these insights. The nongifted children did not have the insights spontaneously and hence did benefit. Thus the gifted children were better able to deal with novelty spontaneously.

Ability to Automatize Information Processing

Several converging lines of evidence in the literature support the claim that automatization ability is a key aspect of intelligence. For example, I (Sternberg, 1977) found that the correlation between people–piece (schematic picture) analogy performance and measures of general intelligence increased with practice, as performance on these items became increasingly automatized. Skilled reading is heavily dependent on automatization of bottom-up functions (basic skills such as phonetic decoding), and the ability to read well is an essential part of crystallized ability—whether it is viewed from the standpoint of theories such as Cattell's (1971), Carroll's (1993), or Vernon's (1971), or from the standpoint of tests of crystallized ability, such as the verbal portion of the SAT. Poor comprehenders often are those who have not automatized the elementary, bottom-up processes of reading and hence do not have sufficient attentional resources to allocate to top-down comprehension processes.

Theorists such as Jensen (1982) and Hunt (1978, 1980) have attributed the correlation between such tasks as choice reaction time and letter matching to the relation between speed of information processing and intelligence (see Nettelbeck, 2011). Indeed, there is almost certainly some relation, although I believe it is much more complex than these theorists seem to allow for. But a plausible alternative hypothesis is that at least some of that correlation is due to the effects of automatization of processing: Because of the simplicity of these tasks, they probably become at least partially automatized fairly rapidly, and hence can measure both rate and asymptote of automatization of performance. In sum, then, although the evidence is far from complete, there is at least some support for the notion that rate and level of automatization are related to intellectual skill.

The ability to deal with novelty and the ability to automatize information processing are interrelated, as shown in the example of the automatization of reading described in this section. If one is well able to automatize, one has more resources left over for dealing with novelty. Similarly, if one is well able to deal with novelty, one has more resources left over for automatization. Thus performances at the various levels of the experiential continuum are related to one another.

These abilities should not be viewed in a vacuum with respect to the componential subtheory. The components of intelligence are applied to tasks and situations at various levels of experience. The ability to deal with novelty can be understood in part in terms of the metacomponents, performance components, and knowledge acquisition components involved in it. *Automatization* refers to the way these components are executed. Hence the two subtheories considered so far are closely intertwined. Now we need to consider the application of these subtheories to everyday tasks, in addition to laboratory ones.

INTELLIGENCE AND THE EXTERNAL WORLD OF THE INDIVIDUAL

According to the contextual subtheory, intelligent thought is directed toward one or more of three behavioral goals: *adaptation to an environment, shaping of an environment,* or *selection of an environment.* These three goals may be viewed as the functions toward which intelligence is directed. Intelligence is not aimless or random mental activity that happens to involve certain components of information processing at certain levels of experience. Rather, it is purposefully directed toward the pursuit of these three global goals, all of which have more specific and concrete instantiations in people's lives (Cianciolo & Sternberg, 2018; Sternberg et al., 2000).

Adaptation

Most intelligent thought is directed toward attempts to adapt to one's environment. The requirements for adaptation can differ radically from one environment to another—whether environments are defined in terms of families, jobs, subcultures, or cultures. Hence, although the components of intelligence required in these various contexts may be the same or quite similar, and although all of them may involve (at one time or another) dealing with novelty and automatization of information processing, the concrete instantiations that these processes and levels of experience take may differ substantially across contexts. This fact has an important implication for our understanding of the nature of intelligence. According to the triarchic theory in general, and the contextual subtheory in particular, the processes, experiential facets, and functions of intelligence remain essentially the same across contexts, but the particular instantiations of these processes, facets, and functions can differ radically. Thus the content of intelligent thought and its manifestations in behavior will bear no necessary resemblance across contexts. As a result, although the mental elements that an intelligence test should measure do not differ across contexts, the vehicle for measurement may have to differ. A test that measures a set of processes, experiential facets, or intelligent functions in one context may not provide equally adequate measurement in another context. To the contrary, what is intelligent in one culture may be viewed as unintelligent in another.

Different contextual milieus may result in the development of different mental abilities. For example, Puluwat navigators must develop their large-scale spatial abilities for dealing with cognitive maps to a degree that far exceeds the adaptive requirements of contemporary Western societies (Gladwin, 1970). Similarly, Kearins (1981) found that Australian Aboriginal children probably develop their visual–spatial memories to a greater degree than do Australian children of European descent. The latter are more likely to apply verbal strategies to spatial memory tasks than are the Aboriginal children, who employ spatial strategies. This greater development is presumed to be due to the greater need the Aboriginal children have for using spatial skills in their everyday lives. In contrast, members of Western societies probably develop their abilities for thinking abstractly to a greater degree than do members of societies in which concepts are rarely dealt with outside their concrete manifestations in the objects of the everyday environment.

One of the most interesting differences among cultures and subcultures in the development of patterns of adaptation is in the matter of time allocation, a metacomponential function. In Western cultures in general, careful allocation of time to various activities is a prized commodity. Our lives are largely governed by careful scheduling at home, school, work, and so on. There are fixed hours for certain activities, and fixed lengths of time within which these activities are expected to be completed. Indeed, the intelligence tests we use show our prizing of time allocation to the fullest. Almost all of them are timed in such a way as to make completion of the tests a nontrivial challenge. A slow or cautious worker is at a distinct disadvantage.

Not all cultures and subcultures view time in the same way that we do. For example, among the Kipsigi, schedules are much more flexible; hence these individuals have difficulty understanding and dealing with Western notions of the time pressure under which people are expected to live (Super & Harkness, 1982). In Hispanic cultures, such as Venezuela, my own personal experience indicates that the press of time is taken with much less seriousness than it is in typical North American cultural settings. Even within the continental United States, though, there can be major differences in the importance of time allocation (Heath, 1983; Suzuki, Short, & Lee, 2011).

The point of these examples has been to illustrate how differences in environmental press and people's conception of what constitutes an intelligent response to it can influence just what counts as adaptive behavior. To understand intelligence, one must understand it not only in relation to its internal manifestations in terms of mental processes and its experiential manifestations in terms of facets of the experiential continuum, but also in terms of how thought is intelligently translated into action in a variety of different contextual settings. The differences in what is considered adaptive and intelligent can extend even to different occupations within a given cultural milieu. For example, I (Sternberg, 1985d) have found that individuals in different fields of endeavor (art, business, philosophy, physics) view intelligence in slightly different ways that reflect the demands of their respective fields.

Shaping

Shaping of the environment is often used as a backup strategy when adaptation fails. If one is unable to change oneself to fit the environment, one may attempt to change the environment to fit oneself. For example, repeated attempts to adjust to the demands of one's romantic partner may eventually lead to attempts to get the partner to adjust to oneself. But shaping is not always used in lieu of adaptation. In some cases, shaping may be used before adaptation is ever tried, as in the case of the individual who attempts to shape a romantic partner with little or no effort to shape him- or herself so as to suit the partner's wants or needs better.

In the laboratory, examples of shaping behavior can be seen in strategy selection situations where one essentially molds the task to fit one's preferred style of dealing with tasks. For example, in comparing sentence statements, individuals may select either a verbal or a spatial strategy, depending on their pattern of verbal and spatial ability (MacLeod et al., 1978). The task is "made over" in conformity to what they do best.

Selection

Selection involves renunciation of one environment in favor of another. In terms of the rough hierarchy established so far, selection is sometimes used when both adaptation and shaping fail. Sometimes one attempts to shape an environment only after attempts to leave it have failed. Other times, one may decide almost instantly that an environment is simply wrong and feel that one need not or should not even try to fit into or to change it. For example, every now and then we get a new graduate student who realizes almost immediately that he or she came to graduate school for the wrong reasons, or who finds that graduate school is nothing at all like the continuation of undergraduate school he or she expected. In such cases, the intelligent thing to do may be to leave the environment as soon as possible, to pursue activities more in line with the student's goals in life.

To conclude, adaptation, shaping, and selection are functions of intelligent thought as it operates in context. They may (although they need not) be employed hierarchically, with one path followed when another one fails. It is through adaptation, shaping, and selection that the components of intelligence, as employed at various levels of experience, become actualized in the real world. In this section, it has become clear that the modes of actualization can differ widely across individuals and groups, so that intelligence cannot be understood independently of the ways in which it is manifested.

INSTRUCTIONAL INTERVENTIONS BASED ON THE THEORY

The triarchic theory has been applied to instructional settings in various ways, with considerable but not total success (Sternberg, 2010b; Sternberg & Grigorenko, 2004, 2007; Sternberg, Grigorenko, & Zhang, 2008; Sternberg, Jarvin, & Grigorenko, 2009; Sternberg et al., 2014). The componential subtheory has been applied in teaching the learning of vocabulary from context to adult study participants (Sternberg, 1987), as mentioned earlier. Experimental study participants were taught components of decontextualization. There were three groups, corresponding to three types of instruction that were based on the theory (see Sternberg, 1987, 1988). Control study participants either received no relevant material at all, or else received practical items but without theory-based instruction. Improvement occurred only when study participants were given the theory-based instruction, which involved teaching them how to use contextual cues, mediating variables such as matching parts of speech, and processes of decontextualization.

The experiential subtheory was the basis for the program (Davidson & Sternberg, 1984) that successfully taught insight skills (selective encoding, selective combination, and selective comparison) to children roughly 9–11 years of age. The program lasted 6 weeks and involved insight skills as applied to a variety of subject matter areas. An uninstructed control group received a pretest and a posttest, like the experimental group, but no instruction. We found that the experimental study participants improved significantly more than the controls, both when participants were previously identified as gifted and when they were not so identified. Moreover, we found durable results that lasted even 1 year after the training program, and we found transfer to types of insight problems not specifically used in the program.

The contextual subtheory served as the basis for a program called Practical Intelligence for Schools, developed in collaboration with a team of investigators from Harvard (Gardner, Krechevsky, Sternberg, & Okagaki, 1994; Okagaki & Sternberg, 1993; Sternberg, Okagaki, & Jackson, 1990) and based on Gardner's (2006) theory of multiple intelligences as well as on the triarchic theory. The goal of this program is to teach practical intellectual skills to children roughly 9–11 years of age in the areas of reading, writing, homework, and test taking. The program is completely infused into existing curricula. Over a period of years, we studied the program in a variety of school districts and obtained significant improvements for experimental versus uninstructed control study participants in a variety of criterion measures, including study skills measures and performance-based measures of performance in the areas taught by the program. The program has been shown to increase practical skills, such as those involved in doing homework, taking tests, or writing papers, as well as school achievement (Williams et al., 2002; see Detterman & Sternberg, 1982, for a discussion of attempts to increase intelligence).

We have sought to test the theory of successful intelligence in the classroom. In a first set of studies, we explored the question of whether conventional education in school systematically discriminates against children with creative and practical strengths (Sternberg & Clinkenbeard, 1995; Sternberg, Ferrari, Clinkenbeard, & Grigorenko, 1996; Sternberg et al., 1999). Motivating this work was the belief that the systems in most schools strongly tend to favor children with strengths in memory and analytical abilities. However, schools can be unbalanced in other directions as well.

One school we visited in Russia in 2000 placed a heavy emphasis on the development of creative abilities—much more so than on the development of analytical and practical abilities. While on this trip, we were told of yet another school (catering to the children of Russian businessmen) that strongly emphasized practical abilities, and in which children who were not practically oriented were told that eventually they would be working for their classmates who were practically oriented.

To validate the relevance of the theory of successful intelligence in classrooms, we have carried out a number of instructional studies. In one study, we used the Sternberg Triarchic Abilities Test (Sternberg, 1993). The test was administered to 326 children around the United States and in some other countries who were identified by their schools as gifted by any standard whatsoever (Sternberg et al., 1999). Children were selected for a summer program in (college-level) psychology if they fell into one of five ability groupings: *high-analytical, high-creative, high-practical, high-balanced* (high in all three abilities), or *low-balanced* (low in all three abilities). Students who came to Yale were then assigned at random to four instructional groups, with the constraint that roughly equal numbers with each ability pattern be assigned to each group. Students in all four instructional groups used the same introductory psychology textbook (a preliminary version of Sternberg, 1995) and listened to the same psychology lectures. What differed among them was the type of afternoon discussion section to which they were assigned. They were assigned to an instructional condition that emphasized either memory, analytical, creative, or practical instruction. For example, in the memory condition, they might be asked to describe the main tenets of a major theory of depression. In the analytical condition, they might be asked to compare and contrast two theories of depression. In the creative condition, they might be asked to formulate their own theory of depression. In the practical condition, they might be asked how they could use what they had learned about depression to help a friend who was depressed.

Students in all four instructional conditions were evaluated in terms of their performance on homework, a midterm exam, a final exam, and an independent project. Each type of work was evaluated for memory, analytical, creative, and practical quality. Thus all students were evaluated in exactly the same way. Our results suggested the utility of the theory of successful intelligence. This utility showed itself in several ways.

First, we observed when the students arrived at Yale that the students in the high-creative and high-practical groups were much more diverse in terms of racial, ethnic, socioeconomic, and educational backgrounds than were the students in the high-analytical group, suggesting that correlations of measured intelligence with status variables such as these may be reduced by using a broader conception of intelligence. Thus the kinds of students identified as strong differed in terms of the populations from which they were drawn, in comparison with students identified as strong solely by analytical measures. More importantly, just by expanding the range of abilities measured, we discovered intellectual strengths that might not have been apparent through a conventional test.

Second, we found that all three ability tests—analytical, creative, and practical—significantly predicted course performance. When multiple-regression analysis was used, at least two of these ability measures contributed significantly to the prediction of each of the measures of achievement. In particular, for homework assignments, significant beta weights were obtained for analytical (.25) and creative (.16) ability measures; for the independent project, significant weights were obtained for the analytical (.14), creative (.22), and practical (.14) measures; for the exams, significant weights were obtained for the analytical (.24) and creative (.19) measures (Sternberg et al., 1999). Perhaps as a reflection of the difficulty of deemphasizing the analytical way of teaching, one of the significant predictors was always the analytical score. (However, in a replication of our study with low-income African American students from New York, Deborah Coates of the City University of New York found a different pattern of results. Her data indicated that the practical tests were better predictors of course performance than were the analytical measures, suggesting that which ability test predicts which criterion depends on population as well as mode of teaching.)

Third and most important, there was an aptitude–treatment interaction, whereby students who were placed in instructional conditions that better matched their pattern of abilities outperformed students who were mismatched. In particular, repeated-measures analysis revealed statistically significant effects of match for analytical and creative tasks as a whole. Three of five practical tasks also showed an effect. In other words, when students are taught in a way that fits how they think, they do better in school (see Cronbach & Snow, 1977, for a discussion of the difficulties in eliciting aptitude–treatment interactions). Children who have high levels of creative and practical abilities, but who are almost never taught or assessed in a way that matches their pattern of abilities, may be at a disadvantage in course after course, year after year.

A follow-up study (Sternberg, Torff, & Grigorenko, 1998) examined learning of social studies and science by third graders and eighth graders. The 225 third graders were students in a very low-income neighborhood in Raleigh, North Carolina. The 142 eighth graders were largely middle- to upper-middle-class students studying in Baltimore, Maryland, and Fresno, California; these children were part of a summer program sponsored by the Johns Hopkins University for gifted students. In this study, students were assigned to one of three instructional conditions. Randomization was by classroom. In the first condition, they were taught the course that basically they would have received had there been no intervention. The emphasis in the course was on memory. In a second condition, students were taught in a way that emphasized critical (analytical) thinking. In the third condition, they were taught in a way that emphasized analytical, creative, and practical thinking. All students' performance was assessed for memory learning (through multiple-choice assessments), as well as for analytical, creative, and practical learning (through performance assessments).

As expected, students in the successful-intelligence (analytical, creative, practical) condition outperformed the other students in terms of the performance assessments. For the third graders, respective means were highest for the triarchic (successful-intelligence) condition; second highest for the critical-thinking condition; and lowest for the memory condition for memory, analytical, and creative performance measures. For practical measures, the critical-thinking mean was insignificantly higher than the triarchic mean, but both were significantly higher than the memory mean. For the eighth graders, the results were similar. One could argue that this pattern of results merely reflected the way students were taught. Nevertheless, the result suggested that teaching for these kinds of thinking succeeded. More important, however, was the result that children in the successful-intelligence condition outperformed the other children even on the multiple-choice memory tests. In other words, to the extent that the goal is just to maximize children's memory for information, teaching for successful intelligence is still superior. It enables children to capitalize on their strengths and to correct or to compensate for their weaknesses, and it allows them to encode material in a variety of interesting ways.

We extended these results to reading curricula at the middle school and high school levels (Grigorenko, Jarvin, & Sternberg, 2002). In a study of 871 middle school students and 432 high school students, we taught reading either triarchically or through the regular curriculum. Classrooms were assigned randomly to treatments. At the middle school level, reading was taught explicitly. At the high school level, reading was infused into instruction in mathematics, physical sciences, social sciences, English, history, foreign languages, and the arts. In all settings, students who were taught triarchically substantially outperformed students who were taught in standard ways. Effects were statistically significant at the .001 level for memory, analytical, creative, and practical comparisons.

Thus the results of three sets of studies suggest that the theory of successful intelligence is valid as a whole. Moreover, the results suggest that the theory can make a difference not only in laboratory tests, but in school classrooms and even the everyday lives of adults as well. At the same time, the studies have weaknesses that need to be remedied in future studies. The samples were relatively small and not fully representative of the entire U.S. population. Moreover, the studies have examined a limited number of alternative interventions. All interventions were of relatively short duration (up to a semester-long course). In addition, future studies should look at durability and transfer of training.

In one study (Sternberg et al., 2014), we attempted to upscale our efforts to hundreds of teachers and many thousands of fourth-grade students located in elementary schools across the United States. The results were not particularly encouraging. Although triarchic instruction was better than alternative instruction in some conditions, it was not better in other conditions. When one obtains null results, of course there can be many interpretations. But one thing was clear: Our small staff lost control of fidelity of implementation. That is, we did not always have good control over how well the programs were implemented. Unfortunately, we had a similar experience in an upscaled teaching-for-wisdom study (Sternberg, Jarvin, & Reznitskaya, 2008; Sternberg, Reznitskaya, & Jarvin, 2007). The bottom line is that if one is seeking to implement an intervention program on a large scale, one needs sufficient monitors of the implementation to ensure fidelity to the pedagogical principles of the program.

In sum, the triarchic theory serves as a useful basis for educational interventions; in our own work, it has shown itself to be a basis for interventions that improve students' performance relative to that of controls who do not receive the theory-based instruction.

ASSESSMENT STUDIES

One of the primary venues for assessing abilities is university admissions. When universities make decisions about selective admissions, the main quantitative data they have available to them are typically (1) GPA in high school or its equivalent, and (2) scores on standardized tests (Lemann, 2000). Is it possible to create assessments that are psychometrically sound and that provide incremental validity over existing measures, without destroying the cultural and ethnic diversity that makes a university environment a place in which students can interact with and learn from others who are different from themselves?

The Rainbow Project

The Rainbow Project (for details, see Sternberg, 2009, 2010a; Sternberg, Bonney, Gabora, Karelitz, & Coffin, 2010; Sternberg, Bonney, Gabora, & Merrifield, 2012; Sternberg & the Rainbow Project Collaborators, 2005, 2006) was a first project designed to enhance university admissions procedures at the undergraduate level. The Rainbow measures were intended to supplement the SAT in the United States, but they can supplement any conventional standardized test of abilities or achievement. In the theory of successful intelligence, abilities and achievement are viewed as being on a continuum—abilities are largely achieved (Sternberg, 1998, 1999)—so it is not clear that it matters greatly exactly what test is used, given that most of the tests used are highly *g*-loaded.

The SAT is a comprehensive examination currently measuring verbal comprehension and mathematical thinking skills, with a writing component recently added. A wide variety of studies have shown the utility of the SAT and similar tests as predictors of university and job success, with success in college typically measured by GPA (Schmidt & Hunter, 1998). Taken together, these data suggest reasonable predictive validity for the SAT in predicting undergraduate performance. Indeed, traditional intelligence or aptitude tests have been shown to predict performance across a wide variety of settings. But as is always the case for a single test or type of test, there is room for improvement. The theory of successful intelligence provides one basis for improving prediction and possibly for establishing greater equity and diversity, which is a goal of most higher-educational institutions (Bowen, Kurzweil, & Tobin, 2006). It suggests that broadening the range of skills tested to go beyond analytic skills, to include practical and creative skills as well, might significantly enhance the prediction of undergraduate performance beyond current levels. Thus the theory does not suggest *replacing,* but rather *augmenting,* the SAT and similar tests (such as the ACT or, in the United Kingdom, the A-levels) in the undergraduate admissions process. Our collaborative team of investigators sought to study how successful such an augmentation could be. Even if we did not use the SAT, ACT, or A-levels in particular, we still would need some kind of assessment of the memory and analytical abilities these tests measure.

Methodological Considerations

In the Rainbow Project, data were collected at 15 schools across the United States, including 8 four-year undergraduate institutions, 5 community colleges, and 2 high schools.

The participants were 1,013 students predominantly in their first year as undergraduates or their final year of high school. In this chapter, analyses only for undergraduate students are discussed because they were the only ones for whom my colleagues and I had data available regarding undergraduate academic performance. The final number of participants included in these analyses was 793.

Baseline measures of standardized test scores and high school GPAs were collected to evaluate the predictive validity of current tools used for undergraduate admission criteria, and to provide a contrast for the current measures. Students' scores on standardized university entrance exams were obtained from the College Board.

The measure of analytical skills was provided by the SAT, plus multiple-choice analytical items we added to measure inference of meanings of words from context, number series completions, and figural matrix completions.

Creative skills were measured by multiple-choice items and by performance-based items. The multiple-choice items were of three kinds. In one, students were presented with verbal analogies preceded by counterfactual premises (e.g., money falls off trees). They had to solve the analogies as though the counterfactual premises were true. In a second, students were presented with rules for novel number operations—for example, *flix,* which involves numerical manipulations differing as a function of whether the first of two operands is greater than, equal to, or less than the second. Participants had to use the novel number operations to solve presented math problems. In a third, participants were first presented with a figural series involving one or more transformations; they then had to apply the rule of the series to a new figure with a different appearance, and complete the new series. These measures are not typical of assessments of creativity and were included for relative quickness of participants' responses and relative ease of scoring (cf. Niu & Sternberg, 2003). Also, they measured various types of creativity (Sternberg, 2005a).

Creative skills were also measured with open-ended measures. One measure required writing two short stories with a selection from among unusual titles, such as "The Octopus's Sneakers"; one required orally telling two stories based on choices of picture collages; and the third required captioning cartoons from among various options. Open-ended performance-based answers were rated by trained raters for novelty, quality, and task-appropriateness. Multiple judges were used for each task, and satisfactory reliability was achieved (Sternberg & the Rainbow Project Collaborators, 2005, 2006).

Multiple-choice measures of practical skills were of three kinds. In one, students were presented with a set of everyday problems in the life of an adolescent and had to select the option that would best solve each problem. In another, students were presented with scenarios requiring the use of math in everyday life (e.g., buying tickets for a ball game) and had to solve math problems based on the scenarios. In a third, students were presented with a map of an area (e.g., an entertainment park) and had to answer questions about navigating effectively through the area depicted by the map.

Practical skills were also assessed with three situational-judgment inventories: the Everyday Situational Judgment Inventory (Movies), the Common Sense Questionnaire, and the College Life Questionnaire, each of which taps different types of tacit knowledge. The general format of tacit-knowledge inventories has been described elsewhere (Sternberg et al., 2000), so only the contents of the inventories used in this study are described here. The movies presented everyday situations that confront undergraduates, such as a student's asking for a letter of recommendation from a professor who shows, through nonverbal cues, that he does not recognize the student very well. Participants then had to rate various options for how well they would work in response to each situation. The Common Sense Questionnaire provided everyday business problems, such as being assigned to work with a coworker whom one cannot stand. The College Life Questionnaire provided everyday university situations for which a solution was required.

Unlike the creativity performance tasks, in the practical performance tasks the participants were not given a choice of situations to rate. For each task, participants were told that there was no "right" answer, and that the options described in each situation represented variations on how different people approach different situations.

Consider examples of the kinds of items participants might find on the Rainbow assessment. An example of a creative item might be to write a story using the title "3516" or "It's Moving Backward." Another example might show a collage of pictures in which people are engaged in a wide variety of activities helping other people. A participant would then orally tell a story based on the collage. An example of a practical item might show a movie in which a student has just received a poor grade on a test. His roommate has had a health crisis the night before, and he has been up all night helping him. His professor hands him back the test paper, with a disappointed look on her face, and suggests to the student that he study harder next time. The movie then stops. Participants would then have to describe how the student might handle the situation. Or the participants might receive a written problem describing a conflict with another individual with whom a student is working on a group project. The project is getting mired down in the interpersonal conflict. The participants had to indicate how the student might resolve the situation to get the project done.

All materials were administered in either of two formats. A total of 325 of the university students took the test in paper-and-pencil format, whereas a total of 468 students took the test on the computer via the World Wide Web. No strict time limits were set for completing the tests, although the instructors were given rough guidelines of about 70 minutes per session. The time taken to complete the battery of tests ranged from 2 to 4 hours.

As a result of the lengthy nature of the complete battery of assessments, participants were administered parts of the battery in an intentionally incomplete overlapping design. The participants were randomly assigned to the test sections they were to complete. Details about the use of this procedure are given in Sternberg and the Rainbow Project Collaborators (2006).

Creativity in the Rainbow Project (and the subsequent Project Kaleidoscope) was assessed on the basis of the novelty and quality of responses. Practicality was assessed on the basis of the feasibility of the products with respect to human and material resources.

Findings

The analysis described below is a conservative one that does not correct for differences in the selectivity of the institutions at which the study took place. In a study across so many undergraduate institutions differing in selectivity, validity coefficients will seem to be lower than is typical because an A at a less selective institution counts the same as an A at a more selective institution. When we corrected for institutional selectivity, the results described below became stronger. But correcting for selectivity has its own problems (e.g., on what basis does one evaluate selectivity?), and so uncorrected data are used in this chapter. We also did not control for university major: Different universities may have different majors, and the exact course offerings, grading, and populations of students entering different majors may vary from one university to another, rendering control difficult.

When we examined undergraduate students alone, the sample showed slightly higher mean SAT scores than those found in undergraduate institutions across the United States. The standard deviation was above the normal 100-point standard deviation, meaning that we did not suffer from restriction of range. Our means, although slightly higher than typical, were within the range of average undergraduate students.

Another potential concern was pooling data from different institutions. We pooled data because in some institutions we simply did not have large enough numbers of cases for the data to be meaningful.

Some scholars believe that there is only one set of skills that is highly relevant to school performance—what is sometimes called *general ability*, or *g* (e.g., Jensen, 1998). These scholars believe that tests may appear to measure different skills, but when statistically analyzed, show themselves just to be measuring the single general ability. Did the Rainbow tests actually measure distinct analytical, creative, and practical skill groupings? Factor analysis addressed this question. Three meaningful factors were extracted from the data: practical performance tests, creative performance tests, and multiple-choice tests (including analytical, creative, and practical). In other words, multiple-choice tests, regardless of what they were supposed to measure, clustered together. Thus method variance proved to be very important. The results show the importance of using multiple formats to measure skills, precisely because method is so important in determining factorial structure. The results show the limitations of exploratory factor analysis in analyzing such data, and also of dependence on multiple-choice items outside the analytical domain. In the ideal situation, one wishes to ensure that one controls for method of testing in designing aptitude and other test batteries.

Undergraduate admissions offices are not interested, exactly, in whether these tests predict undergraduate academic success. Rather, they are interested in the extent to which these tests predict school success *beyond* those measures currently in use, such as the SAT and high school GPA. In order to test the incremental validity provided by Rainbow measures above and beyond the SAT in predicting GPA, we conducted a series of hierarchical regressions that included the items analyzed above in the analytical, creative, and practical assessments.

If one looks at the simple correlations, the SAT (both verbal and math), high school GPA, and the Rainbow measures all predicted first-year undergraduate GPA. But how did the Rainbow measures fare on incremental validity? In one set of analyses, the SAT (both verbal and math) and high school GPA were included in the first step of the prediction equation because these are the standard measures used today to predict undergraduate performance. Only high school GPA contributed uniquely to prediction of undergraduate GPA. Inclusion of the Rainbow measures roughly doubled prediction (percentage of variance accounted for in the criterion) over that obtained with the SAT alone.

These results suggest that the Rainbow tests add considerably to the predictive power of the SAT alone. They also suggest the power of high school GPA in prediction, particularly because it is an atheoretical composite that includes within it many variables, including motivation and conscientiousness.

Studying group differences requires careful attention to methodology and sometimes has led to erroneous conclusions (Hunt & Carlson, 2007). Although one important goal of the Rainbow Project was to predict success in the undergraduate years, another important goal involved developing measures that would reduce ethnic group differences in mean levels. There has been a lively debate as to why there are socially defined racial group differences, and as to whether scores for members of underrepresented minority groups are over- or underpredicted by SATs and related tests (see, e.g., Bowen & Bok, 2000; Rushton & Jensen, 2005; Sternberg, Grigorenko, & Kidd, 2005; Turkheimer, Haley, Waldron, D'Onofrio, & Gottesman, 2003). There are a number of ways one can test for group differences in these measures, each of which involves a test of the size of the effect of ethnic group. Two different measures were chosen: ω^2 (omega squared) and Cohen's *d*.

There were two general findings. First, in terms of overall differences, the Rainbow tests appeared to reduce ethnic group differences, relative to traditional assessments of abilities like the SAT. Second, in terms of specific differences, it appears that the Hispanic American students benefited the most from the reduction of group differences. The African American students, too, seemed to show a reduction in difference from the European American mean for most of the Rainbow tests, although a substantial difference appeared to be maintained with the practical performance measures.

Although the group differences were not perfectly reduced, these findings suggest that measures can be designed that reduce ethnic and racial group differences on standardized tests, particularly for historically disadvantaged groups such as African American and Hispanic American students. These findings have important implications for reducing adverse impact in undergraduate admissions.

The SAT is based on a conventional psychometric notion of cognitive skills. Using this notion, it has had substantial success in predicting undergraduate academic performance. The Rainbow measures alone roughly doubled the predictive power of undergraduate GPA when compared to the SAT alone. In addition, the Rainbow measures predicted substantially beyond the contributions of the SAT and high school GPA. These findings, combined with encouraging results regarding the reduction of between-ethnicity differences, make a compelling case for furthering the study of the measurement of analytic, creative, and practical skills for predicting success at a university.

One important goal for this research was, and for future studies still is, the creation of standardized assessments that reduce the different outcomes between different groups as much as possible to maintain test validity. The measures described here suggest results toward this end. Although the group differences in the tests were not reduced to zero, the tests did substantially attenuate group differences relative to other measures such as the SAT. This finding could be an important step toward ultimately ensuring fair and equal treatment for members of diverse groups in the academic domain.

The principles behind the Rainbow Project apply at other levels of admissions as well. For example, we (Hedlund, Wilt, Nebel, Ashford, & Sternberg, 2006) have shown that the same principles can be applied in admissions to business schools, also with the result of increasing prediction and decreasing ethnic (as well as gender) group differences. Another study (Stemler, Grigorenko, Jarvin, & Sternberg, 2006) has found that including creative and practical items in augmented Advanced Placement psychology and statistics examinations can reduce ethnic group differences on the tests. Comparable results were found for the Advanced Placement physics examination (Stemler, Sternberg, Grigorenko, Jarvin, & Sharpes, 2009). And the same principles were employed in a test for assessing the abilities of students in elementary school (Chart, Grigorenko, & Sternberg, 2008).

It is one thing to have a successful research project, and another actually to implement the procedures in a high-stakes situation. We have had the opportunity to do so. The results of a second project, Project Kaleidoscope, are reviewed here.

Project Kaleidoscope

Tufts University in Medford, Massachusetts, has strongly emphasized the role of active citizenship in education. It has put into practice some of the ideas from the Rainbow Project. In collaboration with former Dean of Admissions Lee Coffin, my colleagues and I instituted Project Kaleidoscope, which represents an implementation of the ideas of the Rainbow Project, but goes beyond that project to include in its assessment the construct of wisdom (for more details, see Sternberg, 2007, 2010a, 2010b, 2010c; Sternberg et al., 2010, 2012).

For all of the over 15,000 students applying to the School of Arts and Sciences and the School of Engineering at Tufts, we placed on the 2006–2007 application questions designed to assess wisdom (analytical and practical), intelligence, and creativity synthesized (WICS)—an extension of the theory of successful intelligence (Sternberg, 2003c). The program still continues, but the data reported here are for the first year, for which we have more nearly complete data (see Sternberg, 2010a).

The WICS theory extends the theory of successful intelligence on the basis of the notion that some people may be academically and even practically intelligent, but unwise—as in the case of numerous corporate and political scandals in which the perpetrators were smart, well educated, and foolish. The conception of wisdom used here is the balance theory of wisdom (Sternberg, 2003c), according to which wisdom is the application of intelligence, creativity, and knowledge for the common good, by balancing intrapersonal, interpersonal, and extrapersonal interests over the long and short terms, through the infusion of positive ethical values. Unwise people often fail on the ethical dimension, or skirt its edges (Sternberg, 2012a).

The questions are optional. Whereas the Rainbow Project was done as a separate set of high-stakes tests administered with a proctor, Project Kaleidoscope was (and continues to be) done as a section of the Tufts-specific supplement to the Common Application. It just was not practical to administer a separate high-stakes test battery such as the Rainbow measures for admission to one university. Moreover, the advantage of Project Kaleidoscope is that it got us away from the high-stakes testing situation in which students must answer complex questions in very short amounts of time under incredible pressure.

Students were encouraged to answer just a single question, so as not overly to burden them. Tufts University competes for applications with many other universities, and if the Tufts application had been substantially more burdensome than those of competitor schools, it would have put Tufts at a real-world disadvantage in attracting applicants. In the theory of successful intelligence, individuals with such intelligence capitalize on strengths and compensate for or correct weaknesses. Our format gave students a chance to capitalize on a strength.

As examples of items, a creative question asked students to write stories with titles such as "The End of MTV" or "Confessions of a Middle-School Bully." Another creative question asked students what the world would be like if some historical event had come out differently—for example, if Rosa Parks had given up her seat on the bus. Yet another creative question, a nonverbal one, gave students an opportunity to design a new product or an advertisement for a new product. A practical question queried how students had persuaded friends of an unpopular idea they held. A wisdom question asked students how a passion they had could be applied toward a common good.

Creativity and practicality were assessed in the same way as in the Rainbow Project. Analytical quality was assessed by the organization, logic, and balance of the essay. Wisdom was assessed by the extent to which the response represented the use of abilities and knowledge for a common good by balancing one's own, others', and institutional interests over the long and short terms through the infusion of positive ethical values.

Note that the goal was (and still is) not to replace the SAT and other traditional admissions measurements (e.g., GPA and class rank) with some new test. Rather, it was to reconceptualize applicants in terms of academic/analytical, creative, practical, and wisdom-based abilities, using the essays as one but not the only source of information. For example, highly creative work submitted in a portfolio could also be entered into the creativity rating, as could evidence of creativity through winning of prizes or awards. The essays were major sources of information, but if other information was available, the trained admissions officers used it.

Among the applicants who were evaluated as being academically qualified for admission, approximately half completed an optional essay in the first year and two-thirds in later years. Doing these essays had no meaningful effect on chances of admissions. However, *quality* of essays or other evidence of creative, practical, or wisdom-based abilities did have an effect. For those applicants given an A (top rating) by a trained admission officer in any of these three categories, average rates of acceptance were roughly double those for applicants not getting an A. Because of the large number of essays (over 8,000), only one rater rated applicants except for a sample to ensure that interrater reliability was sufficient, which it was.

Many measures did not look like conventional standardized tests, but had statistical properties mimicking them. We were therefore interested in convergent–discriminant validation of our measures. The correlation of our measures with a rated academic composite that included SAT scores and high school GPA were modest but significant for creative thinking, practical thinking, and wise thinking. The correlations with a rating of quality of extracurricular participation and leadership were moderate for creative, practical, and wise thinking. Thus the pattern of convergent–discriminant validation was what we had hoped for.

The average academic quality of applicants in the Tufts School of Arts and Sciences rose slightly in 2006–2007, the first year of the project, in terms of both SAT and high school GPA. In addition, there were notably fewer students in what before had been the bottom third of the pool in terms of academic quality. Many of those students, seeing the new application, seem to have decided not to bother to apply. Many more strong applicants applied.

Thus adopting these new methods does not seem to result in less qualified applicants applying to the institution and being admitted. Rather, the applicants who are admitted are *more* qualified, but in a broader way. Perhaps most rewarding were the positive comments from large numbers of applicants that they felt our application gave them a chance to show themselves for who they were. Of course, many factors are involved in admissions decisions, and Project Kaleidoscope ratings were only one small part of the overall picture.

We did not get meaningful differences across ethnic groups—a result that surprised us, given that the earlier Rainbow Project reduced but did not eliminate differences. And after a number of years in which applications by underrepresented minorities were relatively flat in terms of numbers, during 2006–2007 they went up substantially. In the end, applications from African Americans and Hispanic Americans increased significantly, and admissions of African Americans were up 30% and of Hispanic Americans up 15%. So the Project Kaleidoscope results, like those of the Rainbow Project, showed that it is possible to increase academic quality and diversity simultaneously, and to do so for an entire undergraduate class at a major university, not just for small samples of students at some scattered schools. Most importantly, we sent a message to students, parents, high school guidance counselors, and others that we believe there is more to a person than the narrow spectrum of skills assessed by standardized tests, and that these broader skills can be assessed in a quantifiable way.

The Panorama Project

When I went to Oklahoma State University in 2010 as provost and senior vice president, Vice President for Enrollment Management Kyle Wray and his team of admissions officers instituted the Panorama Project, which was loosely based on Kaleidoscope but was oriented toward the very different group of students applying to Oklahoma State University as opposed to Tufts University. I left Oklahoma State before formal results were collected, but the admissions office was pleased with the results, and the project continues today.

BEYOND TRADITIONAL THEORIES OF INTELLIGENCE

The triarchic theory consists of three interrelated subtheories that attempt to account for the bases and manifestations of intelligent thought; as such, it represents an expanded view of intelligence that departs from traditional, general, and dichotomous theoretical perspectives. The componential subtheory relates intelligence to the internal world of the individual. The experiential subtheory relates intelligence to the experience of the individual with tasks and situations. The contextual subtheory relates intelligence to the external world of the individual. The elements of the three subtheories are interrelated: The components of intelligence are manifested at different levels of experience with tasks, and in situations of varying degrees of contextual relevance to a person's life. The components of intelligence are posited to be universal to intelligence; thus the components that contribute to intelligent performance in one culture do so in all other cultures as well. Moreover, the importance of dealing with novelty and the automatization of information processing to intelligence are posited to be universal. But the manifestations of these components in experience are posited to be relative to cultural contexts. What constitutes adaptive thought or behavior in one culture is not necessarily adaptive in another culture. Moreover, thoughts and actions that would shape behavior in appropriate ways in one context might not shape them in appropriate ways in another context. Finally, the environment one selects will depend largely on the available environments and on the fit of one's cognitive abilities, motivation, values, and affects to the available alternatives.

CHAPTER 6

Redefining Intelligence with the Planning, Attention, Simultaneous, and Successive Theory of Neurocognitive Processes

Jack A. Naglieri
Tulio M. Otero

Practitioners and test authors have become increasingly conscious of the need for theory-based intelligence tests. Although several theories of intelligence have been attached to traditional ability tests such as the Wechsler scales (Plucker & Esping, 2014), one theory, first described by Das, Kirby, and Jarman (1979), was used explicitly to develop a new way to construct an intelligence test. In 1997, Naglieri and Das (1997a) published the Cognitive Assessment System (CAS), which was based on a neurocognitive theory called *planning, attention, simultaneous, and successive* (PASS) processing. These authors argued that a neurocognitive theory of intelligence provides the foundation necessary for test construction and is equally important for test interpretation. They also suggested that traditional IQ tests, which were based largely on the work of the U.S. military (see Naglieri, 2015), were too limited and could be improved if the constructs that were measured were related to brain functions. Naglieri and Das anticipated that the PASS neurocognitive approach would yield better diagnostic information, have relevance to instructional decision making, and be more appropriate for diverse populations (Naglieri & Otero, 2011, 2017).

The PASS neurocognitive theory is a concept of intelligence and human learning that is best measured with tests devised explicitly to measure the four PASS processes. PASS theory has been most recently operationalized in the Cognitive Assessment System—Second Edition (CAS2; Naglieri, Das, & Goldstein, 2014a), the CAS2: Español (Naglieri, Moreno, & Otero, 2017), the CAS2: Brief (Naglieri, Das, & Goldstein, 2014b), and the CAS2: Rating Scale (Naglieri, Das, & Goldstein, 2014c). We describe these measures comprehensively in Chapter 15 of this book. In this chapter, we focus on the PASS theory upon which all of these measures are based.

The PASS theory and the CAS2 provide a neurocognitive perspective on ability that differs from that of traditional batteries (those including, in part, subtests requiring verbal and quantitative knowledge). These batteries have been used since the Army mental testing program described by Yoakum and Yerkes (1920) almost 100 years ago. The PASS theory, as operationalized by the CAS and CAS2, has created an opportunity to move the field of intelligence and ability testing forward by emphasizing (1) that a *test* of intelligence should be based on a *theory* of intelligence and (2) that the test should measure basic neurocognitive processes defined by the intellectual demands of the test, not the content of the questions. Naglieri and colleagues further assert that a test of intelligence should be designed explicitly to measure specific constructs defined by the theory. This assertion raises two important questions: First, what is a theory? Second, what is a neurocognitive process? Both questions are answered next.

A *theory* is an organized set of concepts that explains a phenomenon or set of phenomena, preferably in the most parsimonious manner. Theories are concise, coherent, systematic, predictive, and broadly applicable, often integrating and generalizing many hypotheses. As such, a test of neurocognitive functions should measure psychological processes on the basis of a coherent theory that provides useful information in a concise and systematic way. There are different definitions in the literature for the term *psychological process*. However, all definitions share the notion that a psychological process involves the performance of some composite cognitive activity. Moreover, a test of neurocognitive processing should measure *thinking* apart from *knowing*.

Consider the four test questions that appear in Figure 6.1. The verbal analogy requires *knowledge* of verbal concepts (*girl, woman, boy*, etc.) and relationships among those concepts. To answer the first question in Figure 6.1 (top left), the child needs to understand that a girl becomes a woman, and similarly that a boy becomes a man. The relationships between the younger and older persons need to be comprehended to arrive at the correct answer. The second question (middle left) requires *knowledge* of a number series: The child must examine the series and detect that the numbers double from 3 to 6 and 6 to 12. The third question (bottom left) requires that the relationship between a pair of chords (C^7 and F major) is understood to figure out that an E^7 would be followed by an A major chord. In these examples, the examinee must know certain facts to understand the relationships among the words, numbers, and musical chords. In the fourth example—the drawing at right, in which only shapes are provided—the relationships among the shapes must be understood to answer the question (small oval becomes big; small rectangle also becomes big), but knowledge of the names of the shapes is not needed. In these examples, the solution is based on the examinee's ability to *recognize and understand the relationships* between the words, numbers, musical notations, or shapes. Despite these differences in content, the thinking is the same (Simultaneous processing, in PASS theory).

As noted above, a theory of intelligence did not influence the content of traditional IQ tests first introduced more than 100 years ago (Naglieri, 2015). In recent years, considerable efforts have been made to reconceptualize already published tests within some theoretical model. For example, the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014) has been linked to the Cattell–Horn–Carroll (CHC) view of intelligence (called a *theory of cognitive abilities* in Chapter 3 of this volume), but was never developed on the basis of that view. We suggest that applying a view of intelligence to already entrenched tests does not help the field advance. Instead, we advocate that a modern test of intelligence should be based on a clearly defined theory. Our choice is the PASS theory. In this chapter, we discuss the origins of PASS theory, describe three functional

Girl is to woman as boy is to ____?
a. Sister
b. Woman
c. Man
d. Brother

Which number is next in the series:
3, 6, 12, ____?

Which chord comes next?
C^7, F, E^7, ____?

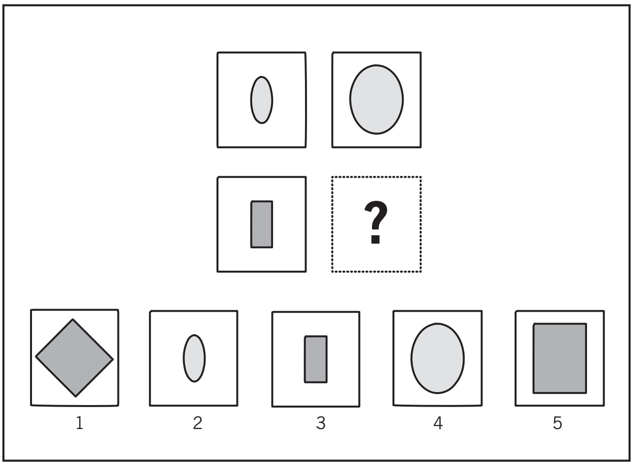

FIGURE 6.1. An illustration of the same kind of thinking applied to different content.

units of the brain as originally articulated by Luria, explain how the PASS processes were operationalized, and summarize the current empirical support for the theory.

ORIGINS OF THE PASS THEORY

The functional aspects of brain structures as delineated in the work of Alexander Luria (1966, 1973a, 1973b, 1980) were the underpinnings of PASS theory (Naglieri & Das, 1997a). Naglieri and Das used Luria's work as a blueprint for defining the important components of a neurocognitive view of intelligence (Das, Naglieri, & Kirby, 1994; Naglieri & Das, 1997a; Naglieri et al., 2014a) because they believed strongly that a test of intelligence should be based on a *theory of intelligence,* and that a working theory of intelligence should be based on an understanding of basic neurocognitive processes and consistent with neuropsychology and neuroscience. Their efforts represented the first time that a specific researched neurocognitive theory was used to reconceptualize the concept of intelligence and develop a specific tool to measure that theory.

Luria theorized that human cognitive functions can be conceptualized within a framework of three separate but related brain systems that provide four basic psychological processes. The three brain systems are referred to as *functional units* because the neurocognitive mechanisms work in separate but interrelated systems. Although Luria lacked the sophisticated neuroscientific resources that exist today, his conceptualization of how the brain functions still stands as valid. For example, studies using functional imaging technology (Avram et al., 2013; Yeo et al., 2011; Zaytseva et al., 2014) have shown that each area of the brain participates in numerous large- and small-scale functional systems within and across cortical and subcortical brain structures (for supportive research in the neuroscience literature, see Koziol, Barker, Joyce, & Hrin, 2014; Koziol, Beljan, Bree, Mather, & Barker, 2016,).

Luria (1973b) stated that "each form of conscious activity is always a complex functional system and takes place through the combined working of all three brain units, each of which makes its own contribution" (p. 99). Luria's assertion remains fundamentally true. Cognition and behavior *are products of functional brain networks,* and these networks have a profound impact on constructs such as attention, executive function, learning and memory, and information processing. Much of early neuropsychology has traditionally interpreted tests within a serial-order processing paradigm (Koziol et al., 2014): First we perceive, then we think, and then we react.

Children, adolescents, and adults are continuously responding to an ever-changing, dynamic environment, however. This makes a static paradigm insufficient for understanding and measuring neurocognitive processes, as well as for interpreting test performance. As we are constantly bombarded by external and internal stimuli, there must be some brain mechanisms that allow us to funnel and direct information by activating and inhibiting different brain regions dynamically. Once information is selected for further processing, there must be some way for different brain regions to communicate to integrate the required information. Whether in our daily lives or during psychological assessment, there must also be a mechanism for allowing the brain to shift from the demands of one task to the demands of another. In other words, there must be a process allowing different parts of the brain to communicate and interact as we continuously adapt to ever-changing demands of different tasks.

Brain regions never function in seclusion, but any given cortical region is characterized by a certain degree of information-processing specificity for a cognitive ability or facet of cognitive operations (Friston, 2002; Johnson, 2005). This specificity is referred to as *functional specialization.* As originally put forth by the work of Luria, effective performance on any given task is characterized by the functional integration of distal brain regions. This integration represents the momentary, dynamic, context-specific communications that convey information via subsets of anatomical connections among a limited number of brain regions engaged by a cognitive process (Koziol & Stevens, 2012).

The functional architecture of the brain is characterized by reciprocal connections across several brain profiles of the cerebro-cortical, cortical–basal ganglia, cerebro-cerebellar, and basal ganglia–cerebellar circuitry systems (Bostan, Dum, & Strick, 2010, 2013; Bostan & Strick, 2010; Koziol, Budding, & Chidekel, 2013). As an example, Yeo and colleagues (2011) have consistently observed seven patterns of cortical networks in adults, adolescents, children, and infants, as assessed through resting-state neuroimaging technologies (Uddin, Supekar, & Menon, 2013). These networks are fundamental for adapting to the rapidly changing demands of our environments, including undergoing assessment of neurocognitive functions. These networks are the fronto-parietal network, ventral attention network, dorsal attention network, visual network, limbic network, sensory–motor network, and default mode network. Examples of some of these networks and how they add to our understanding of PASS processes are provided below.

The *fronto-parietal network* is the "cognitive control" network, which includes working memory functions. It is typically engaged when information or rules need to be kept in mind to guide behavior during effortful cognitive task performance. The network consists of the dorsolateral prefrontal cortex, the anterior cingulate cortex, the anterior prefrontal cortex, the lateral cerebellum, the anterior insula, the caudate nucleus, and the inferior parietal lobule.

The *ventral attention network* provides salience information and allows for the identification of objects and of what these objects are used for. It includes the temporo-parietal junction, the supramarginal gyrus, the frontal operculum, and the anterior insula. The *dorsal attention network* is within the intraparietal sulcus and frontal eye fields; it participates in goal-directed executive control processes by managing spatial attention and attentional shifting, in conjunction with identifying where objects are and knowing how to use them. The interaction of the ventral and dorsal networks guides purposeful behavior as we constantly interact with our dynamically changing environmental events. After we become aware of something we need to orient to, dorsal fronto-parietal regions become activated, and the dorsal network is central to selective attention (Corbetta, Patel, & Shulman, 2008). When we attend to a constantly changing environment, however, both ventral and dorsal networks become activated.

The *visual network* is made up of the occipital lobe and lateral temporal and superior parietal regions; it connects with the superior parietal lobe and intraparietal sulcus, both of which are linked to the dorsal attention network. The visual network is involved in sustaining attention, suppressing attention to irrelevant stimuli, and interacting with these control systems to help direct attention. Other neural networks include the limbic, sensory–motor, and default mode networks. The *limbic network* acts together with other systems to provide motivational and reward influences. This network consists of the dorsal anterior cingulate and the bilateral insulae, and it provides a cortical signal of salient events, including errors. The *motor network* is composed of the primary, supplementary, and premotor cortex, along with the sensory cortex, putamen, thalamus, and cerebellum. The *default mode network* includes the anterior medial prefrontal cortex, the posterior cingulate, and the dorsomedial prefrontal and medial temporal systems. This network is active when external stimuli are at a minimum.

The four basic neurocognitive processes responsible for cognitive activity and behavior represent a "working constellation" (Luria, 1966, p. 70) of networks. Just as different neural networks come into play in an integrative fashion for a particular task, a person may perform the same task with different contributions of the PASS processes, along with the application of the person's knowledge and skills. The central assumption that underlies cognitive interventions is based on this interplay between cognitive activity and behavior (Naglieri & Pickering, 2010). This interplay also helps to explain how different PASS profiles may explain the same profile of academic strengths and weaknesses.

Although effective functioning is accomplished through the integration of all processes as demanded by the particular task, not every process is involved equally in every task. In addition, a task may be approached via a different combination of processes, depending on how the task was initially taught or learned. For example, tasks like math calculation may be dominated by a single process (e.g., planning), while tasks such as reading decoding may be strongly related to another process (e.g., successive), while also recruiting other neurocognitive processes. Reading comprehension of familiar text may, for example, recruit both simultaneous and successive processes, while reading something composed of unfamiliar content may require an additional process to be recruited.

Description of Luria's Three Functional Units

The function of Luria's first functional unit provides regulation of cortical arousal and attention; the second codes information, using simultaneous and successive processes; and the third provides for strategy development, strategy use, self-monitoring, and control of cognitive activities. These functional units also intersect with functional networks. The functional units and networks of the brain provide the infrastructure necessary to interact with the environment, acquire knowledge, and learn.

First Functional Unit

The attention–arousal system is the first of these three functional units of the brain, and is located primarily in the brainstem, the diencephalon, and the medial regions of the cortex (Luria, 1973b). This unit provides the brain with the appropriate level of arousal or cortical tone, as well as directive and selective attention. When many stimuli are presented to a person who is then required to pay attention to only one stimulus, the inhibition of responding to other (often more salient) stimuli and the focusing of attention to the target stimulus depend on the first functional unit. Luria (1973b) stated that optimal conditions of arousal are needed before the more complex forms of attention, involving "selective recognition of a particular stimulus and inhibition of responses to irrelevant stimuli" (p. 271), can occur. Moreover, only when individuals are aroused sufficiently and their attention is focused adequately can they utilize processes in the second and third functional units.

Contemporary neuroscience literature continues to support Luria's initial description of the three functional units and offers additional observations. The brain's default mode network (resting state) becomes increasingly active as goal-directed cognitive tasks and behavior are required. This network is anchored in two brain regions referred to as *hubs*, or centers of primary neural activity. The anterior medial prefrontal cortex and the posterior cingulate cortex are the two central hubs. These regions relate to two subsystems: the dorsomedial prefrontal subsystem and the medial temporal lobe subsystem. The arousal–attention system described by Luria activates these higher brain centers by initial suppression of the default mode network and activation of the ventral and dorsal attention networks.

The ventral attention network informs other brain regions about the importance of what is being attended to externally. The dorsal attention network's role is to shift the focus of attention. Because we are constantly interacting and adapting to demands in the world, this system plays a critical role in that process. The dorsal attention network, in essence, reorients attention to what is relevant to the demands of the task or situation, and specifies the parameters for action by informing other parts of the brain (i.e., frontal systems) about "how to do" something (Koziol et al., 2013). Thus the first functional network, along with its related networks, allows for orientating, sustaining, and reorienting attention to what has relevance at any moment in time. It also activates the fronto-parietal system and facilitates simultaneous and successive processes.

Second Functional Unit

The second functional unit provides for simultaneous and successive processing though the activation and coactivation of the fronto-parietal network and the temporo-parietal junctions of both the right and left hemispheres. Activation of the parietal regions is key to both simultaneous and successive processing, as this region is considered the association cortex—a zone in which many related functions (such as attention, spatial representation, working memory, eye movements, an assortment of other sensory information, and the guidance of actions) come together.

Simultaneous processing involves integrating stimuli into groups so that the interrelationships among the components are understood. For example, for a person to produce a diagram correctly when given the instruction "Draw a triangle above a square that is to the left of a circle under a cross," the relationships among the different shapes must be comprehended correctly. Another example is comprehending the main idea of a story or movie. In short, simultaneous processing involves *understanding and appreciating how the separate parts of a task result in a final product*. Whereas simultaneous processing involves working with stimuli that are interrelated, successive processing is important whenever actions or information form a chain-like progression.

Successive processing is the primary neurocognitive process used in the production of sequences of sounds used to make words, decoding of unfamiliar words, production of syntactic aspects of language, and speech articulation. Other examples of successive processing include following a sequence such as the order of operations in a math problem, and learning a new series of physical and cognitive actions (such as in a sport, a dance, or a board game). Initial learning of almost any new activity or task often requires the use of successive processing. Whereas simultaneous processing involves integration of separate elements into a cohesive whole, successive processing allows the learner to acquire the steps needed to solve a task.

Third Functional Unit

The third functional unit is associated with the prefrontal areas of the frontal lobes of the brain (Luria, 1980) and interacts with the networks already mentioned, as well as the fronto-parietal and the somatosensory networks. Luria stated that "the frontal lobes synthesize the information about the outside world . . . and are the means whereby the behavior of the organism is regulated in conformity with the effect produced by its actions" (1980, p. 263). This functional unit provides for the programming, regulation, and verification of behavior, and is responsible for behaviors such as asking questions, solving problems, and self-monitoring (Luria, 1973b). Other responsibilities of the third functional unit include the regulation of voluntary activity, conscious impulse control, and various linguistic skills such as spontaneous conversation. The third functional unit provides for the most complex aspects of behavior, including personality and consciousness (Das, 1980). The frontal lobes interact with posterior areas of the brain, establishing the fronto-parietal network. This network consists of the dorsolateral prefrontal cortex, anterior cingulate, anterior insula, caudate nucleus, and inferior parietal lobe. The left hemisphere's fronto-parietal network is responsible for internally guided behavior; the right hemisphere's is activated by external influences when situations or information are unfamiliar and require problem solving. From a network perspective, the frontal systems of the brain need to have reciprocal interactions with posterior cortices and subcortical regions to produce the most complex of human behaviors.

Additional support for Luria's initial conceptualizations is provided by research examining the PASS processes and brain functions. For example, Luria initially described simultaneous processing as a function of the occipito-parietal region, whereas he described successive processing as a function of a fronto-temporal region (each region with a bilateral location). Researchers from Japan (Okuhata, Okazaki, & Maekawa, 2009) studied the two processes via electroencephalography. They investigated patterns during six tasks of the CAS (Naglieri & Das, 1997a), three from the Simultaneous scale and three from the Successive scale. The results showed two significantly distinguishable patterns corresponding to the two types of processing. Both processes are localized in the posterior part of the brain, as Luria suggested. Similarly, McCrea (2007) showed that simultaneous processing is strongly dependent on occipito-parietal activity, whereas successive processing shows fronto-temporal specificity, with some evidence of interhemispheric coordination across the prefrontal cortex. McCrea's results provide support for the validity of two of the PASS processes. In addition, Christensen, Goldberg, and Bougakov (2009) provided a substantive summary of brain imaging research that supports both Luria's conceptualizations and the PASS processes.

Functional Units: Influences and Issues

In simplest terms, the three functional units involve four PASS processes (see Figure 6.2). The first functional unit involves attention, which assists with focus and resistance to distractions; the second functional unit involves simultaneous processing, which is used when thinking about how ideas or things go together, and successive processing, which is used to manage information or actions in a specific order; and the third functional unit involves planning, which is used when thinking about how to do something before or during an action.

Luria's organization of the brain into functional units also accounts for the interaction of brain structures with the environment. He stated that "perception and memorizing, gnosis and praxis, speech and thinking, writing, reading and arithmetic, cannot be regarded as isolated or even indivisible faculties" (1973b, p. 29). That is, it is not possible to identify a reading or writing spot in the brain; instead, a consideration of the concept of units of the brain that provide a function is necessary. Luria described the advantage of this approach:

> It is accordingly our fundamental task not to "localize" higher human psychological processes in limited areas of the cortex, but to ascertain by careful analysis which groups of concertedly working zones of the brain are responsible for the performance of complex mental activity; when contributions [are] made by each of these zones to the complex functional system; and how the relationship between these concertedly working parts of the brain in the performance of complex mental activity changes in the various stages of its development. (p. 34)

Activities such as reading and writing can be analyzed and linked as constellations of activities to specific working zones of the brain that support them (Luria, 1979, p. 141). Because the brain oper-

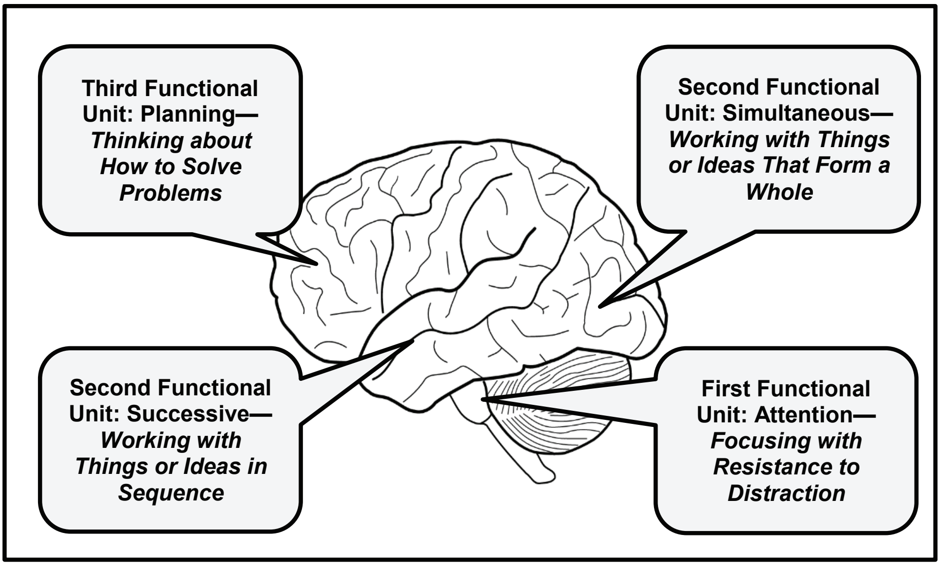

FIGURE 6.2. Luria's three functional units, the four PASS processes, and areas of the brain. Graphic by Jack A. Naglieri.

ates as an integrated functional system, dedicated networks have not been identified for domains typically assessed in psychological assessments. In fact, what we find are ever-changing patterns of dynamic brain network interactions. Disturbances in interaction patterns may cause disorganization in the entire functional system (Das & Varnhagen, 1986).

Luria's concept of dynamic functional units provides the foundation for the PASS processes. These basic neurocognitive processes are firmly based on biological correlates, yet develop within a sociocultural milieu. In other words, they are influenced in part by a person's cultural experiences. Luria (1979) noted that "the child learns to organize his memory and to bring it under voluntary control through the use of the mental tools of his culture" (p. 83). Kolb, Gibb, and Robinson (2003) have also noted that although "the brain was once seen as a rather static organ, it is now clear that the organization of brain circuitry is constantly changing as a function of experience" (p. 1). Similarly, Stuss and Benson (1990) recognized this interplay and especially the use of speech as a regulatory function when they stated:

> The adult regulates the child's behavior by command, inhibiting irrelevant responses. The child learns to speak, the spoken instruction shared between the child and adult are taken over by the child, who uses externally stated and often detailed instructions to guide his or her own behavior. By the age of 4 to 4½, a trend towards internal and contract speech (inner speech) gradually appears. The child begins to regulate and subordinate his behavior according to his/her speech. Speech, in addition to serving communication thought, becomes a major self-regulatory force, creating systems of connections for organizing active behavior inhibiting actions irrelevant to the task at hand. (p. 34)

Luria stressed the role of the frontal lobes in language, organization, and direction of behavior and speech as cultural tools that further the development of the frontal lobes and self-regulation. Cultural experiences thus actually help to accelerate the *utilization* of planning and self-regulation, as well as the other PASS processes. It follows, then, that lack of appropriate experiences that foster the development of speech and language can interfere with the use of planning and self-regulation (see Abdul Aziz, Fletcher, & Bayliss, 2017).

Luria (1979) also pointed out that abstraction and generalizations are themselves products of the cultural environment. Children learn, for example, to attend selectively to relevant objects through playful experiences and conversations with adults. Even simultaneous and successive processes are influenced by cultural experiences (e.g., learning songs, poems, or rules of games). Naglieri (2003) has summarized the influence of social interaction on children's use of plans and strategies, and the resulting changes in performance on classroom tasks.

The relationship between the third and first functional units is particularly strong. The first functional unit works in cooperation with, and is regulated by, higher systems of the cerebral cortex, which receive and process information from the external world and determine an individual's dynamic activity (Luria, 1973b). In other words, the first functional unit has a reciprocal relationship with the cortex. It influences the tone of the cortex and is itself influenced by the regulatory effects of the cortex. These influences are made possible through the ascending and descending systems of the reticular formation, which transmit impulses from lower parts of the brain to the cortex and vice versa (Luria, 1973b).

Functional connectivity (communication) among the functional units described by Luria can be further explained in terms of the current neuroscience literature. The term *functional integration* describes communication across distal brain regions (Koziol et al., 2016). This refers to "transient, dynamically changing, ongoing, and context specific regional interactions that convey information though a subset of anatomical connections among a limited handful of brain regions engaged by a particular cognitive process" (Koziol & Stevens, 2012). Therefore, the third and first functional units are characterized by regional functional segregation and specialization, as well as functional integration.

Facilitating communication across regions of the brain is achieved by the functional hubs, or brain regions that play a critical role in information sharing among distributed brain networks within all sensory and motor systems. Hwang, Hallquist, and Luna (2013) studied the development of functional hubs in 99 children, adolescents, and young adults. Connections among cerebellar, subcortical, and cortical regions increased with age. These increased connections highlight the reciprocal connectivity originally discussed by Luria. For PASS theory, this means that attention and planning are necessarily related strongly because attention is often under the conscious control of planning. That is, planning of behavior dictates the allocation of limited attentional resources. The interplay between attention and planning helps explain how these two components of PASS theory are related to executive function.

Although definitions of *executive function* vary considerably (Goldstein, Naglieri, Princiotta, & Otero, 2014), most theorists agree that it is necessary for purposeful behavior so that goals are achieved. The frontal lobes (especially the dorsolateral and ventromedial regions), in combination with midbrain structures in the basal ganglia and the cerebellum, are key to efficient executive functioning (Otero & Barker, 2014). A task that measures executive function should (1) be relatively unfamiliar, so that the examinee must develop a way to solve the problem; (2) require self-monitoring and error correction; (3) involve selective attention in settings where a well-learned response must be inhibited; and (4) draw upon methods of working with information that needs to be remembered over a short period of time. The CAS2 Planning and Attention tests include many of these attributes of executive function.

OPERATIONALIZATION OF PASS THEORY

The initial operationalization of PASS theory in the CAS (Naglieri & Das, 1997a) has undergone considerable experimental examination (for summaries of research, see Naglieri & Conway, 2009; Naglieri & Otero, 2011, 2017). To provide more ways to measure PASS constructs, several new measures were included in the CAS2 (Naglieri et al., 2014a), CAS2: Español (Naglieri et al., 2017), CAS2: Brief (Naglieri et al., 2014b), and CAS2: Rating Scale (Naglieri et al., 2014c) (see Chapter 15, Figure 15.1). These new measures take different amounts of time to administer, can be used in a wide variety of settings by professionals of different qualification levels, and can be employed for different purposes. The CAS2 (English and Spanish) are intended for highly trained assessment professionals (e.g., psychologists, school psychologists); the CAS2: Brief is appropriate for a wider range of assessment professionals; and the CAS2: Rating Scale can be used by assessment professionals as well as teachers who have been provided with appropriate training.

The main goal in the development of the CAS2 (English) and CAS2: Español, the CAS2: Brief, and the CAS2: Rating Scale is to provide several ways of applying PASS theory to gain a better understanding of students' learning and learning problems. The CAS2 provides the most complete examination of the four PASS neurocognitive abilities, as well as additional scales such as Executive Function, Working Memory, and others. This version will be used most often in comprehensive evaluations, typically in response to a referral for determining whether a student has a disorder in basic psychological processing that is affecting academic or social performance and for selecting interventions that address cognitive and academic needs. The CAS2: Brief is intended to be used in situations when a fast measure of PASS is needed for screening or reevaluation. The CAS2: Rating Scale provides a way for a user of the CAS2 or the CAS2: Brief to determine whether behaviors related to PASS processes have been observed by a teacher. This rating scale also provides a way to inform teachers about the PASS theory and the behaviors associated with the four neurocognitive abilities. We describe all of these measures in detail in Chapter 15 of this volume.

Operationalization of PASS theory in the CAS2 suite of measures was based on a careful analysis of the cognitive processing demands of the prospective subtests and behavioral items. Several guiding principles were established. First, the kind of thinking (i.e., planning, attention, simultaneous, successive) required to solve each subtest had to match the theoretical description of the respective neurocognitive construct. That is, the Planning subtests had to evaluate *how* the student completed the relatively simple task; the Attention subtests had to measure the extent to which the examinee could focus on the appropriate part of the stimulus and ignore distractions; the Simultaneous subtests had to require understanding of the way information presented in each item was related to information in that item; and the Successive subtests had to be sensitive to the student's ability to work with information arranged in a specific sequence.

Second, the PASS subtests had to require a minimum amount of knowledge. This meant that traditional IQ subtests such as Vocabulary, Information, Similarities, and Arithmetic on the WISC-V, for example, would not be included in the CAS2. The idea that a test of ability should include questions that are not contaminated with knowledge is not new. The originators of traditional IQ tests recognized the obstacles verbal tests can present for those with limited educational backgrounds. In fact, Yoakum and Yerkes (1920) stated that test questions that do not rely on knowledge are necessary, "in order that injustice by reason of relative unfamiliarity with English may be avoided" (p. 19).

Third, the PASS subtests had to be administered in a sequence that would maximize validity. For example, the CAS and CAS2 subtest administration follows the sequence of Planning, Simultaneous, Attention, and Successive. The Planning subtests come first in the sequence because the examinee is given freedom to complete the task in any way that seems best, as long as the basic instructions are followed (e.g., write XO under the number 1, OO under the number 2, and so on). The examiner's directions explicitly state, "You can do it any way you want," so that the student is given the opportunity to initiate a strategy to complete the task. This, according to Goldberg (2009), is an essential aspect of frontal lobe functioning, which the Planning tasks are intended to measure. The remaining sequence of CAS and CAS2 subtests was also carefully determined. Simultaneous subtests come second because, unlike the Planning subtests, the first two of these subtests do not involve paper and pencil and contain multiple-choice items. The Attention subtests are very structured and follow the Planning subtests, so that the overall test sequence moves from less to more structured. Finally, the Successive subtests come last because these take a short amount of time and require no paper-and-pencil activities. Fourth, the PASS subtests should vary based on their content. This improves interest, but also allows for assessing each PASS process across modalities (see Table 6.1).

Operationalization of Planning

Planning is a neurocognitive ability used to determine, select, and apply strategies to solve problems where initiation, self-monitoring, and self-correction are especially important (Naglieri & Otero, 2017). Planning is essential to success on tasks that require an awareness of the need for a solution, monitoring of how well things are going, consideration of alternative solutions, and judging whether continuing with a behavior or changing to a different one is most beneficial (Shadmehr, Smith, & Krakauer, 2010). To measure planning, a test question *must* allow a student to solve a novel problem for which there is no previously acquired strategy, and minimal constraints should be placed on the way the student chooses to complete the task. For example, all the Planning subtests on the CAS2 and CAS2: Brief (Naglieri et al., 2014a, 2014b) allow the examinee to decide how to complete the tasks, using whatever methods seem best. For this reason, the test scores reflect efficiency, measured by how long it takes to complete the task with the highest number of correct responses.

Observable behaviors included in the CAS2: Rating Scale can provide insight into a student's

TABLE 6.1. Content or Requirement of CAS2 and CAS2: Brief Subtests

use of planning. Observations of how well a student can solve new problems, and especially how well a student can think of several ways to solve the same problem, can give insight into how well a child is using planning processing. Good planning involves having a goal in mind when various strategies are being considered, applying a strategy, and deciding whether the result is consistent with the intention. The use of planning, however, can be influenced by the nature of the instruction. For example, the role of planning will be encouraged if instruction allows the child to consider multiple ways to solve problems. If, however, classroom instruction is very structured and each student is taught to use the same method of solving problems, then the role of planning will be suppressed.

Operationalization of Attention

Operationalizing the measurement of attention calls for tasks requiring a child to focus selectively on a particular stimulus while inhibiting responses to competing stimuli presented over time (Naglieri et al., 2014a). Luria stated that optimal conditions of arousal are needed for the more complex forms of attention involving "selective recognition of a particular stimulus and inhibition of responses to irrelevant stimuli" (1973b, p. 271).

The Attention subtests on the CAS2 and CAS2: Brief were constructed so that each stimulus is multidimensional and the task requires responding to the most salient part. For example, on one Attention subtest, the student is instructed to tell the color a word is printed in (red) and resist responding to the word (blue). This task is known as the *Stroop test,* named after John Ridley Stroop, who first published a paper about it in English over 80 years ago (Stroop, 1935). This kind of a task requires selective focus of attention over time and resistance to distraction. The CAS2 Attention subtests we describe in Chapter 15 of this volume demand focused, selective, sustained, and effortful activity.

Classroom behaviors can yield insights into a student's ability to attend to instruction and resist distractions over time. For this reason, the CAS2: Rating Scale includes items for teachers regarding how well a student can stay focused in the classroom. Poor attention is inferred when a teacher endorses items suggesting that a student can only work for a short period of time, has difficulty listening and following directions, and cannot concentrate except when distractions are minimal. It is important to note, however, that off-task behavior at home or the classroom can also indicate a failure in control of attention, which can be detected by a low score on the Planning scale of the CAS2.

Operationalization of Simultaneous Processing

The development of subtests to measure simultaneous processing called for test items requiring an examinee to integrate separate stimuli into a single whole or interrelated group (Naglieri et al., 2014a). Some of these tasks include visual–spatial demands; others require comprehension of grammatical relationships. The spatial aspect of simultaneous processing involves both the perception of stimuli as a group or whole and the formation of visual images. The grammatical dimension of simultaneous processing allows for the integration of words into ideas through the comprehension of word relationships, prepositions, and inflections, which are important for deriving meaning. The diversity of the stimuli in the Simultaneous processing subtests of the CAS2 and CAS2: Brief was important, to demonstrate that test question content (verbal vs. visual–spatial) and test requirement (memory vs. little memory) is secondary to the main goal—organization of item content into a coherent and meaningful whole. The Simultaneous processing subtests of the CAS2 and CAS2: Brief are described in Chapter 15 in this volume.

Classroom behaviors can also provide insight into a student's Simultaneous processing. For example, the CAS2: Rating Scale items ask if the student likes (1) to work with "hands-on" materials and visual–spatial tasks; (2) to draw designs, especially three-dimensional ones; and (3) to work with patterns. Simultaneous processing is also involved in reading a whole word and in understanding grammar, verbal concepts, and patterns in language. It is additionally involved in reading comprehension and following a discussion to obtain the overall concept or main point. Overall, whenever any task requires integrating many parts into an organized whole, simultaneous processing is involved.

Operationalization of Successive Processing

The development of the CAS2 Successive processing subtests required tasks involving working with information that is arranged in a specific serial order (Naglieri et al., 2014a). These subtests involve the perception of sequences, as well as the repetition of words, sentences, and numbers in a specific order. Successive processing is necessary for recall of information verbatim, as well as for phonological analysis and the syntax of language (Das, Naglieri, & Kirby, 1994). To ensure that the successive processing is measured across the auditory and visual modalities, a visual subtest has been added to the CAS2. All Successive processing tasks demand working with information in order; however, the sequencing of information is most critical to success on these subtests.

Classroom behaviors can provide information about a student's ability to work with information in order or sequentially. For example, the student's success with blending sounds in sequence (e.g., decoding unfamiliar words, spelling) is an indication of good successive processing. The CAS2: Rating Scale includes items that assist in understanding whether a child has difficulty with successive processing by asking questions about classroom and learning activities that are based on a strict order.

EMPIRICAL SUPPORT FOR THE THEORY

The fundamental validity of PASS theory is rooted in the neuropsychological work of Luria (1966, 1973a, 1973b, 1980), who associated areas of the brain with basic psychological processes as described earlier in this chapter. Luria's research was based on an extensive combination of his and other researchers' understanding of brain functions, amply documented in his book *The Working Brain* (1973b). Using Luria's three functional units as a foundation, Das and colleagues (Das, 1972; Das, Kirby, & Jarman, 1975, 1979; Das, Naglieri, & Kirby, 1994) initiated the task of finding ways to measure the processes associated with these brain areas. These efforts included extensive analysis of the methods used by Luria, related procedures used within neuropsychology, experimental research in cognitive and educational psychology, and related areas. The initial operationalization of Luria's conceptualization of basic psychological processes led to the research summarized in several books (e.g., Das, Naglieri, & Kirby, 1994; Kirby, 1984; Kirby & Williams, 1991; Naglieri, 1999; Naglieri & Das, 1997b, Naglieri et al., 2014a; Naglieri & Otero, 2011, 2017), demonstrating that the PASS processes associated with Luria's concept of the three functional units could be measured. This work also illustrated that the theoretical conceptualization of basic psychological processes had considerable potential for application. The publication of the CAS2 has provided additional evidence for PASS theory (Naglieri & Otero, 2017).

Relationships between PASS and Achievement

Explaining current academic strengths and needs, as well as predicting future achievement, is a critically important use of intelligence tests. The examination of the relationship between ability and achievement is, therefore, an essential aspect of validity. Examining the relationship between ability and achievement, however, is complicated by the fact that traditional ability tests often have content similar to that of achievement tests. It would seem reasonable that an ability test should measure something different than an academic achievement test does, but this is not always true. The verbal and quantitative portions of some ability tests are remarkably like questions found in achievement tests used to measure knowledge and skills. The similarity between ability and achievement test questions has been amply documented by Naglieri and Bornstein (2003) and Naglieri (2008).

All traditional IQ tests include measures of word knowledge, just as tests of achievement do. For example, examinees are required to define a word like *bat* on subtests included in the Stanford–Binet Intelligence Scales, Fifth Edition (SB5; Roid, 2003) and the WISC-IV and WISC-V (Wechsler, 2003, 2014), just as they are required to do in the Woodcock–Johnson Tests of Achievement (WJ III; Woodcock, McGrew, & Mather, 2001). The WJ III Cognitive battery contains a Verbal Comprehension subtest that has an item like this: "Tell me another word for *small*," and the WJ III Achievement battery contains this Reading Vocabulary question: "Tell me another word for *little*." In addition, an item on the WJ III Reading Vocabulary achievement test is "Tell me another word for [examiner points to the word *big*]," and in the Cognitive battery the examiner asks something like "Tell me another word for *tiny*." Additionally, both the WJ III Cognitive and Achievement batteries contain vocabulary tests. The WJ III Cognitive tests also require the subject to name as many examples as possible from a given category in a 1-minute time period, and the same question appears on the Oral Expression subtest of the Wechsler Individual Achievement Test—Second Edition (WIAT-II; Psychological Corporation, 2001). Although these examples do not constitute a complete list of item overlap, they do represent the most strikingly similar questions.

Test questions requiring math achievement also appear on ability and achievement tests. For example, the SB5 contains Quantitative Reasoning items, one of which requires the child to calculate the total number of stars on a page (e.g., two stars in one box plus four in a second box plus one in a third box). Similarly, the WISC-V Arithmetic subtest requires the child to count the number of butterflies pictured on a page, and the Information subtest asks questions like "How many days are there in a week?" Although the scores these test items yield are used to determine a child's level of intelligence, very similar items appear on the WIAT-II. For example, Numerical Operations on the WIAT-II requires the child to determine the total number of marbles shown (e.g., 3 + 5). Similarly, Applied Problems in the WJ III Achievement battery asks the child to count the number of crayons pictured on the stimulus book (e.g., 4). Additionally, an SB5 Quantitative Reasoning item requires the child to complete a simple math problem (e.g., 4 + 2 = ?), just as the WJ III Math Fluency (e.g., 5 + 2 = ?) and the WIAT-II Numerical Operations (e.g., 2 + 2 = ?) achievement tests do. There is an obvious problem when questions on tests of achievement and intelligence are so similar, yet the interpretations of the scores on these tests are considerably different. A student's knowledge of math or verbal skills should be used to understand academic achievement, but not to determine level of intelligence.

Using items with similar content across achievement and ability tests is ill advised, for several reasons. First, because the correlation between ability scores (especially verbal scores) and achievement scores has been considered a source of evidence for the validity of IQ tests, these correlations should be considered overestimates of the relationship, due to overlapping content. The authors and/or publishers of ability tests with this content should justify how similar questions can be used across tests that were designed for different purposes. Second, having ability test questions that require knowledge very similar to that required by achievement tests may increase their predictive validity artificially, but at a cost to those with limited educational backgrounds as well as those who are learning English.

Ability and Achievement Test Correlations

Therefore, it is important to understand how well traditional intelligence tests and the more modern tests designed to measure ability differently correlate with achievement. This question was examined by Naglieri (1999), who first reported that the correlations of achievement test scores with scores on the CAS (see Naglieri & Rojahn, 2004) and the Kaufman Assessment Battery for Children (K-ABC; Kaufman & Kaufman, 1983b) were as high as or higher than those found for the WISC-III (Wechsler, 1991) and the WJ-R (Woodcock & Johnson, 1989). More recent findings are provided next.

Table 6.2 provides a summary of the correlations between several ability and achievement tests, based on published data. The method used to summarize the correlations was simple. The respective test manuals were consulted, and the average correlation (using Fisher *z* transformations) between the scale scores yielded by an ability test and a total achievement score was computed. To examine the findings for each ability test with and without the scales that clearly have academic content, two average correlations were obtained: one with all the scales of the particular ability test, and one excluding the scales with obvious academic content.

The data for the WISC-V and WIAT-III came from the WISC-V's technical and interpretive

TABLE 6.2. Average Correlations between Ability and Achievement Tests

Ability and achievement tests	Scales on each ability test	Scale correlation with total achievement	Average of all scales	Average of scales without achievement
WISC-V and WIAT-II (*n* = 201)	Verbal Comprehension	.74	.53	
	Visual Spatial	.46		.47
	Fluid Reasoning	.40		
	Working Memory	.63		
	Processing Speed	.34		
WJ IV Cognitive and WJ IV Achievement (*n* = 825)	Comprehension–Knowledge	.50	.54	
	Fluid Reasoning	.71		
	Auditory Processing	.52		
	Short-Term Working Memory	.55		.50
	Long-Term Retrieval	.43		
	Visual Processing	.45		
KABC-II and WJ III Achievement (*n* = 167)	Sequential/Gsm	.43	.53	.48
	Simultaneous/Gv	.41		
	Learning/Glr	.50		
	Planning/Gf	.59		
	Knowledge/GC	.70		
CAS and WJ III Achievement (*n* = 1,600)	Planning	.57	.59	
	Simultaneous	.67		
	Attention	.50		
	Successive	.60		

Note. WJ-IV scales: Comprehension–Knowledge = Vocabulary and General Information; Fluid Reasoning = Number Series and Concept Formation; Auditory Processing = Phonological Processing. All average correlations were obtained by using Fisher *z* transformations.

manual (Wechsler, 2014, Table 5.13). The relationship between ability and achievement with and without the influence of those portions of the WISC-V that clearly require verbal knowledge was examined by using the two procedures just mentioned. The average correlation of all five WISC-V scales with the WIAT-III Total Achievement score was .53, and the average of the WISC-V scales with the Verbal Comprehension Index excluded was .47. The latter correlation is likely a more accurate assessment of the relationship between ability and achievement because it eliminated overlapping content to the extent possible. The same approach was taken with data from the WJ IV Tests of Cognitive Abilities and Achievement (Schrank, McGrew, & Mather, 2014, Table 5.7) and the KABC-II (Kaufman & Kaufman, 2004b). The results were similar, regardless of the ability test or achievement test used (see Table 6.2).

The results reveal a clear pattern across the WISC-V, WJ III, and KABC-II: The correlation between scores on each of these tests and achievement scores was higher when the scales that demand verbal knowledge were included. The best explanation for why this pattern emerged is the similarity in content across the two kinds of tests. Some (e.g., Lohman & Hagan, 2001) argue that this is evidence of validity. It seems clear, however, that the correlations between achievement test scores and ability tests that demand knowledge of words and arithmetic are *artificially inflated* because of the shared content. The correlations between the scores from ability scales that do not require knowledge and the total achievement test score are more accurate estimates of the relationship.

There was no need to eliminate a scale from the CAS for this analysis because it does not include tests that demand so much knowledge. As seen in Table 6.2, the average correlation between the PASS scales and achievement was .59—higher than the correlations obtained both when achievement was excluded from all the other ability tests and when it was not excluded. The results are clear: Academic content can be substantially reduced in ability tests without compromising validity.

PASS Profiles

One of the most important uses of an ability test that has scales organized on a conceptual or theoretical basis is to detect a pattern of cognitive strengths and weaknesses that can help explain academic success and failure and contribute to a diagnosis of specific learning disability (SLD) (Naglieri & Otero, 2017) or some other disability. Practitioners have the choice to analyze the scales that represent conceptual or theoretical constructs, as well as the subtests that make up the scales. The analysis of subtest and scale variation on, for example, the Wechsler scales has been advocated by Kaufman (1994) and others (e.g., Sattler, 1988) as a way to identify a child's intellectual strengths and/or weaknesses. Information about strengths and weaknesses is then used to generate hypotheses that are integrated with other information, so that decisions can be made regarding eligibility, diagnosis, and treatment. This approach has been widely used, even though some have argued that subtest profile analysis does not provide useful information (e.g., Dombrowski & Watkins, 2013; McDermott, Fantuzzo, & Glutting, 1990). Naglieri (1999) and Naglieri and Otero (2017) have further proposed that subtest analysis is problematic because of limitations in subtest reliability and validity, as well as the paucity of research supporting the many interpretations which have been proposed for subtests (see WISC-V review by Naglieri, 2016). Scale-level, rather than subtest-level, analysis that is based on a theory can be used to identify a specific pattern of strengths and weaknesses to understand a student's learning difficulty. The pattern can then be used to guide eligibility decisions (see Naglieri, 2011) and interventions (Naglieri & Pickering, 2010).

In order to examine the patterns of strengths and weaknesses at the scale level on several measures of ability for students with SLD, attention-deficit/hyperactivity disorder (ADHD), and autism spectrum disorder (ASD), mean scores found in the technical manuals of the WISC-V, WJ III, KABC-II, and CAS have been summarized and are reported in Table 6.3. The findings must be considered with recognition that the samples were not matched on demographic variables across the various studies, the accuracy of the diagnoses may not have been verified, and some of the sample sizes were small. Notwithstanding these limitations, the findings provide important insights into the extent to which these various tests are likely to yield scalelevel profiles that are distinctive, theoretically logical, and relevant to instruction.

The results of this analysis are presented in two ways. First, a graphic display of the mean scores is provided in Figure 6.3, so that the patterns of strengths and weaknesses can be clearly understood. Second, the difference between each scale

TABLE 6.3. Scale Variability within Each Ability Test by Diagnostic Group

Test	Index or scale	ASD	SLD	ADHD
WISC-V	Verbal Comprehension	0.2	–2.0	1.5
	Visual Spatial	2.6	2.2	1.0
	Fluid Reasoning	4.1	1.4	1.3
	Working Memory	–2.6	–3.3	–1.5
	Processing Speed	–4.4	1.9	–2.1
WJ III	Comprehension–Knowledge	1.7	–0.7	–0.7
	Long-Term Retrieval	1.7	–4.7	–4.7
	Visual–Spatial Thinking	3.7	5.3	2.3
	Auditory Processing	4.7	4.3	3.3
	Fluid Reasoning	–1.3	2.3	5.3
	Processing Speed	–9.3	–3.7	–4.7
	Short-Term Memory	–1.3	–2.7	–0.7
KABC-II	Sequential/Gsm	1.6	–0.5	–1.0
	Simultaneous/Gv	–2.4	2.2	–1.9
	Learning/Glr	5.4	–1.6	1.5
	Planning/Gf	0.0	0.9	–0.3
	Knowledge/Gc	–4.6	–1.1	1.5
CAS	Planning	5.9	2.5	–7.4
	Simultaneous	3.0	1.9	2.2
	Attention	–9.0	2.9	1.3
	Successive	0.1	–7.4	3.9

and the average standard score for all the scales in each ability test was computed and is presented in Table 6.3. The results of the summary of scale profiles for the WISC-V, WJ III, KABC-II, and CAS suggest that some of these tests yield more distinct profiles than others do across the groups of children with SLD in reading decoding, ADHD, and ASD.

Specific Learning Disability

The scores for students with SLD in reading decoding across all scales on the WISC-V profile was lowest for the Working Memory Index, but there was little variability among the scores. The Working Memory Index was only 3.3 standard score points lower than the average or this group. The WJ III mean scores for students with SLD in reading decoding were all within the average range and showed some variability. The lowest score was for Long-Term Retrieval (a knowledge-dense scale). All the KABC-II scores were in the 80s, and there was little variability among the scales. The CAS profile showed the most variability across the four PASS scales, with a very low score of 82.9 on the Successive scale. These findings are consistent with the view that students with SLD in reading decoding also have considerable difficulty with tasks that involve sequencing of information (Das, Janzen, & Georgiou, 2007).

Reading researchers generally agree that phonological skills play an important role in early reading, and some have suggested this to be the major cause of reading disability in children (Stanovich, 1988; Wagner, Torgesen, & Rashotte, 1994). One of the most frequently cited articles in the field, by Torgesen, Wagner, and Rashotte (1994), proposes that phonological skills are causally related to normal acquisition of reading skills. Support for this claim can also be found in the relationship between prereaders' phonological scores and their reading development 1–3 years later (e.g., Bradley

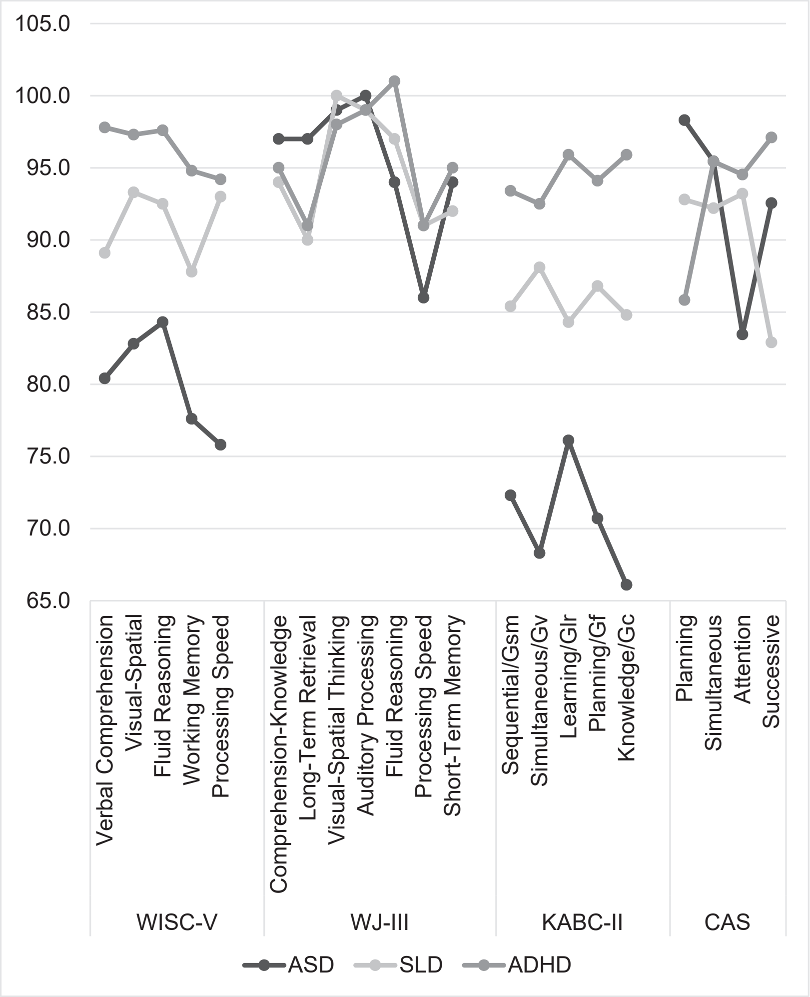

FIGURE 6.3. A graphic display of the mean scores on the WISC-V, WJ III, KABC-II, and CAS for groups of children with SLD in reading decoding, ADHD, or ASD.

& Bryant, 1985). Moreover, Share and Stanovich (1995) concluded that there is strong evidence that poor readers, as a group, are impaired in a very wide range of basic tasks in the phonological domain. Das, Naglieri, and Kirby (1994) suggested, however, that underlying a phonological skills deficit is a specific deficit in successive processing that leads to word-reading deficits.

The results of the current summary are consistent with previous research. Das, Mishra, and Kirby (1994) found that the Successive scale scores from the CAS were better than a test of phonemic segmentation at distinguishing normal readers from children with dyslexia. Additional studies have since supported the hypothesis that PASS processes, especially successive processing, are as important as phonological skills (Das, Parrila, & Papadopoulos, 2000). Several recent studies of Canadian First Nations children are particularly important. Das and colleagues (2007) reported that successive processing made a unique contribution to predicting both word identification and reading pseudowords (word attack). Furthermore, the poor readers demonstrated a significant weakness on the CAS Successive scale, both in relation to the norm and in relation to their scores on the other three CAS scales. Similarly, Naglieri, Otero, DeLauder, and Matto (2007) reported Successive scale deficits for bilingual children with reading disabilities who were administered the CAS in

English and Spanish. In addition, 90% of the children with reading disabilities had cognitive weaknesses on both the English and Spanish versions of the CAS.

In contrast to the relationship between reading decoding and successive processing, disability in reading comprehension has been shown to be primarily related to deficits in simultaneous processing (Das, Kar, & Parrila,1996; Das, Naglieri, & Kirby, 1994; Naglieri & Das, 1997b). In a study conducted with English-speaking children in India, Mahapatra, Das, Stack-Cutler, and Parrila (2010) found that children with comprehension problems had a substantially lower mean score on the CAS Simultaneous scale. These studies further suggest that PASS profiles could have utility for diagnosis of reading disabilities, as suggested by Naglieri (1999, 2011).

Attention-Deficit/Hyperactivity Disorder

The intelligence test profiles for students with ADHD showed that all the scores for the scales on the WISC-V, WJ III, and KABC-II were within the average range. There was some variability in the scores on the WJ III, with the lowest scores being on Long-Term Retrieval and Processing Speed tests (like the findings for the students with SLD). These findings suggest that none of these tests provided evidence of a cognitive problem related to ADHD. However, on the CAS, children with ADHD showed a low score on the Planning scale. Difficulty with planning (i.e., executive function) for children with ADHD is consistent with the view that ADHD is a disorder related to frontal lobe functioning (Goldberg, 2009). A low score on the CAS Planning, not Attention, scale reported in this summary may seem illogical, but it is consistent with Barkley's (1997) view that ADHD is a failure of self-control (i.e., planning in the PASS theory), rather than a failure of attention. The research summarized here confirms Barkley's view.

Naglieri, Salter, and Edwards (2004) were the first to report a weakness in planning, not attention, for children with ADHD. Canivez and Gaboury (2016) found that the CAS was accurate at distinguishing between students meeting *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR) criteria for ADHD and matched controls. PASS scores were related significantly to ADHD characteristics, demonstrating both distinct group differences and diagnostic utility. Importantly, Naglieri and Conway (2009) found that PASS profiles for children with ADHD were different from those for children with SLD, as well as those with anxiety disorders. In summary, the findings of profile analysis suggest that determining whether a child with ADHD has a deficit in planning as measured by the CAS/CAS2 may be important for both diagnosis and intervention (Goldstein & Naglieri, 2006; Naglieri & Pickering, 2010).

Autism Spectrum Disorder

The results for individuals with ASD show that Processing Speed scores on the WISC-V and WJ III were relatively low for this group. The low Processing Speed scores provide little insight into the cognitive characteristics of these students because the interpretability of these scores on these batteries is unclear. For example, the WISC-V manual lists more than 40 abilities that may be involved in completing the three subtests that make up the Processing Speed Index. In contrast, the PASS profile, which shows a low Attention scale score, is consistent with the conceptualization of individuals with ASD as having "difficulties in disengaging and shifting attention" (Klinger, O'Kelley, & Mussey, 2009, p. 214). The findings for those with ASD, like the results for those with SLD and ADHD, show that the PASS processes as measured by the CAS result in cognitive profiles that may inform differential diagnosis in these three groups.

The research on scale-level profiles across the several ability tests has suggested that most tests' profiles look similar, except for the PASS scores from the CAS. As a group, children with SLD in reading decoding had a specific weakness on the Successive processing scale. This is consistent with the view of Das (see Das, 2009; Das, Naglieri, & Kirby, 1994) that reading failure results from a deficit in sequencing of information (successive processing). Those with ADHD performed poorly on the Planning scale, but adequately on the remaining PASS constructs. This finding is consistent with Barkley's (1997) and Goldberg's (2009) views of ADHD as a failure of self-control related to frontal lobe function. Finally, the PASS profile for individuals with ASD is consistent with Klinger and colleagues' (2009) description of these individuals as having difficulty with disengaging and shifting attention. Together, these findings support the view that PASS has relevance for understanding the neurocognitive processing components of these disorders, which in turn has implications for diagnosis and intervention.

It is important to note that Glutting, McDermott, Konold, Snelbaker, and Watkins (1998) suggested some time ago that research concerning profiles for children with specific disorders is confounded because the "use of subtest profiles for both the initial formation of diagnostic groups and the subsequent search for profiles that might inherently define or distinguish those groups" (p. 601). They suggested that researchers should "begin with unselected cohorts (i.e., representative samples, a proportion of which may be receiving special education), identify children with and without unusual subtest profiles, and subsequently compare their performance on external criteria" (p. 601). Naglieri (2000) followed this methodology, using PASS theory and the concepts of *relative weakness* and *cognitive weakness* (Naglieri, 1999). A relative weakness is found when a score is significantly lower than a student's mean PASS score; this is determined by using the ipsative methodology originally proposed by Davis (1959) and modified by Silverstein (1982, 1993). In contrast, a cognitive weakness is found when a child has a significantly low score relative to the student's average PASS score, *and* the low score also falls below some cutoff designed to indicate what is typical or average, perhaps 85 (16th percentile rank). The difference between a relative weakness and a cognitive weakness, therefore, is that the determination of a cognitive weakness is based on dual criteria (a low score relative to the child's mean, *and* a low score relative to the norm group). It is also important that a cognitive weakness be accompanied by an achievement test weakness comparable to the level of the PASS scale cognitive weakness. Children who have both a PASS cognitive weakness and an achievement test weakness should be considered candidates for special educational services if other appropriate conditions are met.

The utility of PASS profiles was studied by Naglieri (2000), using a nationally representative sample of 1,597 students ages 5–17 years. The sample included students in regular (*n* = 1,453) and special (*n* = 144) educational settings. Because these data were obtained before the original CAS was published, there was no way the results of the test influenced the groups in which these students were placed. Analysis of the PASS profiles suggested that the relative-weakness method identified children who earned average scores on the CAS as well as on achievement, and that approximately equal percentages of children from regular and special education classes had a relative weakness. That is, the concept of relative weakness did *not* identify children who achieved differently from children in regular education. By contrast, children with a PASS score significantly below the students' PASS average *and* below the average classification (i.e., a cognitive weakness) earned lower achievement scores. In addition, students with a PASS scale cognitive weakness were more likely to have been identified and placed previously in special education. Finally, the presence of a cognitive weakness was significantly related to achievement, whereas the presence of a relative weakness was not.

The findings related to relative weaknesses partially support arguments against the use of profile analysis (see Glutting et al., 1998, for a summary). However, the findings related to cognitive weaknesses support the PASS-theory-driven approach that includes the dual criteria of a relative and a normative weakness in a PASS process. These criteria are part of the discrepancy–consistency method, which is used to inform the use of the CAS/CAS2 to make a diagnosis of SLD (for details, see Naglieri, 1999, 2011; Naglieri & Otero, 2017). It is important to note that this approach is different from a subtest analysis approach because the method uses the PASS-theory-based scales included in the CAS/CAS2.

Racial/Ethnic Differences

The need for tests of ability to be appropriate for diverse populations has been recognized since Yoakum and Yerkes (1920) description of the Army Alpha and Beta tests. Fair assessment has become progressively more important as the characteristics of the U.S. population have changed. The issue is more than an aspiration with the requirement in the Individuals with Disabilities Education Improvement Act of 2004 that assessments must be nondiscriminatory. It is therefore critical that any measures used for evaluation of ability be evaluated for test bias. The psychometric analysis should include internal evidence such as reliability, item difficulty, and factor structure, as well as the presence of construct-irrelevant influences (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 2014). The issue of fairness is related most clearly to the theoretical perspective taken by the test authors.

Efforts to improve test fairness have led some researchers to suggest that conceptualizing intelligence in terms of neuropsychological abilities would make tests more appropriate for diverse populations (Fagan, 2000; Naglieri, 2005; Suzuki & Valencia, 1997). These authors have stressed the construct-irrelevant influences of verbal and quantitative tests included in traditional IQ tests, and have suggested that measures of cognitive processes that do not rely on tests with language and quantitative content are more appropriate for assessment of culturally and linguistically diverse populations. Although there is considerable evidence for the validity of general intelligence as measured by traditional IQ tests (see Jensen, 1980), researchers have traditionally found a mean difference of about 12–15 points between blacks and whites on measures of IQ that include verbal, quantitative, and nonverbal tests (Kaufman & Lichtenberger, 2006). Results for newer intelligence tests have been different.

The first evidence of smaller race differences for a test of ability that did not include traditional measures of vocabulary and math was reported in the original K-ABC interpretive manual (Kaufman & Kaufman, 1983a). For children ages 2.5 to 12.5, without controls for background variables, whites (*n* =1,569) scored 7 points higher than blacks (*n* = 807) and 3 points higher than Hispanics (*n* = 160) on the Mental Processing Index (MPI) (i.e., the total test score). These differences are considerably smaller than the differences of 16 points and 11 points, respectively, reported for the WISC-R (Wechsler, 1974) Full Scale IQ (Kaufman & Kaufman, 1983a, Tables 4.36 and 4.37; Kaufman, Lichtenberger, Fletcher-Janzen & Kaufman, 2005, Table 6.7). Naglieri (1986) examined this question further in a study of 172 fifth-grade students (86 whites and 86 blacks, matched on basic demographic variables) who were administered the K-ABC and the WISC-R. The difference between the groups on WISC-R Full Scale IQ was 9.1, but the difference for the K-ABC was 6.0. Results for the KABC-II (Kaufman & Kaufman, 2004a) showed a similar reduction in race/ethnic differences. When gender and mothers' education were controlled for, black children at ages 3–18 years earned mean MPIs that were only 5 points lower than the means for white children (Kaufman & Kaufman, 2004a, Tables 8.7 and 8.8; Kaufman et al., 2005, Table 6.7). Similar findings have been reported for the CAS.

Naglieri, Rojahn, Matto, and Aquilino (2005) compared PASS scores on the CAS for 298 black children and 1,691 white children. They found a CAS Full Scale mean score difference of 4.8 points in favor of white children when demographic variables were controlled for via regression analyses. In a similar examination of test fairness, Naglieri, Rojahn, and Matto (2007) compared PASS scores from the CAS of Hispanic and white non-Hispanic children. The study showed that the two groups differed by 6.1 points when unmatched samples were used, 5.1 when samples were matched on basic demographic variables, and 4.8 points when demographic differences were statistically controlled for. Researchers have also examined children with limited English-language skills.

The examination of PASS scores when the CAS: English and CAS: Spanish were administered to the same students provides an important complement to the large-scale studies of test fairness. Naglieri, Otero, and colleagues (2007) compared scores on the CAS when it was administered in English and Spanish to bilingual children (*n* = 40) referred for reading difficulties. They found a 3.0-point difference between the CAS Full Scale scores for the two versions, and these scores were highly correlated (.96). Otero, Gonzales, and Naglieri (2013) replicated that study with another group of students of varying levels of English-language proficiency referred for reading problems; they found CAS Full Scale scores that differed by less than 1 point, and a high correlation between the scores (.94).

Results for the CAS2 Full Scale scores were reported in the test manual (Naglieri et al., 2014a). Standard scores for African American and non–African American children and adolescents ages 5–18 years differed by 6.3 points without controls for demographic variables, and 4.5 points with such controls. Similarly, without controls for demographic variables, Hispanics and non-Hispanics differed on the CAS Full Scale scores by 4.5 points; with controls for demographic characteristics, the difference was 1.8.

The findings presented above for racial/ethnic differences are best understood when placed within the context of differences found on traditional intelligence tests. Table 6.4 provides a summary of standard score differences by race for the Stanford–Binet IV (SB-IV; Thorndike, Hagen, & Sattler, 1986), WJ III, WISC-V, K-ABC, KABC-II, CAS, and CAS2. The results for the WISC-V were reported by Kaufman, Raiford, and Coalson (2016); the results for the SB-IV were reported by Wasserman and Becker (2000); and the results for the WJ-III were reported by Edwards and Oakland (2006). The race differences for the K-ABC normative sample were reported by Kaufman and

TABLE 6.4. Mean Score Differences in Total Scores by Race by Intelligence Test

Test	Difference
SB-IV (matched samples)	12.6
WISC-V (normative sample)	11.6
WISC–IV (normative sample)	11.5
WJ- III (normative sample)	10.9
WISC–IV (matched samples)	10.0
WISC-V (statistical controls normative sample)	8.7
K-ABC (normative sample)	7.0
K-ABC (matched samples)	6.1
KABC-2 (matched samples)	5.0
CAS-2 (normative sample)	6.3
CAS (statistical controls normative sample)	4.8
CAS-2 (statistical controls normative sample)	4.3

Note. The data for these results are reported for the SB-IV from Wasserman and Becker (2000); for the Woodcock–Johnson III from Edwards and Oakland (2006); for the K-ABC from Naglieri (1986); for the KABC-II from Lichenberger, Sotelo-Dynega, and Kaufman, (2009); for the CAS from Naglieri, Rojahn, Matto, and Aquilino (2005); for the CAS2 from Naglieri, Das, and Goldstein (2014a); for the WISC-IV from O'Donnell (2009); and for the WISC-V from Kaufman, Raiford, and Coalson (2016).

Kaufman (1983a), and similar race differences for the KABC-II were summarized by Lichtenberger, Sotelo-Dynega, and Kaufman (2009). Differences for the CAS and CAS2 were reported by Naglieri and colleagues (2005) and Naglieri and colleagues (2014a), respectively.

The results provided in Table 6.4 illustrate that measuring ability as a cognitive process, in contrast to traditional concepts of IQ, provides a more equitable way to assess diverse populations. The findings suggest that as a group, traditional IQ tests showed differences in ability scores between the races that were about twice as large as those found for cognitive processing tests such as the K-ABC, CAS, and CAS2. All the tests with the largest differences between the racial/ethnic groups included in Table 6.4 have verbal and quantitative content demanding knowledge that is very similar to the knowledge required by standardized achievement tests (see Naglieri & Bornstein, 2003). The results suggest that using a cognitive processing approach to measure ability results in smaller racial/ethnic differences without a loss of (1) capacity to predict achievement or (2) in the case of PASS theory, sensitivity to learning problems—both of which are critical components of validity.

CLOSING STATEMENTS

In this chapter, we have described the neuropsychological and neuroscientific foundations of PASS theory. We have reviewed Luria's original conceptualizations of how the brain functions, and have integrated that understanding with current knowledge in neuroscience, which continues to validate Luria's original conceptualizations. Our underlying aim has been to illustrate through logic and research findings that PASS theory is parsimonious, yet powerful for assessing diverse populations. Our hope is to attract both new and seasoned practitioners by presenting a coherent theory that provides useful information about the neurocognitive abilities being measured to explain why people fail or succeed because we focus on how one thinks versus what one knows.

We have provided the rationale and empirical support for a revolutionary step in the field of intellectual assessment: an effort to move from IQ to a theory of human neurocognitive functioning. We see our approach as one that works *because* it departs considerably from traditional IQ, is grounded in a theory of how the brain works, and takes a neurocognitive approach instead of building upon the outdated foundation of the U.S. Army mental tests. We have presented scientific evidence that the PASS scores derived from the CAS/CAS2 (1) are more predictive of achievement test scores than the scores from any other ability test; (2) yield distinctive profiles for different children with different disabilities; (3) can be used for SLD eligibility determination in a manner consistent with federal law; (4) offer the most equitable way to measure diverse populations; and (5) can be readily used for instructional planning and interventions. But the most important advantage of PASS theory is that it assists us in understanding the underlying reasons for success and failure in school and life.

Our overarching goal has been to encourage practitioners to embrace the conceptualization of intelligence in terms of neurocognitive abilities, which can be instrumental in helping children achieve their greatest potential. PASS theory is an innovative way of thinking about intelligence, and the CAS2 is a way to measure PASS neurocognitive processes (as we describe in Chapter 15, this volume).

We suggest that practitioners manage the transition from traditional IQ tests to those that measure neurocognitive abilities with the assurance that an evolutionary step in our field is needed, given all that has been learned in the past 100 years. As a founding father of the United States, Thomas Jefferson, once said, "I am not an advocate for frequent changes in laws. But laws must go hand in hand with the progress of the human mind. As that becomes more developed, more enlightened, as new discoveries are made, new truths discovered and opinions change, institutions must advance also to keep pace with the times." Only though revolutionary change can we improve the evaluation of intelligence and better meet the needs of the children and adolescents we serve.

ACKNOWLEDGMENT

We acknowledge Luremy Fraga for her excellent feedback on selected portions of this chapter.

CHAPTER 7

The Parieto-Frontal Integration Theory

Assessing Intelligence from Brain Images

Richard J. Haier
Rex E. Jung

No one argues that a student's intelligence is the only important factor for predicting academic success, but consistent empirical research shows that it is more important than family resources, motivation, or quality of schools and teachers. These other factors are not unimportant—but, for example, earnest and expensive efforts to improve schools and overcome other disadvantages have had no appreciable effect on academic achievement gaps. We believe that an understanding of the neuroscience of intelligence offers new insights and a new basis for discussing education reforms that include what we know about intelligence. That is the rationale for this chapter. We have not written a review of relevant studies, but we provide this overview of the relevance of brain imaging studies of intelligence to education.

HOW WE THINK ABOUT AND ASSESS INTELLIGENCE

Before getting to brain imaging, we start with a brief review of how intelligence is defined and assessed, and of the evidence that intelligence is the best predictor of academic success. Most intelligence research is based on the empirical observation that scores on all tests of mental abilities correlate positively with each other. This finding suggests that there is a common general mental ability underlying all mental abilities. This common ability is called the *g* factor, or *g* for short, and was first observed by Spearman (1904) more than 100 years ago. There is not universal agreement that *g* is the most important intelligence factor or the only way to account for common variance among different tests. Nonetheless, *g* is still the basis for most intelligence research, especially in the neurosciences.

The *g* factor typically is estimated, not measured. This distinction is a key point (Haier, 2014). There is no assessment of intelligence as a quantity like weight or distance. Intelligence quotient (IQ) points and other mental ability test scores have meaning only in relation to other individuals. Whereas 2 inches are exactly twice the length of 1 inch, and 20 pounds is exactly twice the weight of 10 pounds, a person with an IQ of 140 is not twice as smart as a person with an IQ of 70. That's why we most accurately interpret intelligence test scores as percentiles. The best intelligence tests provide a good estimate of the *g* factor, and the best research design includes multiple mental tests across a range of abilities, so a *g* factor can be extracted statistically. A *g* factor extracted from one battery of mental ability tests correlates almost perfectly with a *g* factor extracted from another battery, as long as both batteries sample a wide range of abilities and include a wide range of test scores (Johnson, Bouchard, Krueger, McGue, & Gottesman, 2004).

INTELLIGENCE AS THE STRONGEST PREDICTOR OF EDUCATIONAL ACHIEVEMENT

The strong evidence for the predictive validity of intelligence test scores and the *g* factor has been reviewed in many places (Haier, 2017; Hunt, 2011; Mackintosh, 2011). Here we are concerned with the question of how much variance in educational achievement can be attributed to intelligence. The answer depends somewhat on the age of students, but overall the weight of evidence from the most well-designed research studies shows that a high proportion of variance in educational achievement is due to intelligence. No single other variable accounts for more of the variance. For example, one classic study examined a battery of cognitive test scores for over 70,000 English school children at age 11, and their educational achievement in 25 subject areas 5 years later at age 16 (Deary, Strand, Smith, & Fernandes, 2007). The researchers used multiple measures of both mental ability and achievement, so they were able to extract a latent *g* score and a latent achievement score, based on the common variance among the respective batteries of tests. From a research design view, this is a powerful assessment method, and it is combined with the also powerful elements of an extremely large sample and a prospective timeline. Results were clear. The correlation between the two latent variables was .81, which accounts for about 66% of the variance (correlations squared estimate the amount of variance accounted for in one variable by the other). This estimate leaves a hefty 34% of variance for the influence of all other variables (effort, school quality, teacher effectiveness, family resources, etc.), but it verifies that a student's intelligence, defined as a general ability factor, is the single strongest predictor of academic achievement.

A similar study looked at two large samples (*N*'s = 2,520 and 4,969) that included both young and teenage students (ages 4–6 and 14–19). Different cognitive test batteries were used in each sample, and achievement tests in reasoning, math, and writing were administered (Kaufman, Reynolds, Liu, Kaufman, & McGrew, 2012). Overall, the correlation between a latent *g* factor and a latent achievement factor was .83, or 69% of the variance; but when analyzed by age, the correlations were even larger in the older students (ranging from .77 in the young to .94 in the teens; this range translates to 59–88% of the variance). These results essentially replicate those of the Deary and colleagues (2007) English student study with respect to the large amount of variance in achievement explained by a general intelligence factor.

Socioeconomic status (SES) is also widely recognized as a key variable for educational achievement, but SES measures typically are confounded with intelligence scores because the kinds of variables that contribute to SES (such as education and income) also are highly related to intelligence. There is a complex literature on this topic, but when both intelligence and SES variables are used in the same study to predict academic performance in large, diverse samples, the weight of evidence clearly favors the central role of intelligence. For example, a study of 155,191 college students showed that SAT scores, which are good estimates of the *g* factor (Frey & Detterman, 2004), predicted academic performance about the same with or without SES; SES added no additional predictive power (Sackett, Kuncel, Arneson, Cooper, & Waters, 2009).

THE PARIETO-FRONTAL INTEGRATION THEORY

What about the variables that influence intelligence? There is a vast research literature on this question, but the weight of evidence clearly shows that genes play a major role (Haier, 2017), accounting for up to about 80% of variance by the teenage years. The overwhelming evidence for this finding has not been embraced or even much acknowledged in the field of education. This omission may be because of the erroneous belief that genes are completely deterministic and create absolute limitations for students. In fact, genes are probabilistic, and this fact creates positive and optimistic opportunities for education reform (Asbury & Plomin, 2014). One aspect of emerging findings from large, multinational cohorts is that there are genes in common for intelligence and for specific brain characteristics. A review of the genetic literature here is not necessary for understanding the promise of neuroimaging for assessing intelligence and identifying its neurobiological elements. Our contribution is a model of brain relationships to intelligence, the parieto-frontal integration theory, and this theory is the focus for the remainder of this chapter.

In 2007, we published a review of 37 imaging studies that correlated a variety of intelligence measures with functional brain variables like regional cerebral glucose metabolic rate and regional blood flow, and with structural variables like gray and white matter volumes (Jung & Haier, 2007). This review resulted in a model based on the brain areas most closely associated with intelligence across studies. Most of the salient areas were in the parietal and frontal lobes, so we called the model the *parieto-frontal integration theory* or PFIT. The model identified 14 areas labeled according to Brodmann area (BA) nomenclature (see Figure 7.1), and we discussed how efficient information flow among these areas might be related to individual differences in intelligence. Our model emphasized that brain areas relevant to intelligence are distributed throughout the brain, contrary to a popular view at the time that the frontal lobes alone are responsible for intelligence. Moreover, the fact that quantifiable neuroimaging variables correlated with intelligence test scores demonstrated that the scores are not meaningless artifacts, as some anti-IQ advocates had argued.

The PFIT regions suggest distinguishable information processing stages that contribute to intelligence. This is a summary of the proposed stages (Colom, Karama, Jung, & Haier, 2010):

1. Occipital and temporal areas process sensory information in the first processing stage: the extrastriate cortex (BAs 18 and 19) and the fusiform gyrus (BA 37), involved with recognition, imagery and elaboration of visual inputs, as well as Wernicke's area (BA 22) for analysis and elaboration of syntax of auditory information.
2. Integration and abstraction of the sensory information by parietal BAs 39 (angular gyrus), 40 (supramarginal gyrus), and 7 (superior parietal lobule) correspond to the second processing stage.
3. The parietal areas interact with the frontal lobes in the third processing stage, and this interaction underlies problem solving, evaluation, and hypothesis testing. Frontal BAs 6, 9, 10, 45, 46, and 47 are underscored by the model.
4. The anterior cingulate (BA 32) is implicated for response selection and inhibition of alternative responses, once the best solution is determined in the previous stage.
5. Finally, white matter, especially the arcuate fasciculus, is thought to play a critical role in reliable and efficient communication of information across these brain processing networks.

At the time we published this review, the PFIT was recognized as the most comprehensive model of brain–intelligence correlates (Hunt, 2007) and as a source of testable hypotheses about the putative brain networks involved. For example, the information-processing sequence from stages 1 to 4 might repeat itself many times over seconds or minutes during reasoning, and the sequence and/or the speed of progression through the sequence might differ among people of different intellectual abilities. Whether the same networks and sequences described men and women, or the young and the old, were also open questions. Research continues on these and other questions. Perhaps the most interesting question for this chapter is

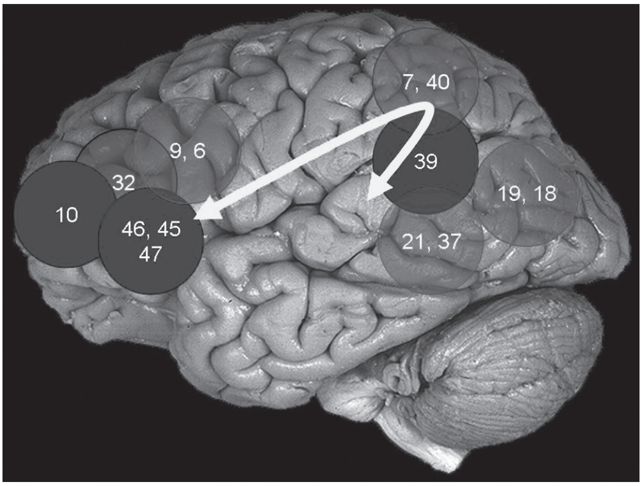

FIGURE 7.1. Brain regions by Brodmann area (BA) associated with better performance on measures of intelligence and reasoning that define the PFIT model. Numbers denote specific BAs; dark circles show left-hemisphere findings; light circles show bilateral findings. The arrow indicates the arcuate fasciculus white matter pathway. From Jung and Haier (2007). Copyright © Cambridge University Press. Reprinted by permission.

whether the PFIT could be used to predict IQ from brain images. There is a long, unsuccessful history of trying to do this, but there is new optimism, as we explain shortly below.

We have described the neuroimaging studies of intelligence from the first one in 1988 (Haier et al., 1988) up to the 2007 PFIT as Phase One in the attempt to link brain variables to intelligence (Haier, 2009). Phase Two has seen approximately 100 additional studies since 2007, and these have included much larger samples and advanced image acquisition and analysis techniques. Many of these studies have supported the PFIT and confirmed the distributed nature of brain areas related to intelligence, even in children (Kim et al., 2016) and in patients with brain lesions (Barbey, Colom, & Grafman, 2013; Barbey, Colom, Paul, & Grafman, 2014; Glascher et al., 2009, 2010). Most of the newer studies show that parietal and frontal areas have the strongest associations with intelligence. A group of German researchers replicated and extended our 2007 PFIT paper (Basten, Hilger, & Fiebach, 2015). Whereas the PFIT was based on a qualitative analysis, they used a quantitative method (voxel-based morphometry) to find common brain areas where structural and functional measures were related to individual differences in intelligence across 28 studies with a combined sample of over 1,000 participants. The findings supported a parieto-frontal network of areas related to intelligence and added some other areas that might be involved, pending replication.

Studies with newer imaging methods show that the integrity of white matter fibers throughout the brain is related to IQ (Penke et al., 2012a, 2012b). As noted, other studies that include imaging and genetic analyses show that there are likely genes in common for brain structures and intelligence. For example, a study of Australian twins reported that white matter integrity is most hereditable in frontal and parietal areas, and that IQ scores were correlated to some of these tracts (Chiang et al., 2009, 2011, 2012; Kohannim et al., 2012).

CAN INTELLIGENCE BE ASSESSED WITH NEUROIMAGING?

It had been apparent from the earliest studies that neuroimaging might provide a new means of assessing intelligence based on brain function and structure, in place of psychometric measures. The PFIT ushered in a basis for such attempts by identifying specific brain areas and networks to target. Despite all the studies showing such brain correlates of intelligence, however, the goal of predicting IQ from neuroimages has been elusive. Wide individual differences both in intelligence and in brain characteristics make prediction difficult. In fact, a number of attempts using multivariate statistical approaches have claimed some success, but until recently all have failed to be cross-validated in independent samples. A major problem is that not all brains work the same way, so a subset of areas important for intelligence in one person may not be the same as the subset for another person.

A powerful tool for brain imaging is graph analysis, which has opened the door to predicting intelligence from brain images (Stam & Reijneveld, 2007; van den Heuvel & Sporns, 2011; van den Heuvel, Stam, Kahn, & Pol, 2009). *Graph analysis* is a statistical method that establishes how any designated brain area (called a *node*) is connected to all other brain areas (analogous to how flights from your local airport are connected to all other airports around the world). The method can be applied to structural or function data (say, gray matter volume or white matter integrity or blood flow during a cognitive task). The essence of the method is to find correlations among many spots in the brain, to identify what areas systematically vary in their structural or functional connectivity with other areas. Networks of brain areas can be identified by using this method, and the number and strength of connections among areas can be quantified. Areas with many connections to other areas are called *hubs*. Some connections reach far across the brain, whereas other connections are more local. For example, an early study using graph analysis on 207 individuals found that IQ scores were related to connections among many areas, including ones identified in the PFIT (Santarnecchi, Galli, Polizzotto, Rossi, & Rossi, 2014).

There are now many studies that use graph analyses of one kind or another to investigate structural and functional connectivity across the entire brain and to examine how differences in connectivity among people relate to differences in cognitive abilities. A major study like this was published in 2015 as part of the Human Connectome Project, a multinational collaboration (Finn et al., 2015). In our view, it is the first study including an independent sample for cross-validation to predict IQ from functional magnetic resonance imaging (fMRI). This research is a remarkable achievement. Here is what the researchers did (as described by Haier, 2017, p. 182):

> They started with fMRI data from 126 people collected during six sessions, including four task and

> two resting conditions. The typical analysis would have compared the average connectivity for the entire group among the task and rest conditions. These researchers, however, focused on individual differences. The simple question was whether connectivity patterns were stable within a person. To address this question, functional connectivity patterns among 268 brain nodes (making up 10 networks) were calculated for each person separately for each session. Not only was the connectivity pattern stable within a person when the two resting conditions were compared, it was also stable across the four different tasks. In addition, each person's pattern was unique enough that it could be used to identify the person. Because these remarkable results combined stability and uniqueness, the connectivity pattern was characterized as a brain fingerprint. Of particular interest to us, individual brain fingerprints predicted individual differences in fluid intelligence. It gets even better. The strongest correlations with fluid intelligence were in frontoparietal networks. And, best of all, cross-validation was included in the report. The authors note, "These results underscore the potential to discover fMRI-based connectivity 'neuromarkers' of present or future behavior that may eventually be used to personalize educational and clinical practices and improve outcomes." They conclude, "Together, these findings suggest that analysis of individual fMRI data is possible and indeed desirable. Given this foundation, human neuroimaging studies have an opportunity to move beyond population-level inferences, in which general networks are derived from the whole sample, to inferences about single subjects, examining how individuals' networks are functionally organized in unique ways and relating this functional organization to behavioral phenotypes in both health and disease."

Haier (2017, pp. 118–119) speculates on a possible use of these findings:

> Imagine if colleges and universities gave applicants for admission a choice between submitting either SAT scores or a brain image . . . SAT scores are a ood estimate of general intelligence and that is an important reason they are good predictors of academic success. Can a better estimate of intelligence or predictor of academic success be extracted from a brain image? This is an empirical question, and a positive answer is probably far less scary than you might think. In fact, brain images are likely to be more objective, especially structural images, and not sensitive to a host of factors that potentially can influence psychometric test scores, like motivation or anxiety. Whether you are a good test-taker or not is irrelevant for getting a scan. Brain images generally are less expensive than SAT preparation courses or formal IQ testing and getting a brain image is far less time consuming. There is no preparation, you spend about 20 minutes in the scanner, and you can have a nap during structural image acquisition.

Of course, more research is required to confirm the brain fingerprint story and its relationship to intelligence. In addition to predicting intelligence from brain images, it might be possible to develop a new definition of intelligence based on quantified brain connectivity variables. Measurement of these brain characteristics might replace traditional intelligence tests if neuroimaging-based assessment is found to predict academic and life outcomes better than IQ tests currently do.

Predicting and defining intelligence from neuroimages are key steps toward understanding how the brain and intelligence are related. Understanding the influence of specific genes and networks of genes on intelligence may be potentially more important. Inevitably, advances in this understanding can lead to ways of influencing brain mechanisms that underlie intelligence. It might even be possible to dramatically increase intelligence through methods based on neuroscientific advances, but developing this technology would be a long and difficult endeavor. Understanding the complex cascade of genetic and neurobiological events that underlie the *g* factor and other aspects of intelligence is a formidable task. But the breathtaking sweep of advances in intelligence research over the last four decades suggests that this task is not impossible.

CONCLUSION

Remember that these exciting advances increase our understanding of the single most predictive variable for education and life success. Perhaps increasing intelligence is the key to eliminating achievement gaps. Perhaps neuroimaging assessments will help realize the goal of individualized education based on a student's cognitive strengths and weaknesses. We don't know, but the future of intelligence assessment is already moving beyond psychometrics and deep into the brain itself. And that will change everything.

CHAPTER 8

Intelligence-as-Process, Personality, Interests, and Intelligence-as-Knowledge

A Framework for Adult Intellectual Development

Phillip L. Ackerman

Historically, intellectual assessment of adults has presented several critical challenges to the scientific community. These challenges were first encountered when the scales originally created by Binet and Simon (1905/1916) for children were adapted for testing of adolescents and adults. The results of these assessments yielded confusion and controversy, but eventually were interpreted to mean that middle-aged and older adults, on average, have lower levels of intelligence than the average 18- to 21-year-old. However, it later became clear that the concept of *mental age* is not readily applicable to adults. More importantly, some researchers realized by the middle of the 20th century that the intelligence of children and intelligence of adults differ in important ways, which render traditional IQ-type scores somewhat ambiguous in terms of interpreting an adult's intellect. These ambiguities compromise the validity of predicting an adult's ability to perform intellectually demanding tasks. The *intelligence-as-process, personality, interests, and intelligence-as-knowledge* (PPIK) framework expands on the notions introduced by Cattell (1971, 1987) in his *investment hypothesis*. This framework enables us to understand adult intellect in general, and to consider how the interactions among process-type intellectual abilities; non-ability traits, such as affective (personality) traits and conative (interests, motivation) traits; and an individual's investment of time and effort lead to the development and maintenance of domain knowledge in adulthood. Evidence from this line of inquiry suggests that adults are, on average, far more intelligent than traditional IQ-based assessments suggest. Moreover, the development of intelligence-as-knowledge in late adolescence and adulthood appears to be related to an individual's standing on a relatively small number of constellations of non-ability traits, called *trait complexes*.

BACKGROUND

Binet and Simon

The seminal work by Binet and his colleagues in the late 1800s and early 1900s, which ultimately resulted in the Binet and Simon (1905/1961, 1908/1961) scales, provided a formalized system for the psychological assessment of intelligence that, with relatively few significant changes over the subsequent decades, is still the dominant approach for assessing child intellect.

Binet's major insight was that intelligence *develops* during childhood, such that older children, on average, could be expected to be more intelligent than younger children. This insight was, of course, a substantial departure from the notion of "fixed" intelligence put forth by Spearman (e.g., see

Spearman, 1904) and other psychologists. Binet used this insight to design assessment scales that were age-norm-referenced, so that a child's intelligence was reported specifically with reference to other children of the same age or to those younger or older than the child being assessed. Two other aspects of the Binet–Simon intelligence assessments are also important to note here, as they affected how later developments were applied to the assessment of adult intelligence. First, Binet and Simon (1905/1961) differentiated what they called their "psychological method" of assessing intelligence from two others: the "medical method," which attempts to determine a child's intelligence through examination of the individual's physical capabilities or appearance; and the "pedagogical method," which determines a child's intelligence though assessment of what the child knows (i.e., the assessment of knowledge).

The reason Binet and Simon rejected the medical method is somewhat obviously a question of invalidity: Simply looking at the slope of a child's forehead, or at how closely set his or her eyes are, provides no useful prediction of the child's academic success. But the reason Binet and Simon rejected the pedagogical method of assessing intelligence was one primarily aimed toward socioeconomic equity. They believed that assessing a child's ability to read and write, for example, would be influenced by the class of the child's family: Children in affluent families would be more likely to have access to books, or to have instruction or intellectual experiences outside the classroom that would lead to greater knowledge, when compared to children from less affluent families. So, for example, the items that appear on the Binet–Simon scales (and indeed on subsequent tests inspired by the Binet–Simon scales) do not require that a child know how either to read or write.

When knowledge was assessed in the Binet–Simon scales, the content was limited to those domains representing information that would be widely available to children across a large cross-section of all the socioeconomic strata in a particular culture (defining common words, recognizing common objects from pictures, etc.). The central theme, then, for the Binet–Simon "psychological method" of intelligence assessment, in contrast to the pedagogical method, was to limit knowledge assessment to information that one could expect most (if not all) children to have had substantial exposure to and experience with.

The other aspect of the Binet–Simon framework for intelligence assessment was the testing procedure's requirement that the child put forth his or her *maximal* effort during the test. Binet and Simon recommended individualized approaches to elicit such effort, such as supportive encouragement or strict authority, depending on what the examiner determined was necessary to maximize the child's motivation for performance on the test. Thus the general assumption was that a child's intelligence test performance represented what the child was *capable* of doing intellectually, not necessarily what the child was *likely* to do in the classroom.

The key aspects of the Binet-Simon approach are as follows:

- Preference for the "psychological method" of assessing intelligence of children over the "pedagogical method."
- Specification that intelligence increases with age.
- Assessment of maximal performance rather than typical effort.

Early Studies of Adult Intelligence

The first sign of a conceptual problem in extending the testing inspired by Binet and Simon was essentially a controversy that played out in the pages of *The New Republic* after World War I. Ironically, if Terman (1916) hadn't modified the Binet–Simon procedure of simply reporting that a child was "advanced" or "retarded" in intelligence, in comparison to his or her age peers, by adopting Stern's (1914) *intelligence quotient,* the controversy might have been much less severe than it turned out to be for the community of psychologists involved in intelligence testing. Basically, Binet's approach did not imply that a child's relative standing with respect to similar-age peers was going to be consistent from one year to the next. (In fact, there is ample reason to believe from Binet and Simon's writings that they did not believe in fixed relative standing on intelligence; see Fancher, 1985.) Stern, and later Terman, believed that a child's *relative* standing was indeed constant, such that from a single testing occasion, one could predict the child's relative standing years later. The initial formulation of the IQ (mental age divided by chronological age) by Stern, later modified by Terman by multiplying this value by 100, inevitably yielded scores for adults that made little sense, given that it was not reasonable to expect that the development of intelligence from childhood to adulthood would follow a linear path. Thus it made no sense to talk of a chronological 40-year-old with the mental age of a 20-year-old, or a 20-year-old with the mental age of a 40-year-old. But when the Stanford–Binet was extended to adolescents and adults (Terman, 1916), and administered to a small sample of U.S. Army conscripts in World War I (with comparison to the Army Alpha tests; see Yerkes, 1918), the conclusion was that the average conscript had a mental age of 13 (e.g., see Brigham, 1922). Walter Lippmann (1922) made light of this particular result, and psychologists like Terman (1922) and Boring (1923) attempted to defend the result *as if* such results were meaningful in and of themselves (though see Freeman, 1922, for a more coherent discussion).

Fortunately, some investigators, such as Conrad, Jones, and Hsiao (e.g., see Conrad, 1930; Hsiao, 1927; Jones & Conrad, 1933), decided to focus not on adult IQ per se, but on raw scores from the individual component scales that made up the overall Army Alpha test. What they found, in cross-sectional studies of individuals between 10 and 60 years of age, was that although overall scores were highest among 20-year-olds, two scales of the test showed a strikingly different pattern of results. These scales were Synonym/Antonym and general Information, two scales tapping an individual's vocabulary and general knowledge. For these scales, there was no pattern of lower scores among older individuals. In hindsight, possibilities of *cohort differences*—that is, the fact that the 60-year-olds tested by Conrad and colleagues (e.g., Jones & Conrad, 1933) had been born in an earlier time, with different exposures to language, education, news media, and so on—would have made it impossible to say that by the time the 20-year-olds in the sample reached the age of 60, they would perform as well as or better than the 60-year-olds in the sample (for a discussion of this issue, see Schaie & Strother, 1968).[1]

Nonetheless, there is a fundamental question about how to interpret these particular results, in comparison to the overall pattern of lower average IQ scores for adults beyond the age of 20. Jones and Conrad (1933), for example, concluded that intelligence did decline rapidly after age 20, but the Synonym/Antonym and Information scales "present an unfair advantage to those in the upper age brackets" (p. 271). There are, in retrospect, quite different alternative interpretations. One interpretation might be that what it means for adults to be "intelligent" is different from what it means for children to be "intelligent," and that the scales inspired by Binet and Simon's work were not assessing adult intelligence. After all, the Binet–Simon scales were designed specifically to predict academic success in early childhood years, and the day-to-day intellectual demands on typical 40-year-olds may diverge substantially from those of the elementary school classroom. Another interpretation might be that vocabulary and general knowledge are indicative of adult intelligence, while the other scales are not germane to the adult intellectual experience—with the implication being that middle-aged adults are, on average, just as intelligent as adolescents. Much later, Demming and Pressey (1957) examined adults on a variety of different tasks (e.g., using a telephone directory, getting professional assistance, etc.), and found that middle-aged adults performed much better than young adults or adolescents. Their conclusion was that measures of intelligence that were designed to assess the kinds of tasks more central to an adult's life—many of them centered on an individual's knowledge—were more appropriate for assessing adult intelligence.

Thus the key issues from early studies of adult intelligence are as follows:

- Overall, the intelligence assessments based on or extended from the Binet–Simon scales indicated that intelligence peaks at about age 18.
- The concept of mental age cannot be readily applied to adult intelligence, partly because of the pattern of slowing development as adolescents make the transition to adulthood.
- At the individual scale level (especially in the domains of verbal ability and general knowledge), middle-aged adults may perform as well as or better than adolescents and young adults.

Hebb and Cattell

Donald Hebb (1939, 1942), a neuropsychologist, was the first researcher to come to the conclusion that there are two fundamentally different aspects of adult intelligence. He based his reasoning on clinical examinations of patients who had experienced removal of brain tumors or other surgical losses of brain tissue. Hebb also noted that such brain traumas have different effects on intelligence, depending on whether the trauma is experienced relatively early in life or later in adulthood. Neurological trauma during infancy or childhood, when intelligence ordinarily develops at a rapid rate, has widespread negative effects on intellectual functioning. But for adults, for whom intellectual growth has largely reached plateau levels, some components of intellectual functioning may be substantially compromised by significant loss of neural tissue, while other components appear to be largely preserved. Hebb named these two components *Intelligence* A and *Intelligence B*. Intelligence A was identified as "direct intellectual power" (Hebb, 1942)—and it was hypothesized to represent the aspect of intelligence most involved in new learning, abstract reasoning, and similar aspects that make up the "process" aspect of general intellectual ability. In contrast, Intelligence B was thought to involve "the establishment of routine modes of response to common problems" (p. 289). For Hebb, Intelligence B was more than just an individual's repertoire of knowledge; he viewed it as including vocabulary and verbal comprehension abilities that are essential in an individual's day-to-day occupational functioning, but that also represent skills and procedures acquired through long-term exposure and experience.

Shortly after Hebb's introduction of the Intelligence A and Intelligence B constructs, Cattell (1943), drawing on the psychometric literature, introduced his constructs of fluid intelligence (g_f, as he abbreviated it, or Gf as it is now known) and crystallized intelligence (g_c or Gc). As Cattell noted, Hebb's framework accounted for "two-thirds of [Cattell's] present theory" (p. 179). Cattell's initial theory added to Hebb's framework by integrating research from studies of normal aging, and by hypothesizing a developmental trajectory related explicitly to the growth of Gc out of the investment of Gf during childhood and adolescence (Cattell, 1971, 1987).

Both Hebb (1942) and Cattell (1943) rejected the conclusions of psychologists such as Jones and Conrad, who, as discussed earlier, argued that if intelligence scales showed little or no decline in adulthood, then such tests were not adequate measures of adult intelligence. Instead, Hebb and Cattell argued that it was critical to consider that adult intelligence is composed of both "process"-type abilities that evidence declines in adulthood, and "content"-type abilities that show stable or somewhat increasing scores throughout much of adulthood. Cattell's framework also provided an explicit explanation for why large increases in Gc do not ordinarily take place in adulthood, in that Gf peaks in late adolescence, and that Gf is important for development of further gains in Gc. However, Cattell did not take full account of the importance of *transfer* in the development of new knowledge—an important contribution made later by Ferguson (1954, 1956). That is, Ferguson noted that learning, in the absence of transfer of training, only takes place with infants; by the time an individual has reached adulthood, acquisition of new knowledge and skills is critically dependent on the transfer of knowledge and skills that have already been acquired (Gc). Thus, especially for older individuals, it is most likely that the efficacy of new learning is determined both by individual differences in Gf and by individual differences in the breadth and depth of relevant knowledge and skills, which may serve as a foundation for transfer to the new knowledge and skills.

Of fundamental importance for the current discussion, both Hebb and Cattell proposed that adult intelligence, far from being represented by inevitable decline after about age 20, is associated with two components, of which only one component (Intelligence A/Gf) shows declines after adolescence. The other component (Intelligence B/Gc) does not show such declines, and this component is also of critical importance to the success of adults in intellectually demanding day-to-day activities.

From the work of Hebb and Cattell, the central points are as follows:

- Adult intelligence can be meaningfully divided into two components. One (Intelligence A/Gf) is composed of abstract reasoning, short-term memory, and other process abilities; the other (Intelligence B/Gc) is composed of experiential and educational knowledge and skills.
- Intelligence A/Gf shows rapid development during childhood and plateaus during late adolescence; Intelligence B/Gc develops well into adulthood, and is much better preserved in normal individuals as well as in individuals with various types of neurological traumas.

Cattell's Investment Theory

Although Hebb did not further explore Intelligence A/Intelligence B in later work (though see Hebb, 1949), Cattell individually, and with Horn's contributions, expanded both the theoretical and empirical foundations for his theory of intelligence. Cattell originally proposed that Gc grows out of Gf in childhood, but in a later discussion, Cattell (1971, 1987) proposed that Gc develops specifically as a result of the *investment* of Gf during this period. The details of how this investment takes place were not spelled out or investigated; for example, Cattell noted that development of Gc was "a function both of g_f and a bunch of opportunity, motivation and memory factors" (1987,

p. 152). However, he clearly implied that he considered differentiated Gc knowledge and skills within and between individuals to be the results of the time and intellectual (Gf) effort allocated to particular domains of inquiry. Although Cattell later noted relations between personality traits and measures of academic achievement, these did not play an explicit role in his investment theory.

The other major consideration that Cattell offered in this framework was a distinction between "historical" Gc and "present" Gc, especially with respect to assessing adult intelligence. The problem actually is partly a consequence of the Binet–Simon paradigm for assessing intelligence of children. As discussed earlier, Binet and Simon decided against using the "pedagogical method" of assessing intelligence—that is, assessing what the individual "knows"—because they thought that such measures would be overly influenced by socioeconomic status. So, to the degree that knowledge and skills are assessed by Binet-inspired tests, the content of tests is limited to that which is common to the wider culture. Practically speaking, knowledge and skills assessed on IQ-type tests are those that one can expect all or nearly all children and adolescents to have had ample exposure to. For elementary school children, vocabulary knowledge and verbal comprehension represent domains of common experiences or "core" curricula in the verbal domain; simple math operations (addition, subtraction, multiplication, and division) represent core curricula in the math domain. But as children reach secondary school and beyond, or as they move from school to work, their intellectual experiences become quite varied. For example, high school students often have opportunities for multiple elective courses, whether in different foreign languages, various arts and humanities fields, sciences, and mathematics, leaving a smaller number of common experiences or core courses. Cattell (1987) recognized the inherent problem associated with assessing Gc in adults:

> . . . we begin to ask what happens to crystallized general intelligence, and the traditional intelligence tests that measure it, *after* school. The crystallized intelligence then goes awry both conceptually and in regard to the practical predictions to be made from traditional intelligence tests. In the twenty years following school, the judgmental skills that one should properly be measuring as the expression of learning by fluid ability must become different from different people. If these are sufficiently varied and lack any common core, the very concept of general intelligence begins to disappear.
>
> . . . [The psychologist's] alternatives are then: (a) to sample behavior still more widely than in the traditional test, using a formula expressing the role of fluid intelligence in learning in each of many different fields (an approach which, in practice, might amount to producing as many different tests as there are occupations, etc.); (b) to change completely to fluid intelligence measures . . . ; or (c) to continue to measure by the "school version" of crystallized ability essentially learning on what the individual's intelligence was at the time of leaving school. (Cattell, 1987, pp. 143–144)

That is, to assess current Gc in adults, one would need to assess knowledge and skills as varied as various educational specialties (physical and natural sciences, social sciences, technology, math, engineering, humanities, business, law, medicine), but also nonacademic domains, such as carpentry, plumbing, gardening, popular music, current events, and so on. Otherwise, it would be impossible to determine, for example, whether a carpenter has higher or lower levels of current Gc than a physicist, a concert violinist, or a nurse.

When it comes to assessing Gc in late adolescents and adults, nearly all intelligence researchers have adopted the third strategy described by Cattell—that is, to measure historical Gc, rather than attempt to provide a comprehensive assessment of current Gc. Aptitude test designers take a similar approach: The math content of the SAT is limited to algebra and geometry (which are required in nearly all secondary school programs). No trigonometry or calculus problems appear on these tests, mainly because such courses are often electives that are not completed by significant proportions of students. Even the general tests of the Graduate Record Examinations (GRE), which are completed by students seeking admission to graduate study at the end of their college/university programs, do not test advanced mathematics; they too are limited to the same common core curriculum (algebra and geometry) that high school students complete. In this sense, such tests do not directly assess "current" Gc, but rather content that individuals have acquired in the past. In the case of the GRE, the content may have been acquired 6 or 7 years previous to the administration of the test, making the test much more of an assessment of historical Gc than of current Gc. Nontraditional students, who may be 30 or 40 years old, are thus at a considerable disadvantage in comparison to younger students when it comes to completing tests like the SAT or GRE—given that 10 or 20 (or more) years may have elapsed between the time they acquired algebra and geometry knowledge and skills and the time when such a test occurs, and given that such skills may have been rarely if ever used by these adults in their occupational or avocational activities.

The central issues, then, from Cattell's framework for intellectual development are as follows:

- Investment of Gf capabilities, through some unknown combination of factors, leads to development of Gc.
- For assessment of Gc in adults, either one must develop a wide array of tests that adequately sample the "current" levels of common and a variety of noncommon domains of knowledge and expertise of adults, or one must limit the assessment to "historical" Gc—that is, the knowledge and skills to which nearly all members of the population were exposed as adolescents or children.

Mid-20th-Century Status of Intelligence Assessment of Adults

The introduction of an omnibus test of intelligence specifically designed for adults (Wechsler, 1939) removed the problems caused by the concept of mental age and by reliance on tests that had been extended from assessment of children. Wechsler's test also included consideration of diagnostic medical criteria (e.g., Korsakoff syndrome, organic brain disease) rather than school achievement. Assessment of adult IQ could therefore be accomplished without many of the limitations posed by the earlier extensions of the Binet–Simon scales. Although Wechsler's scale represented a substantial improvement over existing measures, cross-sectional norms still indicated that average peak IQ was obtained by young adults, with declining levels of intelligence as age progressed into middle age and beyond (see Wechsler, 1944). Later studies of longitudinal design (e.g., Owens, 1953) and lagged cross-sectional (also called cross-sequential) design (e.g., see Schaie, 1996) suggested that cohort differences resulted in somewhat exaggerated declines in intellectual abilities with increasing age in adulthood, but with the exception of some Gc (historical) abilities, most other intellectual abilities showed declines with age across most of the adult lifespan. Even considering that Gc (historical) abilities might increase during adulthood (Horn, 1965), the relative gradient of improvement through middle age on Gc was expected to be much smaller than the gradient of decline on Gf abilities. Thus an average intelligence score that equally weighted Gf and Gc abilities was expected to peak no later than the late 20s.

Development of an Alternative Theory

The PPIK theory (Ackerman, 1996) was born from a conclusion that the Binet–Simon paradigm for intelligence assessment of children is inadequate for assessing adults, even with the kinds of innovations provided by the Wechsler Adult Intelligence Scale. To review, the Binet–Simon paradigm consists of four major components, as follows:

1. Intelligence assessment is mainly concerned with individual differences in mental *processes* (e.g., abstract verbal, spatial, numerical reasoning, short-term memory, mathematical computation).
2. Intelligence assessments eliminate (as far as possible) consideration of knowledge acquired through *specific* educational or experiential sources. Knowledge assessed in standard intelligence measures is limited to content that is common to a dominant culture or included in a core educational curriculum.
3. Elicitation of *maximal* effort from the examinee is expected.
4. School achievement is the fundamental criterion for external validation (except for Wechsler's scales, which include medical criteria for validation).

Each of these components seems incomplete for representing the intelligence of adults. Moreover, these conditions appear to reduce or eliminate the possibility of understanding how non-ability traits might influence the development and maintenance of intelligence, from the time that individuals stop sharing most of their educational and vocational experiences in adolescence and beyond. From these initial considerations, I developed four alternative propositions:

1. Although process aspects of intelligence are important to the acquisition of new knowledge and skills (e.g., see Ackerman, 1988), these aspects of intelligence have less importance in adult intelligence, which depends to a substantial degree on prior knowledge and transfer of training (Ferguson, 1956). Thus, in agreement with Cattell's broad theory, Gf (process) abilities are most important during early development, and are less important in adulthood.

2. For adults, Binet's "psychological method" of intelligence assessment is inadequate. It must be supplemented by the pedagogical method—that is, assessment of what adults actually *can do* (i.e., knowledge and skills that are not necessarily common to a core educational curriculum). The pedagogical method requires consideration of *current* Gc, Accordingly, assessments of intellectual knowledge and skills must be both broad and deep, ranging across a wide array of different domains that represent the diversity of expertise in the adult population. Thus intelligence-as-knowledge represents an important component of adult intelligence.

3. In the school system—where educational assessments often involve students' "cramming" for end-of-term examinations, or when the goal is to estimate what a student might be capable of, rather than what the student is likely to do—it makes sense to attempt to assess an individual's maximal performance. However, for an adult, one is arguably more interested in how the individual typically performs, so considerations of likely performance seem to be more relevant to assessing adult intelligence than assessments of maximal performance.

4. One major shortcoming of both the Binet–Simon scales and the Wechsler scales is that while they correlate well with academic performance, these tests correlate significantly, but much less highly, with measures of occupational performance (e.g., see Schmidt & Hunter, 2004). But relatively few adults are engaged as students in educational contexts. A more useful criterion for adults is occupational performance, or performance on relevant intellectual tasks outside the classroom or work environment. In general, tests of general intelligence correlate only moderately at best with adult criteria such as job performance. In hindsight, this result should not be all that surprising because intelligence tests were not originally designed with job performance as the criterion on which the tests were developed or validated.

In addition, through an examination of correlations among personality traits, interest and motivational traits, and intellectual abilities (e.g., see Ackerman, 1997; Ackerman & Heggestad, 1997), it became clear that these non-ability traits play an important role in adult intellectual development. From a theoretical perspective, the justification for finding these relations to be more pronounced in adulthood, compared with children, is that post-secondary educational and occupational environments provide much lower situational "press" than the mandatory secondary school environment. This means that adults are much less constrained in how they engage the intellectual environment, especially once they leave secondary school. With lower situational press, it is generally believed that non-ability traits play an increasingly important role in determining the direction and intensity of an individual's effort (for a review, see Tett & Burnett, 2003).

THE PPIK THEORY OF ADULT INTELLECTUAL DEVELOPMENT

Components of the Theory

There are four components to the PPIK theory: intelligence-as-Process, Personality, Interest, and intelligence-as-Knowledge. These components are defined in turn below.

Intelligence-as-Process

As Cattell (1943) and others have pointed out, performance on any particular test of intelligence is almost certainly determined by both Gf and Gc, although to different degrees, depending on (1) the content of the test (e.g., familiar words or numbers vs. artificial stimuli or novel figures/words); (2) the characteristics of the examinee sample (in terms of their age, prior experiences, education, etc.); and (3) most likely a variety of other test characteristics (e.g., speededness, need for precision in attending or responding, complexity of the items). It is, however, possible to specify that underlying cognitive processes such as Spearman's "eduction of relations" (i.e., abstract reasoning), short-term memory, working memory, and similar operations represent the "process" aspects of intellectual abilities. (As an aside, it is useful to note that because Gc is involved in all intellectually demanding tests, there really is no test that can be reasonably classified as truly "culture-free" or "culture-fair," given that the makeup of Gc is highly determined by the cultural milieu of the individual examinees. Instead, many investigators quite reasonably refer to tests with mostly Gf content as being "culture-reduced.") Intelligence-as-process, whether it is referred to as Cattell's Gf or Hebb's Intelligence A, is envisioned to be (1) dominant early in childhood, reaching a plateau in adolescence; (2) important as a determinant of the level of intellect that can be invested in development of intelligence-as-knowledge; and (3) relevant, but not univocally so, in the acquisition of new knowledge throughout adulthood.

Personality

A meta-analysis we conducted on personality and ability correlations makes it possible to articulate some general trends in the associations between these two families of traits (Ackerman & Heggestad, 1997). Although in general, personality traits do not share a large degree of common variance with measures of intellectual ability, there are some important exceptions. First, the traits of neuroticism, anxiety, and psychoticism all appear to have pervasive significant negative correlations across a wide variety of intellectual abilities, even though the correlations are of modest magnitude. Second, there is a group of personality traits that appear to have generally positive relations with intellectual abilities, especially for the verbal/Gc component of intelligence. These traits have a variety of names—openness to experience, intellectance, culture, need for cognition, and typical intellectual engagement—but in general they refer to an individual's general orientation toward thinking, problem solving, reading, and seeking intellectual and cultural experiences. Scales that represent these traits are often highly correlated, so it is generally concluded that they represent one overarching general personality construct of intellectual orientation (e.g., see von Stumm & Ackerman, 2013).

Other personality traits appear to have more complex associations with intellectual abilities, such as masculinity–femininity, which is generally found to be associated with math and spatial abilities, consistent with gender differences on these types of ability tests. Mixed results have been found for associations between introversion–extroversion and intellectual ability. Although Cattell (1945) speculated that introverts would prefer reading books to going to a social event, and as such should be expected to have higher abilities (especially in the Gc domain), only some studies have supported this conjecture; others have failed to find any significant associations. Undoubtedly, part of the difficulty with this particular trait is the fact that extremes on either end of the introversion–extroversion continuum are considered to be associated with poor adaptation, so that individuals closer to the center of the distribution would be expected to have better overall adaptation to society. If this is correct, the relationship between introversion–extroversion and intellectual abilities should have an inverted-U shape, depending on the particular characteristics of the test sample and the particular assessment scale. This is something that cannot readily be resolved with a linear correlational analysis.

Interests

Examining vocational interests and intellectual abilities provides a much more varied set of associations than for personality traits, partly for reasons that are specific to the nature of interest theories and to the specific design of interest assessments. Historically, vocational interest measures were not designed to provide trait-like scores; the original Strong Vocational Interest Blank (Strong, 1943) provided estimates of similarity between the patterns of likes and dislikes between various job types and the individual completing the questionnaire. So one could inquire, for example, whether those individuals with interests similar to those of engineers or doctors had higher or lower IQ scores than those with interests similar to those of plumbers or carpenters, but it was otherwise impossible to determine associations between intellectual abilities on the one hand, and degree of interest in particular occupations on the other hand (Darley & Hagenah, 1955). In addition, many vocational interest measures were designed in a way to reduce or eliminate associations with intellectual abilities. Typically, individuals are asked to consider which jobs they might like or dislike, independently of whether they think they have the ability to perform the jobs.

By the 1950s, however, vocational psychologists had started to converge on a consensus list of vocational interest traits (e.g., see Guilford, Christensen, Bond, & Sutton, 1954; Roe, 1956), which allowed for correlational assessments of interest–intelligence associations. The current dominant approach to assessing vocational interests, developed by Holland (1959, 1973), has particular importance for interest–intelligence relations, but it has one substantial shortcoming. The shortcoming is that Holland's model is essentially a typology, meaning that it does not readily lend itself to correlational analyses; each individual is described in terms of his or her top interest themes, rather than receiving a score on each of the interest theme traits. Holland's original theory of the development and expression of vocational interests, however, does make explicit connections to intellectual abilities. First, interests are hypothesized to develop as a function of early experiences and challenges; children who are initially successful with math problems or verbal problems, for example, are expected to develop higher levels of self-concept for these domains, in contrast to those children who struggle with the same materials. Thus interests and intellectual ability are expected to be associated: Higher levels of intellectual abilities should lead to greater successes, which in turn should lead to higher self-concept and then to higher levels of interest in the domain, whereas lower levels of intellectual abilities should lead to fewer successes, which in turn should lead to lower self-concept and thus lower levels of interest in the domain. By the time children reach adolescence, there should be an alignment between their patterns of ability strengths and weaknesses and their high and low levels of vocational interests.

As for particular interest themes, Holland originally specified two themes as particularly associated with higher intellectual abilities: *intellectual* interests and *esthetic* interests. In addition, *motoric* interests were identified as being associated with hands-on kinds of skills (one could imagine mechanical reasoning and knowledge as key abilities associated with these interests). *Conforming* interests were thought to be mainly associated with lower-order abilities, such as math computation and perceptual speed abilities. Other interest themes (*supporting* and *persuasive*) were hypothesized to be either uncorrelated with abilities, or negatively associated with intelligence. Because most modern interest assessments do not provide scores for each individual on each of these six interest themes, there have been relatively few sources of evidence to assess these relations. However, based on the existing corpus of data, it appears that interests in two themes (intellectual, which was retitled as *investigative,* and esthetic, which was retitled as *artistic*), are substantially positively correlated with intellectual abilities. Investigative interests are associated with a wide array of intellectual abilities, while artistic interests are mostly associated with Gc abilities. Conforming interests (retitled as *conventional*) are positively correlated with measures of math computation and perceptual speed abilities. The remaining two interest themes (*supporting,* retitled as *social,* and *persuasive,* retitled as *enterprising*) tend to have negligible or negative associations with traditional measures of intellectual abilities (for a review, see Ackerman & Heggestad, 1997).

Intelligence-as-Knowledge

The fourth component of the PPIK theory is the construct of intelligence-as-knowledge. The construct has much in common with Hebb's Intelligence B and Cattell's Gc, but the main differences are these: (1) Within the PPIK framework, current Gc is the central focus, in contrast to historical Gc; and (2) a much broader range of knowledge is included, such as cognitive and perceptual skills, cultural knowledge (e.g., knowledge of current events), occupational knowledge, and avocational knowledge (cooking, gardening, technology, hobbies of various sorts, etc.). Fundamentally, an adult's entire declarative (factual), procedural (skill), and tacit (implicit) knowledge and skill intellectual repertoire is considered to represent his or her intelligence-as-knowledge. A full accounting of an individual's intelligence-as-knowledge would be contained in the answers to the two questions "What do you know?" and "What can you do?"—at least within domains that require cognitive effort to acquire. Of course, not all knowledge and skills are equally indicative of intelligence-as-knowledge. Acquiring knowledge of how to perform neurosurgery or design a nuclear power plant obviously requires greater investment of cognitive effort over a longer period of time than learning all of the different configurations for ordering an automobile from a dealer. One could argue whether learning trivia such as sports team statistics is "intellectual" to a greater or lesser degree than memorizing the scores for all of Beethoven's piano sonatas, but clearly individuals differ in terms of such diverse knowledge in measurable ways. Ultimately, an individual's intelligence-as-knowledge is represented by both the depth and breadth of the person's knowledge across the various topical domains that make up the wider civilization.

Investment

At its core, the PPIK theory considers adult intelligence to be represented by what an individual *can do*—that is, what the individual is capable of accomplishing. This in turn is determined by the individual's relevant repertoire of knowledge and skills (i.e., current Gc). The development of Gc in turn is determined by the individual's investment of both process-type intelligence early in life, and increasingly by the individual's use of transfer of prior knowledge and skills for the development of refined (and in some cases automatized) procedures for accomplishing intellectual tasks. Tasks that are exceptionally novel require greater investments in intelligence-as-process; tasks that are more familiar, or those that represent building on existing knowledge structures, require less investment of intelligence-as-process and depend more on the foundation of existing intelligence-as-knowledge. A few examples might illuminate this particular proposition. Extensive research has suggested that general intelligence, made up of both Gf and Gc components, is importantly related to individual differences in task performance when the task is novel. But with extensive practice and skill development, individual differences in performance on such tasks are less related to general intelligence, and more related to the component skills (e.g., perceptual speed and psychomotor abilities for tasks that require rapid perception, stimulus recognition, and responses). See Ackerman (1988) for an extensive review.

The process of learning to drive a car, or even learning to fly an airplane, for example, has these kinds of characteristics. When a new driver or pilot first confronts the task, it requires a great amount of dedicated attention and cognitive effort to remember all the component tasks that are required for the safe and efficient operation of the vehicle. The use of secondary task probes provides a good indication of the cognitive/intellectual demands of the task. If the operator cannot successfully perform the target task and carry out a secondary task (such as carrying on a coherent conversation), then the target task is presumed to be consuming all of the individual's intellectual effort resources. New drivers or new pilots are ordinarily seriously impaired in attempting to carry out a conversation (or even to sing along to a familiar tune on the radio) when they are first learning the task. But with extensive practice, many aspects of the skills required to drive a car or fly an airplane become part of the intelligence-as-knowledge repertoire, and as such require little involvement from intelligence-as-process resources. Under normal conditions, most adult drivers (and experienced pilots) show little or no significant impairments in task performance while carrying out a conversation at the same time.

Similarly, the effects of declines in Gf/intelligence-as-process with advancing age are often not inherently problematic for task accomplishment in a variety of domains. Michael DeBakey was successfully performing heart bypass surgeries well into his 80s, partly because by the time he reached that age, he had performed over 60,000 such procedures (DeBakey, 1999). There should be little doubt that a 30-year-old MD from a prestigious medical school would have higher Gf abilities than the 80+-year-old Dr. DeBakey, but it is much easier and more effective, in general, to recall the correct answer to a problem that has been previously encountered many times before than it is to derive an answer depending only or mostly on intelligence-as-process resources. There are numerous other examples of middle-aged and older individuals who perform their specialized skills or employ their specialized knowledge at levels exceeding those of much younger professionals, who are expected to have higher Gf abilities but less acquired/Gc skills and knowledge.

Ultimately, though, there is a point at which the demands for new learning cannot be fully compensated by preexisting intelligence-as-knowledge. For example, older musicians may struggle with— new music scores; older dentists may struggle with using 3D computer-aided design/manufacturing systems for creating porcelain crowns; and older behavioral psychologists may struggle with integrating their knowledge with recent advances in studies with functional magnetic resonance imaging systems. In such cases, declines in intelligence-as-process with increasing age may limit or slow the acquisition of relatively novel knowledge and skills. It then becomes a question of whether further investment of intelligence-as-process resources is worth the potential return in terms of new knowledge and skills (e.g., see Posner, 1995).

Actions and Influences in PPIK Theory

According to the original PPIK theory, intelligence-as-knowledge is initially developed, especially during adolescence and through early adulthood, through the investment of Gf/intelligence-as-process resources into Gc as traditionally assessed (such as verbal abilities and general core knowledge). These abilities then jointly influence the development of specialized intelligence-as-knowledge, with key personality traits (e.g., openness to experience, typical intellectual engagement) and interest themes (realistic, artistic, investigative) influencing the direction and intensity of effort toward acquisition and maintenance of intelligence-as-knowledge. Knowledge in the physical sciences and mathematics domains, for example, is more highly influenced by Gf/intelligence-as-process abilities, and by the realistic and investigative interest themes; knowledge in the arts, literature, and social sciences is more highly influenced by Gc (historical), the personality traits of openness to experience and typical intellectual engagement, and both the artistic and investigative interest themes.

TRAIT COMPLEXES AND REVISIONS TO THE PPIK THEORY

In the original specification of the PPIK theory, as noted above, the roles of personality traits and interest themes were considered at the level of individual constructs. Although these non-ability traits were viewed as related to one another (e.g., artistic interests and openness to experience), and as such were thought to have possible influences on one another during development, their actions were considered separately. Subsequent to the initial specification of the theory, a review of the literature and meta-analysis of interest–personality–ability relations, along with a series of empirical studies, together suggested that something more fundamental could be revealed. This led to refinements to the theory.

The first indication of commonality among these traits came from an analysis of interest–personality communality. In contrast to personality–intelligence relations, the associations between personality traits and interest themes are much more substantial, suggesting that there are relatively close associations between particular affective and conative/motivational traits. Enterprising and social interest themes, in particular are associated with personality traits of extroversion and positive affect/well-being. Conventional interests are associated with conscientiousness and traditionalism; investigative and artistic interests are associated with absorption, and a wide array of personality traits is associated with an intellectual orientation (as previously discussed, including openness to experience, typical intellectual engagement, etc.)

Additional communalities were found for traits in the domain of academic self-concept and self-estimates of abilities (e.g., see Ackerman, 1997; Ackerman & Wolman, 2007). It is ultimately useful to consider whether an individual's investment of intelligence-as-process and Gc-type abilities is more influenced by the individual's self-assessments of his or her abilities than by the person's objectively determined abilities.

Trait Complexes

Finding common variance among personality traits and interest themes, along with some intellectual ability traits, led to a suggestion that constellations of groups of traits across trait families are more or less likely to cluster together. From reviewing the literature on cross-trait associations, we (Ackerman & Heggestad, 1997) suggested four constellations of traits: *social, clerical/conventional, science/math,* and *intellectual/cultural,* as shown in Figure 8.1. These are groups of traits that tend to be moderately to highly correlated with one another. For example, this means that, everything else being equal, individuals with high levels of traditionally measured Gc also have higher level of investigative and artistic interests, and higher levels of the personality traits of absorption, openness to experience, and typical intellectual engagement.

There are two noteworthy features of these trait complexes, and one overarching issue not depicted in Figure 8.1. First, these trait complexes were established on the basis of existing data, which means that trait relations that had not been investigated in prior studies would not appear in the representation. Second, of the four identified trait complexes, the science/math complex had no personality traits with substantial associations; this *might* mean that there are no specific personality traits common to this complex of ability and interest themes, but it might also indicate that there are not-yet-identified personality traits that would be associated with these other traits (e.g., see Toker & Ackerman, 2012). Also, the social trait complex contains no abilities. A similar interpretation of this finding might be offered; that is, abilities are not associated with this constellation of personality traits and interest themes. However, it is also possible that what is missing for this trait complex is a reliable and valid indicator of so-called "social intelligence," a construct that has proved elusive to intelligence researchers over the modern history of intelligence assessment (e.g., see Jones & Day, 1997; Thorndike & Stein, 1937). The last point, not directly captured in the figure, is that these are relatively independent or uncorrelated constellations of traits. This means that although an individual's position on one trait complex provides little information about his or her standing on the others, it is quite possible that an individual could have high or low standing on multiple trait complexes.

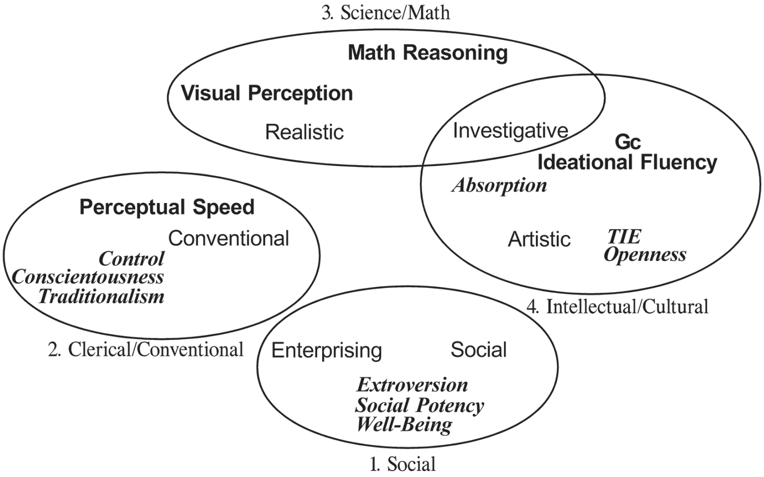

FIGURE 8.1. Trait complexes, including abilities (bold), interests (regular), and personality (italic) traits, showing positive communalities. Number categories are trait complexes. Gc, crystallized intelligence; TIE, typical intellectual engagement. From Ackerman and Heggestad (1997, Figure 7). Copyright © American Psychological Association. Reprinted by permission.

Because of the patterns of ability associations with the personality and interest constructs, we conjectured that these constellations of traits might have facilitative or impeding influences in the development and maintenance of intelligence-as-knowledge, in much the same way that Snow's (1963) concept of *aptitude complexes* might be supportive or not supportive of the acquisition of knowledge and skills in educational contexts. In particular, the intellectual/cultural and science/math trait complexes were hypothesized to be facilitative of new learning and existing knowledge structures in adults, especially in the domains of physical sciences/math and arts/humanities/social sciences, respectively. Higher levels of the social trait complex were expected to have impeding influences on new learning and existing knowledge structures for most academic and related knowledge domains, while the clerical/conventional trait complex was hypothesized to be relatively unrelated to knowledge across a wide range of domains (see Figure 8.2). Furthermore, we hypothesized that with increasing age and development during adulthood, individuals might develop more "coherent" trait complexes; that is, the traits within a complex should become more highly correlated with one another.

Empirical Evidence

There are several implications of the PPIK theory, and some of them have been subjected to empirical testing. The first implication is that if the definition of adult intelligence is broadened from what is assessed by Binet-inspired IQ-type tests to give credit for the breadth and depth of intelligence-as-knowledge, then peak intelligence is less likely to be identified with adolescents and young adults. Or, to put it in Cattell's terms, including Gc (current), either in addition to or instead of Gc (historical), in an evaluation of intelligence will indicate that middle-aged adults fare better than they do on traditional intelligence tests. As Cattell pointed out and as mentioned earlier, to comprehensively assess Gc (current) in adults, one would need to create as many different domain knowledge tests as there are differentiable domains of knowledge—a task that is not realistically feasible.

As a modest attempt to sample a wide range of domains, my students and colleagues and I initially assembled a set of 20 different domain knowledge tests (ranging from physical and social sciences to literature, history, law, business, etc.). We then administered the tests to samples of young adults and middle-aged adults (e.g., Ackerman, 2000; Ackerman, Bowen, Beier, & Kanfer, 2001; Ackerman & Rolfhus, 1999), along with traditional measures of Gf and historical Gc, and a wide array of personality, interest, and self-concept assessments. The pattern of results from these investigations was largely supportive of the PPIK theory. First, with the exception of some science domains (e.g., chemistry and physics), Gc (historical) was a better predictor than Gf of domain knowledge. Also, although middle-aged participants performed more poorly than young adults on Gf tests, and somewhat better on Gc (historical) tests, the domain knowledge scores of middle-aged adults were equal to or better than those of young adults in nearly every domain, with the exception of those domains also most highly associated with Gf abilities. In a sample where ages ranged from 21 to 62 years (Ackerman, 2000), Gf correlated negatively with age (*r* = –.39), Gc (historical) correlated positively with age (*r* = .14), and a general knowledge composite correlated positively with age (*r* = .21). An equally weighted general intelligence composite of Gf and Gc (historical) yielded a negative correlation with age (*r* = –.14). But, a composite that equally weighted Gf, Gc, and a general knowledge composite yielded an essentially zero correlation with age (*r* = –.02), meaning that with this weighting, middle-aged adults were as intelligent as young adults. Combinations that provided greater weight to intelligence-as-knowledge and less proportional weight to Gf would result in positive correlations of intelligence and age across a wide range of adult ages. Similar results were found for knowledge domains that are not primarily academic, such as knowledge of current events (Beier & Ackerman, 2001) and of health (Beier & Ackerman, 2003). Also, for middle-aged adults, individual differences in the acquisition of new knowledge (e.g., technology and health domains) were more highly related to measures of Gc than they were to measures of Gf, partly attributable to transfer of knowledge from existing domain knowledge to novel information (e.g., see Ackerman & Beier, 2006).

Finally, personality traits (such as typical intellectual engagement) and interest themes (such as investigative interests) were also positively associated with individual differences in domain

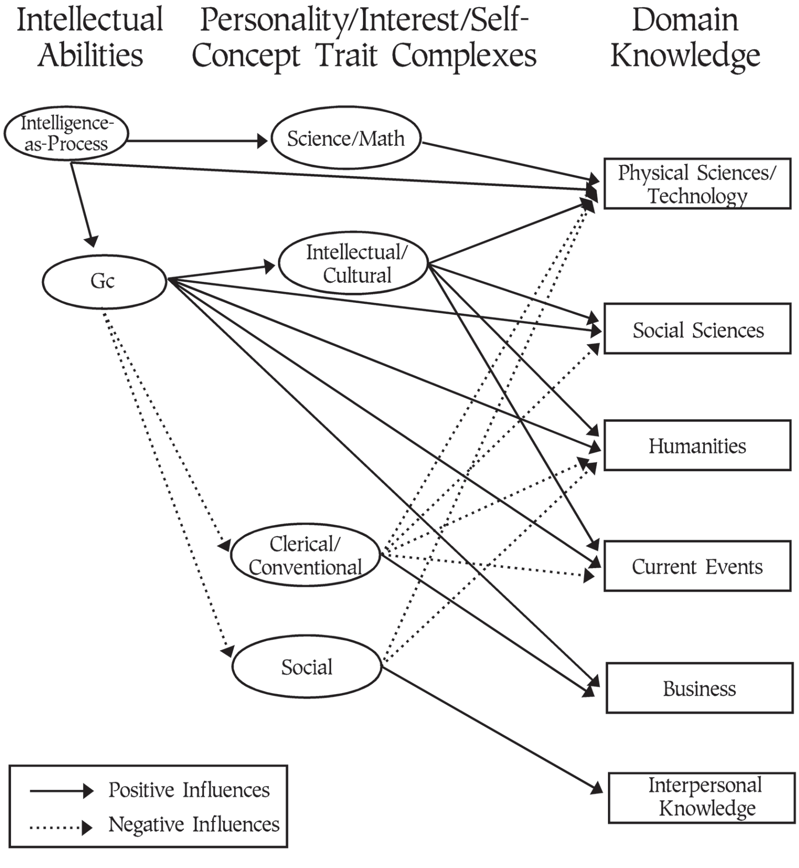

FIGURE 8.2. An illustration of the revised PPIK theory. Shown are positive (facilitative) and negative (impeding) relations between abilities, trait complexes, and individual differences in domain knowledge of adults. Gc, crystallized intelligence.

knowledge, as specified by the PPIK theory. Subsequent studies yielded results consistent with these findings, but also extended the examination of non-ability constructs from individual scales to assessments of trait complexes. In particular, for both young adults and middle-aged adults, scores on the science/math and intellectual/cultural trait complexes were positively associated with domain knowledge in academic domains, and the social trait complex was negatively correlated with knowledge across nearly all domains.

Other Evidence

Although there have been no direct investigations of the PPIK theory in a longitudinal study of adults, various other sources of evidence are consistent with the general tenets of the theory. Studies of the importance of job knowledge (including studies indicating that knowledge is a more potent predictor of job performance than general intelligence) support the emphasis on intelligence-as-knowledge as a key indicator of adult intellect (e.g., see Hunter, 1983; Schmidt, Hunter, & Outerbridge, 1986). Additional studies have supported the PPIK framework in demonstrating the importance of domain-specific knowledge in academic success at the postsecondary level (e.g., Ackerman, Kanfer, & Calderwood, 2013).

Other studies have provided convergent evidence regarding the trait complexes identified in the Ackerman and Heggestad (1997) meta-analysis (e.g., see Armstrong, Day, McVay, & Rounds, 2008; Staggs, Larson, & Borgen, 2007; Sullivan & Hansen, 2004). Finally, several recent studies have shown personality–ability relations during later adulthood, in patterns that are largely supportive of the hypothesized role of non-ability traits in adult intellectual development (e.g., see Ziegler, Cengia, Mussel, & Gertsorf, 2015).

CHALLENGES AND CONTROVERSIES

The PPIK theory provides just one perspective on adult intelligence and adult intellectual development among many competing theories. The most prominent competitor approach is the one that defines intelligence within Spearman's *g* or working memory (for a review, see Ackerman, Beier, & Boyle, 2005). Over the past century, there have been many attempts to localize general intelligence as marked by specific processes or abilities, including Spearman's attempt to identify general intelligence with the Raven's Progressive Matrices test; various attempts in the 1970s and 1980s involving the search for fundamental information-processing building blocks for intelligence; or more recent efforts to identify working memory ability as the central construct for general intelligence or fluid intelligence. None of these efforts have been successful in terms of providing more valid predictors for the academic success of children and adolescents, and to the limited degree that they have been explored, none have improved upon either traditional Binet-inspired tests or knowledge tests for predicting occupational performance for adults.

Yet one should not overlook the evidence that older adults do perform worse than younger adults, on average, on measures of speeded processing or highly Gf-loaded ability tests (Tucker-Drob & Salthouse, 2011), or other evidence that older adults perform more poorly than young adults in new learning, occupational training, and skill acquisition (e.g., Kubeck, Delp, Haslett, & McDaniel, 1996). The PPIK theory does not readily address these issues, except indirectly, to the degree that it provides a framework for understanding under what circumstances a middle-aged adult is likely to have more or less difficulty in acquiring new knowledge and skills (based on the degree of transfer from the individual's repertoire of existing knowledge and skills to the new tasks).

Ultimately, the question remains: What is adult intelligence? Numerous definitions of intelligence have been provided from academics and assessment professionals over the past 100 years. As Ackerman (2017) recently noted "Perhaps it is worthwhile to consider E. L. Thorndike's (1921) proposition: "Realizing that definitions and distinctions are pragmatic, we may then define intellect in general as *the power of good responses from the point of view of truth or fact*" (1921, p. 124; original emphasis). From this perspective, it seems somewhat quaint to think that many of the items on existing intelligence tests are representative, to the degree that they demand processes resembling how adults actually reach "good responses" in the current environment. Questions of general knowledge (common cultural information) can be readily answered by most adults in the space of a few seconds to search the Internet (e.g., "Who was Neil Armstrong?" or "Who wrote the play *Waiting for Godot*?") Similarly, although adults of a "certain age" can easily add, subtract, multiply, or divide a string of numbers in their heads or with paper and pencil, less error-prone (and typically) faster answers can be derived with a calculator, a computer, or the ubiquitous smartphone application. So what does it mean to be "intelligent" in this context? Do we give credit only to those who can retrieve correct information from long-term memory, or is the person who has achieved the requisite skills at rapid information search and retrieval from the Internet or other sources equal in ability? How would different adults perform on an "open-book" test of intelligence, where they can attempt to answer the test questions by using their own memory and mental skills, but they also have access to the kinds of tools they typically use when confronted with similar tasks on a day-to-day basis?

Some items on current intelligence tests will be resistant to online solutions. Items of abstract reasoning, spatial ability, and comprehension are not readily answered with these kinds of external aids, but the nature of some of these items (e.g., abstract reasoning) essentially begs the question of their relevance to the expression of adult intelligence. This question, then, leads me to the main issue: Namely, what activities do adults typically confront that require intelligence? If the task is to determine how many tiles necessary to cover a shower stall, or how much paint is needed to cover a room with two coats, many adults would refer to Internet sources rather than attempting to work out the answers in their heads or with an electronic calculator. Other tasks might have rough analogues to intelligence test items. For example, consider the task of installing a graphics board in a computer, or fixing a lawn mower. An adult unfamiliar with either of these tasks is perhaps more likely to search YouTube for an audio and video demonstration of how to accomplish the task. Under such circumstances, the intellectual task the adult faces is to take note of the critical steps in the demonstration video, and work that into an action plan for accomplishing the goal. One might conjecture that higher-intelligence adults will require fewer viewings or review occasions with the YouTube video, compared to lower-intelligence adults" (Ackerman, 2017, p. 994). But these are open questions that will (let us hope) be answered by future research.

In the final analysis, the PPIK theory attempts to shift the orientation away from a g/Gf/intelligence-as-process orientation, in that it maintains that the vast majority of "intellectually demanding" activities performed by adults are well learned and as such, demand relatively little involvement of intelligence-as-process capabilities. How much weight should be accorded to intelligence-as-knowledge for evaluating adult intelligence? The question cannot be answered by only appealing to correlations between measures, factor structures, age changes, or other aspects of construct validity. The answer to that question will depend on the utility of the assessments for predicting occupational and other kinds of performance in the real world, as a true extension of Binet's approach to predicting academic achievement of children in school.

NOTE

1. Much later, Owens (1953) found that in a sample of 127 men who had originally been tested on the Army Alpha test in 1919 (at about age 18) and then retested in 1950 (at about age 49), there were significant gains in scores on the verbal/information subtests, and mostly stable scores on the other tests.

PART III

Contemporary Intelligence, Cognitive, and Neuropsychological Batteries and Associated Achievement Tests

CHAPTER 9

The Wechsler Preschool and Primary Scale of Intelligence—Fourth Edition, Wechsler Intelligence Scale for Children—Fifth Edition, and Wechsler Individual Achievement Test—Third Edition

Dustin Wahlstrom
Susan Engi Raiford
Kristina C. Breaux
Jianjun Zhu
Lawrence G. Weiss

The Wechsler intelligence scales are a suite of individually administered instruments for assessing the intellectual functioning of children and adults across the lifespan. Of these tests, two are designed specifically for the assessment of children: the Wechsler Preschool and Primary Scale of Intelligence—Fourth Edition (WPPSI-IV; Wechsler, 2012a) for children ages 2 years, 6 months through 7 years, 7 months (i.e., 2:6 through 7:7), and the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014a) for children ages 6:0 through 16:11. Since the original publication of the Wechsler–Bellevue Intelligence Scale in 1939, the Wechsler scales have had a tremendous influence on the field of psychological assessment. They are the most widely used and researched intelligence tests in the field today, due in part to their comprehensiveness, clinical utility, ecological validity, and theoretical soundness (Kamphaus, 1993; Kaplan & Saccuzzo, 2005; A. S. Kaufman, Raiford, & Coalson, 2016; Sattler, Dumont, & Coalson, 2016; Wasserman & Maccubbin, 2002).

The Wechsler family of tests has expanded over the years to include measures of other constructs related to intelligence. One of the more widely used is the Wechsler Individual Achievement Test—Third Edition (WIAT-III; Pearson, 2009), which was developed to address the growing demand for standardized achievement testing in special education and clinical settings. Intelligence and achievement tests are frequently used in conjunction with each other, whether to identify learning disabilities or to assess the impact of clinical syndromes, acquired injury, or delays in other cognitive domains on learning and academic potential. The Wechsler tests facilitate this process by providing statistical linkage between the intelligence and achievement measures, which supplies practitioners with important information to support their clinical interpretations and conclusions. The current chapter provides an overview of the WPPSI-IV, WISC-V, and WIAT-III, beginning with the intelligence tests, and concluding with a joint interpretive section. An appendix provides a clinical case example to illustrate how results from intelligence and achievement measures can be integrated to provide richer clinical information than either type of test provides alone.

HISTORY AND THEORY BEHIND THE WPPSI-IV AND THE WISC-V

For overviews of the theory underlying the Wechsler scales and the history of their development, see Tulsky and colleagues (2003) and A. S. Kaufman and colleagues (2016). David Wechsler's reputation as an astute clinician, and his inclusion of existing measures with proven clinical and practical utility, did not preclude him from considering the most modern theories of the day when constructing his measures. He was inspired by Charles Spearman's and Edward Thorndike's theories of intelligence at the time. Each successive revision of the scales has been based on the latest contemporary knowledge available.

The modern Wechsler theoretical framework of intelligence uses dialectical reasoning to simultaneously consider structural models of intellect (e.g., Cattell–Horn–Carroll [CHC] theory, *g* theory), evidence of clinical utility (e.g., clinical sensitivity, predictive validity, neuroscience), functional models of cognition (e.g., neuropsychological processing theory), and specific ability models (e.g., working memory). The Wechsler theoretical framework continually informs development to ensure that each revision of the scales is innovative, is contemporary, and draws on the best and most current information these different lines of inquiry have to offer.

Modern editions of Wechsler's tests have changed dramatically compared to their original versions. This is evidenced by the fact that 62% of WISC-V subtests have been developed since the publication of the original WISC in 1949, and all the original items on the retained subtests have been replaced. Similarly, 60% of WPPSI-IV subtests have been developed since the publication of the first WPPSI in 1967. Of the WPPSI subtests that have been retained, all of the original item content has been replaced. Reflected in these changes is the updated theoretical structure of the Wechsler scales that results from added subtests of visual–spatial processing (Visual Puzzles) and fluid reasoning (Matrix Reasoning, Figure Weights, and Picture Concepts), new working memory subtests for young children (Picture Memory and Zoo Locations), and a new visual working memory task for school-age children (Picture Span), as well as improved and more developmentally appropriate measures of processing speed for young children (Bug Search, Cancellation, and Animal Coding). These constructs are increasingly recognized as critical contributors to general intellectual ability, as well as to the understanding of intelligence as a dynamic construct that involves the interaction of working memory, processing speed, and fluid reasoning with other cognitive variables (Dang, Braeken, Colom, Ferrer, & Lui, 2014; Jaeggi, Buschkuehl, Jonides, & Perrig, 2008; Pineda-Pardo, Martínez, Román, & Colom, 2016; Salthouse, 1996; Weiss, Saklofske, Holdnack, & Prifitera, 2016). The importance of working memory and processing speed are especially relevant to the childhood populations served by the WPPSI-IV and WISC-V. The development of processing speed (Nettelbeck & Burns, 2010) and working memory skills (Tourva, Spanoudis, & Demetriou, 2016) appears to underlie the development of fluid reasoning, with processing speed mediating developmental gains in working memory as well (Fry & Hale, 1996; Nettelbeck & Burns, 2010).

Furthermore, the Working Memory Index (WMI) is strongly related to reading, writing, and math as measured by standardized achievement tests (Hale, Fiorello, Kavanagh, Hoeppner, & Gaither, 2001; Konold, 1999; Rowe, Miller, Ebenstein, & Thompson, 2012; Wechsler, 2014b), and working memory is related to academic skills such as spelling, reading decoding, reading comprehension, reading fluency, note taking, and following instructions (Bergman-Nutly & Klingberg, 2014; De Clercq-Quaegebeur et al., 2010; Giofrè, Stoppa, Ferioli, Pezzuti, & Cornoldi, 2016; Jacobson et al., 2011; Malstädt, Hasselhorn, & Lehmann, 2012; Wechsler, 2014b).

Although many of these advances have been made by a team of dedicated clinical researchers since Wechsler's death in 1981, he recognized the importance of the processes that underlie working memory, processing speed, and fluid reasoning (even before they were named as such), and utilized subtests measuring these processes in his early intelligence batteries. For example, Digit Span and Arithmetic, which were initially part of Wechsler's Verbal IQ (VIQ), are now primarily considered tests of working memory and fluid reasoning, respectively. Similarly, Digit–Symbol Coding originally contributed to the Performance IQ (PIQ), but is currently understood as a measure of processing speed; and Wechsler also developed the Symbol Search subtest, even though it didn't appear in the earliest editions of this test.

The result of Wechsler's foresight and the changes to the tests since his passing is a suite of tests that, despite being criticized as atheoretical, yield constructs that are aligned very closely with recent models of intelligence. Independent examinations of recent editions of the WISC indicate that it measures several constructs central to CHC-based models of intelligence, including crystallized ability, visual processing, fluid reasoning, working memory, and processing speed (Keith, Fine, Taub, Reynolds, & Kranzler, 2006). These findings have been supported in studies using normative samples from other countries (Chen, Keith, Chen, & Chang, 2009; Georgas, Van de Vijver, Weiss, & Saklofske, 2003; Reverte, Golay, Favez, Rossier, & Lecerf, 2015). Finally, the WISC-V and WPPSI-IV correlate highly with other intelligence tests explicitly based on neurocognitive theories, such as the Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004) and the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007).

WISC-V AND WPPSI-IV TEST FRAMEWORKS AND SUBTESTS

The WISC-V and WPPSI-IV yield subtest scaled scores, index scores, and a general intellectual ability score (the Full Scale IQ [FSIQ]). The subtests that contribute to the composite scores vary between the two instruments, but their test frameworks and many of the subtests for these two measures are similar.

Figures 9.1, 9.2, and 9.3 show the WISC-V and WPPSI-IV composite scores and the subtests that contribute to each score. A great deal of cognitive development takes place during early childhood, so the WPPSI-IV is divided into two batteries for children ages 2:6–3:11 and 4:0–7:7 years to account for these changes. The battery for younger children consists of 5 primary subtests and 2 secondary subtests, whereas the one for older children is composed of 10 primary subtests and 5 secondary subtests. Children in the younger age band take fewer tests with expressive language demands, thus reducing these confounds for a developmental period during which the acquisition of these skills varies widely. The WPPSI-IV younger battery yields an FSIQ, three primary index scores, and three ancillary index scores. The primary index scores are the Verbal Comprehension Index (VCI), the Visual Spatial Index (VSI), and the Working Memory Index (WMI). The ancillary index scores consist of the Vocabulary Acquisition Index (VAI), the Nonverbal Index (NVI), and the General Ability Index (GAI). The older battery provides the same composite scores as the younger battery, but adds two more primary index scores for a total of five, and one more ancillary index score for a total of four. The additional primary index scores include the Fluid Reasoning Index (FRI) and the Processing Speed Index (PSI), and the additional ancillary index score is the Cognitive Proficiency Index (CPI). All primary and ancillary index scores are available in the published test materials.

The WISC-V comprises 10 primary subtests, 6 secondary subtests, and 5 complementary subtests, all of which can be administered to the full age range of 6:0–16:11. The WISC-V yields a Full Scale IQ, five primary index scores, seven ancillary index scores, and three complementary index scores. The primary index scores are the VCI, the VSI, the FRI, the WMI, and the PSI. The ancillary index scores consist of the Verbal (Expanded Crystallized) Index (VECI), the Expanded Fluid Index (EFI), the Quantitative Reasoning Index (QRI), the Auditory Working Memory Index (AWMI), the NVI, the GAI, and the CPI. The VECI and the EFI can be obtained through using tables in a technical report (Raiford, Drozdick, Zhang, & Zhou, 2015) or the scoring software on Q-global or Q-interactive. The remainder of the ancillary index scores are available in the published test materials. The complementary index scores are the Naming Speed Index (NSI), the Symbol Translation Index (STI), and the Storage and Retrieval Index (SRI). All are available in the published test materials.

The WPPSI-IV includes five new subtests: Picture Memory, Zoo Locations, Bug Search, Cancellation, and Animal Coding. Eight new subtests are included in the WISC-V: Visual Puzzles, Figure Weights, Picture Span, Immediate Symbol Translation, Delayed Symbol Translation, and Recognition Symbol Translation.

Descriptions of Cognitive Domains, Composite Scores, and Subtests

Full Scale

The Full scale includes subtests that are routinely used to derive the FSIQ, as well as subtests that may be substituted for one invalid subtest for this

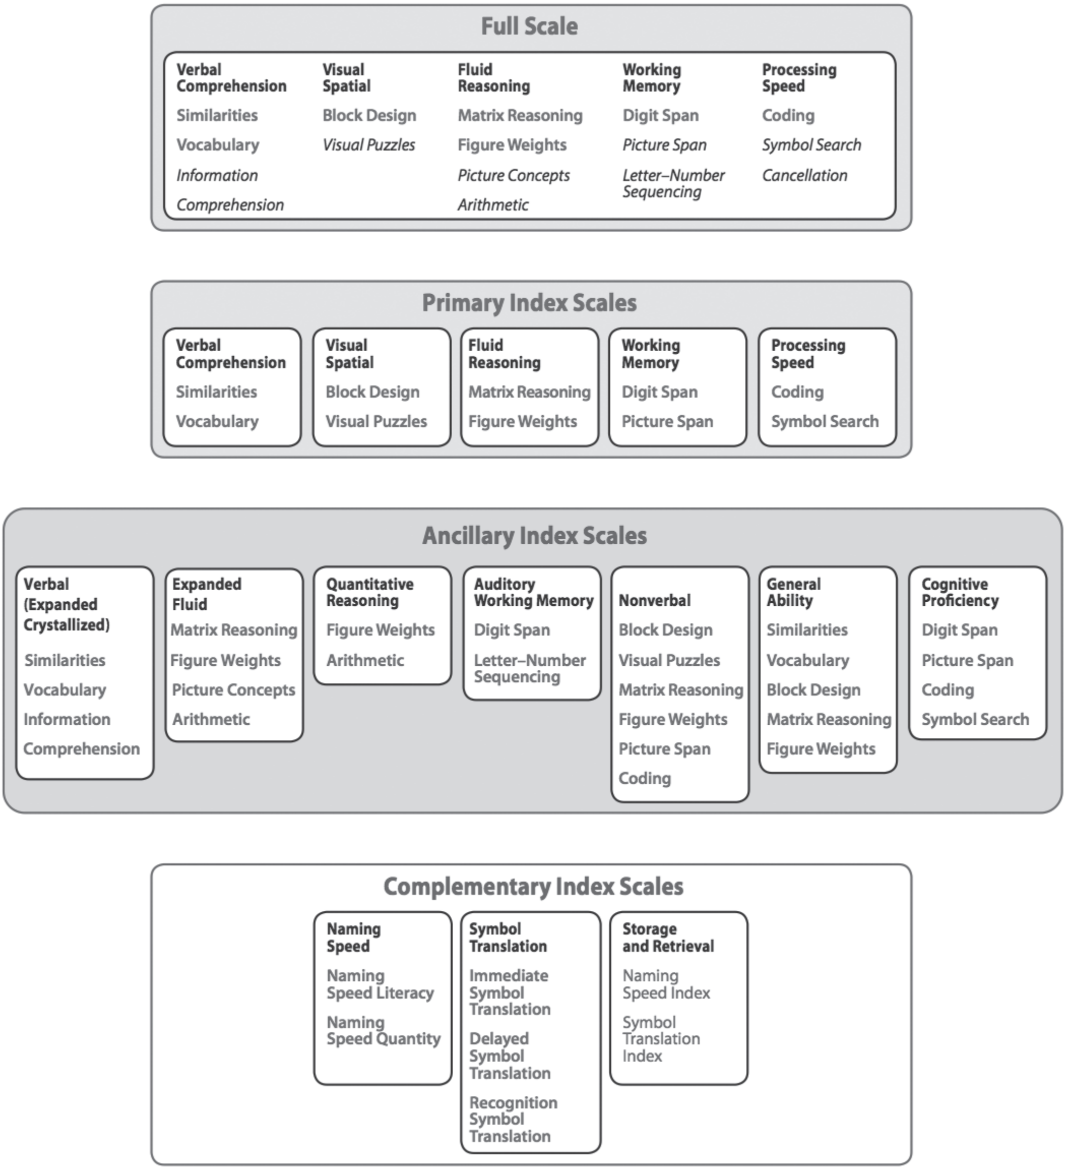

FIGURE 9.1. WISC-V index scores and subtests. Figures found in the manual for the *Wechsler Intelligence Scale for Children®, Fifth Edition (WISC®-V)*. Copyright © 2014 NCS Pearson, Inc. Reproduced with permission. All rights reserved.

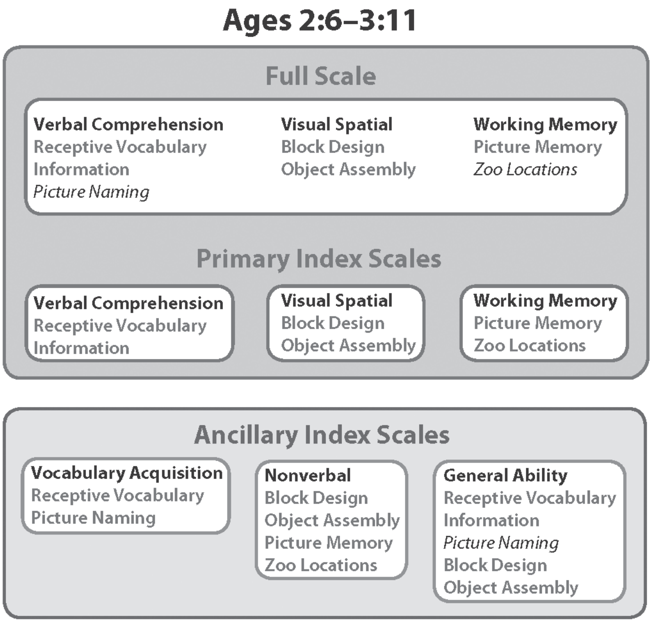

FIGURE 9.2. WPPSI-IV index scores and subtests for ages 2:6–3:11. Figures found in the Manual for the *Wechsler Preschool and Primary Scale of Intelligence®, Fourth Edition (WPPSI®–IV)*. Copyright © 2012 NCS Pearson, Inc. Reproduced with permission. All rights reserved.

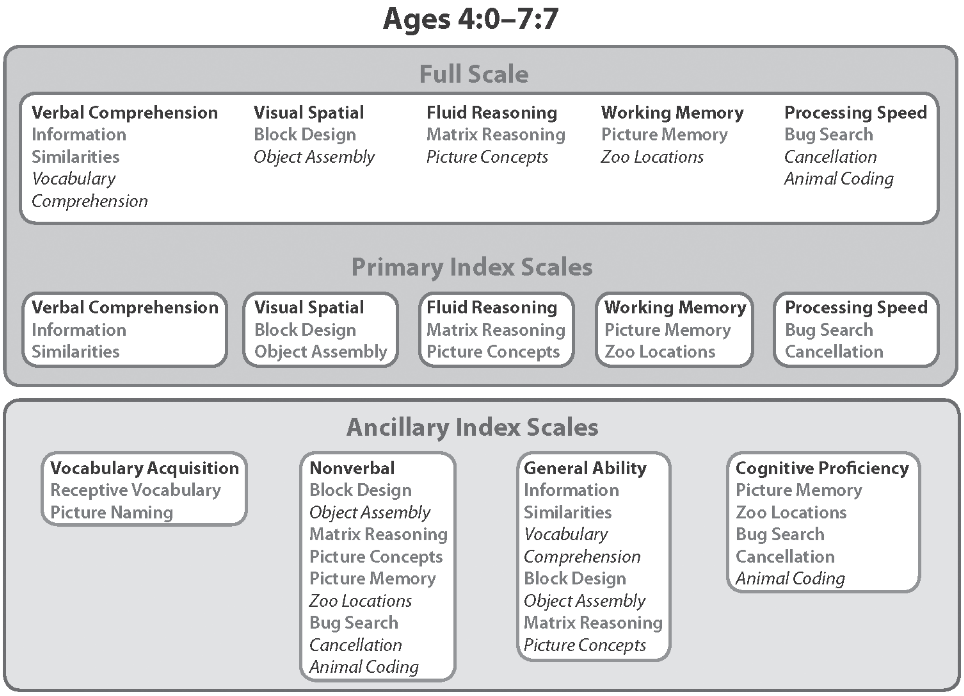

FIGURE 9.3. WPPSI-IV index scores and subtests for ages 4:0–7:7. Figures found in the Manual for the *Wechsler Preschool and Primary Scale of Intelligence®, Fourth Edition (WPPSI®–IV)*. Copyright © 2012 NCS Pearson, Inc. Reproduced with permission. All rights reserved.

purpose. FSIQ is a measure of general intellectual ability that is derived from a subset of subtests on the Full scale. The subtests vary across the WISC-V and WPPSI-IV.

The WISC-V FSIQ is derived from the seven FSIQ subtests. Two of the subtests are drawn from the Verbal Comprehension domain, and two are from the Fluid Reasoning domain. One each are from the Visual Spatial, Working Memory, and Processing Speed domains. Relative to the WISC-IV, the WISC-V FSIQ places greater emphasis on fluid reasoning.

The WPPSI-IV FSIQ subtests vary across the two age bands. The FSIQ for the younger age band is derived from five subtests. Two subtests are drawn from the Verbal Comprehension domain, two from the Visual Spatial domain, and one from the Working Memory domain. For the older WPPSI-IV age band, the FSIQ is derived from six subtests. Two are drawn from the Verbal Comprehension domain, and one each from the Visual Spatial, Fluid Reasoning, Working Memory, and Processing Speed domains. The WPPSI-IV FSIQ for the younger age band places greater emphasis on working memory relative to its predecessor. The FSIQ for the older age band emphasizes working memory more heavily than did the WPPSI–III.

The FSIQ is the most reliable score on the WISC-V and the WPPSI-IV, and is considered to be the best predictor of general intellectual functioning (*g*). It is usually the first score to be considered in profile interpretation, but should be interpreted within the context of the subtests that contribute to it and the primary index scores (A. S. Kaufman et al., 2016; Raiford & Coalson, 2014; Weiss et al., 2016).

Verbal Comprehension Domain

The Verbal Comprehension domain contains a variety of subtests that measure verbal concept formation, verbal reasoning, verbal comprehension and expression, acquired knowledge, and practical knowledge and judgment. The VCI is a composite score that is derived from two subtests in the Verbal Comprehension domain, but the contributing subtests vary across instruments (and across WPPSI-IV age bands). The WISC-V VCI measures the ability to acquire, access, and apply semantic knowledge and verbal reasoning. The WPPSI-IV VCI also involves acquisition, access, and application of semantic knowledge, with an added emphasis on acquired knowledge and long-term retrieval.

Because Verbal Comprehension subtests measure concepts such as semantic or factual knowledge, they require a certain level of exposure to cultural and educational opportunities. However, it would be incorrect to assume that the VCI is simply a reflection of semantic knowledge, learned facts, or education, as individual differences in knowledge acquisition depend not only on opportunity, but also on the application of other cognitive abilities during those experiences to take advantage of opportunity (Weiss et al., 2016) and on intellectual curiosity. As such, Verbal Comprehension subtests also reflect the utilization of experience to learn verbal concepts and the ability to apply them in novel situations.

On the WISC-V, all Verbal Comprehension subtests require some form of verbal response from the examinee. On the WPPSI-IV, some of the floor items allow the child to respond nonverbally by pointing, but all stimuli are presented verbally by the examiner. The younger age band further reduces expressive requirements because receptive vocabulary is included.

Similarities

For each Similarities item, the examinee is presented with two words that represent common concepts and asked to describe how they are alike (e.g., "In what way are fish and birds alike?"). On the WPPSI-IV, there are also picture items requiring the examinee to point to the object that is from the same category as two other objects. Similarities measures verbal concept formation and abstract reasoning. It also involves crystallized intelligence, word knowledge, memory, distinctions between nonessential and essential features, and verbal expression (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Groth-Marnat, 2009; Sattler et al., 2016).

Vocabulary

Vocabulary consists of both picture-naming items and word definition items. For picture-naming items, the examinee names the object presented visually. For word definition items, the examinee defines words that are read aloud by the examiner and presented visually in the stimulus book (e.g., "What does *conceive* mean?"). Vocabulary measures an individual's verbal concept formation and word knowledge. It also measures crystallized intelligence, fund of knowledge, verbal conceptualization, learning ability, long-term memory, and degree of language development (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Groth-Marnat, 2009; Sattler et al., 2016).

Information

Information requires the examinee to answer questions that address a broad range of general knowledge topics (e.g., "Name the country that launched the first man-made satellite"). The WPPSI-IV also contains picture items in which the examinee selects the response option that corresponds to an answer for a general knowledge question. It measures an individual's ability to acquire, retain, and retrieve general factual knowledge. It involves crystallized intelligence, long-term memory, and verbal expression, and the ability to acquire knowledge from formal instruction or other environments (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Groth-Marnat, 2009; Sattler et al., 2016).

Comprehension

Comprehension requires the examinee to use his or her understanding of general principles and social situations to answer questions (e.g., "What is the advantage of keeping money in a bank?"). On the WPPSI-IV, there are also picture questions in which the examinee selects the best response option for a general principle or social situation. The subtest measures practical reasoning and judgment. It also involves verbal comprehension and expression, crystallized knowledge, common sense, and verbal reasoning (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Groth-Marnat, 2009; Sattler et al., 2016).

Receptive Vocabulary

Receptive Vocabulary is available only on the WPPSI-IV. For Receptive Vocabulary, the child looks at a group of four pictures and points to the one the examiner names aloud. It is a measure of receptive language ability and vocabulary development. It also measures lexical knowledge, fund of information, and perception of visual stimuli (Lichtenberger & Kaufman, 2003; Sattler et al., 2016).

Picture Naming

Picture Naming is available only on the WPPSI-IV. For each Picture Naming item, the child names a picture that is displayed in the stimulus book. It measures expressive language ability, as well as acquired knowledge, fund of information, long-term memory, and perception of visual stimuli (Lichtenberger & Kaufman, 2003; Sattler et al., 2016).

Visual Spatial Domain

The Visual Spatial domain contains subtests that measure the ability to evaluate visual details, understand spatial relations among objects, and construct geometric designs using a model. This requires visual spatial processing, synthesis of part–whole relations, attention to visual detail, and (for two of the subtests) visual–motor integration.

The VSI is a composite score that is derived from two subtests in the Visual Spatial domain, but the contributing subtests vary across instruments. The WISC-V VSI includes one task, Block Design, that involves visual–motor construction and uses the same stimuli throughout the subtest (i.e., two-color blocks). Another task, Visual Puzzles, involves mental rotation and varies stimuli throughout the subtest; the puzzles are abstract shapes (e.g., colored squares, circles, triangles). The WPPSI-IV VSI also includes Block Design, but floor items involve use of different (single-colored) blocks. Object Assembly, in which children use physical pieces to assemble puzzles of meaningful stimuli, is the other WPPSI-IV subtest used to obtain the VSI.

Block Design

Block Design requires the examinee to view a constructed model or a picture and to use one-color or two-color blocks to recreate the design within a specified time limit. It measures the ability to analyze and synthesize abstract visual stimuli. It also involves nonverbal concept formation, visual perception and organization, broad visual intelligence, visual–motor coordination, learning, and the ability to separate figure and ground in visual stimuli (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Groth-Marnat, 2009; Sattler et al., 2016).

Visual Puzzles

Visual Puzzles is a new subtest for the WISC-V, adapted from the Wechsler Adult Intelligence Scale—Fourth Edition (WAIS-IV). On Visual Puzzles, examinees reproduce a geometric image by choosing three response options that can be combined to form the image from six available options within a predetermined time limit. It was designed to measure mental and nonmotor construction skills, visual–spatial processing and reasoning, and mental rotation. It is also thought to involve visual working memory, broad visual intelligence, fluid reasoning, and simultaneous processing (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Groth-Marnat, 2009; Sattler et al., 2016).

Object Assembly

Object Assembly is available only on the WPPSI-IV. For Object Assembly, the examinee fits the pieces of a puzzle together to form an identifiable image within specified time limits. It is designed to assess visual–spatial processing and visual–motor integration. It also involves perceptual integration and synthesis of part–whole relationships, nonverbal reasoning, trial-and-error learning, spatial ability, cognitive flexibility, and persistence (Groth-Marnat, 2009; Lichtenberger & Kaufman, 2003; Sattler et al., 2016).

Fluid Reasoning Domain

The Fluid Reasoning domain contains subtests that measure the ability to use reasoning to identify and apply solutions to problems. The FRI is a composite score that is derived from two subtests in the Fluid Reasoning domain. As with the VCI and the VSI, the contributing subtests vary, depending on the instrument. The WPPSI-IV younger age battery does not include the Fluid Reasoning domain because many younger children cannot comprehend the tasks involved.

The WISC-V FRI is derived from two tasks that involve detecting conceptual relations among abstract visual objects and then applying that relation to identify a solution (i.e., Matrix Reasoning and Figure Weights). The WPPSI-IV FRI, available only for ages 4:0–7:7, includes one task that utilizes both realistic pictures and abstract stimuli and requires selection of a single response (i.e., Matrix Reasoning), and another involving a set of realistic pictures that are scanned to determine multiple options which comprise a unified set (i.e., Picture Concepts).

Matrix Reasoning

For each Matrix Reasoning item, the examinee looks at an incomplete matrix or series and selects the missing portion from five response options. This subtest is designed to measure fluid intelligence, classification and spatial ability, simultaneous processing, attention to visual detail, and working memory (Flanagan & Alfonso, 2017; Groth-Marnat, 2009; Sattler et al., 2016).

Figure Weights

Figure Weights is another new subtest for the WISC-V that is adapted from the WAIS-IV. For each item, individuals must balance a scale by identifying the correct response option within a specified time limit. In order to determine the correct response, the examinee must figure out the relationships between shapes that balanced a previous scale and apply these relationships to the incomplete scale. The task measures quantitative and inductive reasoning. It also requires mental flexibility and set shifting (Flanagan & Alfonso, 2017; Flanagan, Alfonso, & Ortiz, 2012; Flanagan & Kaufman, 2009; Sattler et al., 2016).

Picture Concepts

On Picture Concepts, the examinee is presented with two or three rows of pictures and chooses one picture from each row to form a group with a common characteristic. It measures fluid and inductive reasoning, visual-perceptual recognition and processing, conceptual thinking, visual scanning, working memory, and conceptual thinking (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Sattler et al., 2016).

Arithmetic

Arithmetic is available only on the WISC-V. In Arithmetic, the examinee mentally solves a series of orally presented arithmetic problems within a specified time limit (e.g., "Jim buys five stamps, and his mother gives him two more. He then uses one to mail a letter. How many stamps does he have left?"). Arithmetic involves mental manipulation, concentration, and working memory; short- and long-term memory; fluid, quantitative, and logical reasoning; sequential processing; and quantitative knowledge (Benson, Hulac, & Kranzler, 2010; Flanagan & Alfonso, 2017; Sattler et al., 2016).

Arithmetic has been moved from the Working Memory domain of the WISC-IV to the Fluid Reasoning domain of the WISC-V. Including the new Visual Puzzles, Figure Weights, and Picture Span subtests in the WISC-V permitted a split of the former Perceptual Reasoning factor into Visual Spatial and Fluid Reasoning factors, which increased the number of factors in the test model from four to five. This is not surprising because the results of factor analyses can vary, depending on the subtests in the set being tested. In addition, studies of the WISC-IV (Keith et al., 2006; Weiss, Keith, Zhu, & Chen, 2013b) and the WAIS-IV (Benson et al., 2010; Weiss, Keith, Zhu, & Chen, 2013a) had previously indicated that Arithmetic loads on the Working Memory factor in four-factor models, but on Fluid Reasoning in five-factor models. Therefore, the WISC-V confirmatory factor-analytic studies compared several models with Arithmetic on the Fluid Reasoning or the Working Memory factor. These models showed the best fit with Arithmetic on the Fluid Reasoning factor, with a cross-loading on the Working Memory factor. Mental arithmetic based on word problems is a complex mental task involving successful integration of several cognitive abilities, and is therefore highly *g*-loaded.

Working Memory Domain

The Working Memory domain contains subtests that measure the ability to consciously register, maintain, and manipulate auditory and visual information. This requires paying attention and focusing, keeping the information in conscious awareness, mentally processing the information in a manner that conforms to the task demands, and then providing a result.

All of the WISC-V and WPPSI-IV Working Memory subtests involve use of proactive interference. Proactive interference involves repeated exposure to stimuli across items, such that prior exposure interferes with memory for the present item. A number of studies support the effectiveness of this method (Lipinski, Simmering, Johnson, & Spencer, 2010; Makovski & Jiang, 2008; Szmalec, Verbruggen, Vandierendonck, & Kemps, 2011). Its first use with infants and toddlers was described by Piaget (1952).

Proactive interference is particularly important within the WPPSI-IV subtests, which rely on proactive interference to introduce a competing cognitive processing demand that tax working memory. Because a number of challenges related to cognitive development (e.g., limited working memory capacity, distractibility, inability to use rehearsal strategies, lack of comprehension of complex instructions) render complex tasks difficult to teach and perform.

Both of the WPPSI-IV Working Memory subtests involve visual stimuli rather than auditory. At first blush, this may seem to limit the comprehensiveness of construct measurement because there are not auditory working memory subtests on the WPPSI-IV. Whereas the domain-specific storage components of working memory appear to be distinct in young children in the WPPSI-IV age range, and research with young children supports Baddeley's (2012) multicomponent model (Alloway, Gathercole, & Pickering, 2006; Hornung, Brunner, Reuter, & Martin, 2011), memory storage in the visual domain is strongly linked with cognitive processing, but auditory memory storage is not (Alloway et al., 2006; Hornung et al., 2011). This suggests that simple visual memory tasks involving storage alone are preferable to an analogous auditory task when attempting to measure working memory for young children.

The WMI is a composite score that is derived from two subtests in the Working Memory domain. As with other primary index scores, the contributing subtests vary, depending on the instrument. The WISC-V WMI is based on the sum of scaled scores for Digit Span and Picture Span. Both subtests require resequencing of information. However, Digit Span involves numerical auditory stimuli and oral responses, whereas Picture Span involves pictorial stimuli that can feasibly (for many items) be verbally mediated and rehearsed, and either gestured or oral responses. The WPPSI-IV WMI involves Picture Memory, which is similar to Picture Span but does not require resequencing, and Zoo Locations, which involves visual–spatial information and a performance response.

Digit Span

Digit Span is available only on the WISC-V. It has traditionally been composed of two parts: Digit Span Forward and Digit Span Backward. Digit Span Forward requires the examinee to repeat numbers in the same order as read aloud by the examiner, and Digit Span Backward requires the examinee to repeat the numbers in the reverse order of that presented by the examiner. The WISC-V (and the WAIS-IV) have added Digit Span Sequencing, which requires examinees to sequentially order the numbers presented by the examiner. This subtest measures working memory, in addition to auditory short-term memory, sequential processing, and mental manipulation (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Groth-Marnat, 2009; Sattler et al., 2016).

Picture Memory/Picture Span

Picture Span is a new Working Memory subtest for the WISC-V, and Picture Memory is a new Working Memory subtest for the WPPSI-IV. The tasks are very similar; in each, the examinee views a stimulus page with one or more objects for a predefined period and is then asked to select those objects among a larger group of options on a response page. On Picture Span, the examinee is asked only to select the objects seen on the stimulus page in order. Additional credit is awarded if the examinee can select the objects in the order they were presented on the stimulus page. For Picture Memory, the examinee only selects the objects seen on the stimulus page, regardless of order.

These subtests measure visual working memory and working memory capacity; they are similar to other tasks that are known to measure attention, visual processing, and response inhibition (Flanagan & Alfonso, 2017; Flanagan et al., 2012; Flanagan, Alfonso, Ortiz, & Dynda, 2010; Miller, 2010, 2013; Sattler et al., 2016).

Letter–Number Sequencing

Letter–Number Sequencing is only available for the WISC-V. For this task, the examiner reads a sequence of numbers and letters to the examinee, who recalls the numbers in ascending order and the letters in alphabetical order. Similar to Digit Span, it measures sequencing and working memory, as well as auditory sequential processing, immediate auditory memory, attention, numerical ability, auditory working memory, visual–spatial imaging, and processing speed (Flanagan & Alfonso, 2017; Groth-Marnat, 2009; Sattler et al., 2016).

Zoo Locations

Zoo Locations is a visual working memory subtest on the WPPSI-IV. It requires the examinee to view one or more animal cards on a zoo layout for a specified period of time and then re-place them in the correct locations. It is designed to measure visual–spatial working memory (Sattler et al., 2016), similar to established spatial working memory tasks (Blalock & McCabe, 2011; Lipinski et al., 2010). Proactive interference is utilized to increase the working memory load across items.

Processing Speed Domain

The Processing Speed domain contains subtests that measure the ability to use reasoning to identify and apply solutions to problems. The PSI is a composite score that is derived from two subtests in the Processing Speed domain. As with the VCI and the VSI, the contributing subtests vary, depending on the instrument. The WPPSI-IV younger age battery does not include the Processing Speed domain because many younger children have difficulty with the concept of working quickly.

The WISC-V PSI is derived from two tasks that involve simple perceptual speed. One of these tasks, Coding, places demands on associative memory, and the other, Symbol Search, requires visual scanning and discrimination. The WPPSI-IV PSI, available only for ages 4:0–7:7, includes two tasks that involve simple perceptual speed. One of these tasks, Bug Search, is an adaptation that serves as a downward extension of Symbol Search, and the other, Cancellation, involves categorical reasoning as well as visual scanning and discrimination.

Coding

Coding is a WISC-V subtest that requires the examinee to associate symbols paired with numbers, but the exact task demands differ slightly, depending on whether the paper or digital format of the task is being administered. For the paper format, using a key, the examinee draws a symbol in each numbered box within a specified time limit. For the digital format, the examinee taps the symbol associated with the correct number. Both the paper and digital formats of Coding measure processing speed, as well as short-term memory, learning ability, visual acuity, sequential processing, and attention to visual stimuli (Flanagan & Alfonso, 2017; Groth-Marnat, 2009; Sattler et al., 2016). The paper format also measures graphomotor speed due to the writing demands—a construct not measured by the digital format because the correct answers are tapped rather than written. This reduces the unwanted influence of fine motor skills in the measurement of visual processing speed. See “Administration Options,” below, for a more thorough discussion of the digital adaptation of Coding and Symbol Search.

Symbol Search

Similar to Coding, Symbol Search is a WISC-V subtest that can be administered with a paper response booklet or in digital format without a response booklet. However, the two formats are very similar in their response demands. In each, the examinee is required to scan a group of symbols and indicate whether the target symbols match any of the symbols in the group within a specified time limit. In paper, the examinee indicates the correct response by drawing a line through it. For the digital format, the correct answer is tapped. Symbol Search measures visual–motor processing speed, as well as short-term visual memory, perceptual organization, learning ability, perceptual and psychomotor speed, visual–motor coordination, visual discrimination, and attention to visual stimuli (Groth-Marnat, 2009; Sattler et al., 2016).

Bug Search

Bug Search is a WPPSI-IV subtest that is an adaptation and downward extension of Symbol Search for younger children. It requires the examinee to mark a bug in the search group that matches the target. Several modifications make it more age-appropriate than Symbol Search. For example, the stimuli are larger and color-coded to make them easier to discriminate, and the examinee indicates the correct response by using a dauber rather than a pencil. It is intended to measure many of the same constructs as Symbol Search. It measures processing speed, attention, and concentration (Sattler et al., 2016).

Cancellation

On Cancellation, the examinee is required to identify and mark target objects interspersed among distractors. The stimuli are presented in a random array on the first trial and organized into rows on the second trial. Cancellation measures rate of test taking, perceptual speed, visual discrimination, visual scanning, and visual-perceptual processing (Flanagan & Alfonso, 2017; Sattler et al., 2016).

Animal Coding

Animal Coding is a WPPSI-IV subtest that is intended to be an age-appropriate version of Coding. Using a key, the examinee marks shapes that correspond to symbols within a specified time limit. It differs from Coding in that the child marks the correct response by using a dauber rather than a pencil, as well as the fact that there are fewer shape–animal relationships to scan than number–symbol relationships. It is intended to be a measure of visual–motor processing speed that measures constructs similar to those involved in Coding. It measures processing speed (Sattler et al., 2016).

Quantitative Reasoning Index

The QRI is a WISC-V ancillary index score derived from Figure Weights and Arithmetic that is intended to measure the examinee's quantitative reasoning skills. Quantitative reasoning is closely related to *g* (Weiss et al., 2013a, 2013b) and predictive of reading and math achievement, creativity, and success in giftedness programs (Lakin & Lohman, 2011; Robertson, Smeets, Lubinski, & Benbow, 2010). The QRI may be of special interest in cases where a specific learning disability in mathematics is suspected. Low quantitative reasoning may be due to difficulties with mental math manipulation, poor understanding of quantitative relationships, or low working memory, and thus may constitute a specific area of focus for intervention (Wechsler, 2014b; Zheng, Flynn, & Swanson, 2013).

Auditory Working Memory Index

The addition of Picture Span to the WISC-V WMI results in that index's measuring a combination of auditory and visual working memory; this is a departure from previous editions of the WISC, in which the WMI measured auditory working memory only. The AWMI consists of Digit Span and Letter–Number Sequencing, the same subtests used to derive the WISC-IV WMI (though there is an increased emphasis on sequencing, due to the new Digit Span Sequencing condition). In this respect, the AWMI may be useful when an examinee's score is being compared with scores on previous evaluations that included the WISC-IV. Furthermore, contemporary working memory research suggests that domain-specific neuropsychological systems support auditory working memory versus visual–spatial working memory: These are the *phonological loop* and *visuospatial sketchpad*, respectively (Baddeley, 2012). Within this context, the AWMI is a purer measure of auditory working memory processes supported by the phonological loop.

Nonverbal Index

The NVI is derived from subtests that do not require an expressive response. Because it consists of subtests from all available cognitive domains excluding Verbal Comprehension, the NVI can be considered a good measure of general intellectual functioning that minimizes expressive language demands. It may be useful in testing children who are English-language learners (Raiford & Coalson, 2014) or who have language-based clinical disorders, such as autism spectrum disorder with language impairment. However, the NVI requires items to be presented verbally; as such, it should not be considered a "language-free" assessment, nor should it be substituted for measures like the Wechsler Nonverbal Scale of Ability (WNV).

The WISC-V NVI is derived from Block Design, Visual Puzzles, Matrix Reasoning, Figure Weights, Picture Span, and Coding. The WPPSI-IV NVI subtests vary across the two age bands. The NVI for the younger age band is derived from four subtests (i.e., Block Design, Object Assembly, Picture Memory, and Zoo Locations). Two subtests are drawn from the Visual Spatial domain, and two from the Working Memory domain. For the older WPPSI-IV age band, the NVI is derived from five subtests (i.e., Block Design, Matrix Reasoning, Picture Concepts, Picture Memory, and Bug Search). One is drawn from the Visual Spatial domain, two from the Fluid Reasoning domain, and one each from the Working Memory and Processing Speed domains.

General Ability Index and Cognitive Proficiency Index

The GAI and CPI are provided in the published test manuals as ancillary index scores. The GAI is derived from all the subtests that contribute to the FSIQ except for the Working Memory and Processing Speed subtests. The CPI is derived from all four subtests that contribute to the WMI and the PSI. Thus the GAI measures a subset of intellectual functioning with reduced influences of working memory and processing speed, and the CPI represents an index of cognitive processing proficiency that reduces crystallized knowledge, verbal reasoning, and fluid reasoning demands. These index scores may be especially useful in the context of evaluations for specific learning disorders.

Because working memory and processing speed subtests contribute to the FSIQ, lower FSIQ scores may occur in the presence of neurodevelopmental disorders known to be associated with difficulties in working memory and processing speed. These include specific learning disorders, attention-deficit/hyperactivity disorder (ADHD), language disorders, and autism spectrum disorder (Akbar, Loomis, & Paul, 2013; Horowitz-Kraus, 2014; Kasper, Alderson, & Hudec, 2012; Niileksela & Reynolds, 2014; Pimperton & Nation, 2014; Thaler, Bello, & Etcoff, 2012; Travers et al., 2014; Vugs, Cuperus, Hendriks, & Verhoeven, 2013). The lower FSIQ scores may in turn obscure meaningful differences between intellectual ability (represented by the FSIQ) and other cognitive functions (e.g., achievement and memory).

Some have advocated use of the GAI in placement decisions for gifted and talented or similar programs (Rimm, Gilman, & Silverman, 2008). There are indications that some children in gifted education programs tend to obtain higher scores on the GAI than on the CPI or FSIQ. For example, 34% of children in the WISC-V intellectually gifted special group study showed GAI > FSIQ discrepancies. Although a lower percentage, this is similar to findings for the WISC-IV (Raiford, Rolfhus, Weiss, & Coalson, 2005), the WPPSI-IV (Wechsler, 2012a), and the WAIS-IV (Wechsler, 2008). Furthermore, 72% of children in the intellectually gifted special group study obtained GAI > CPI discrepancies.

Discrepancies in which the GAI is higher than the CPI are also implicated in traumatic brain injury and autism spectrum disorder, and the GAI is discrepant from the FSIQ in a multitude of other clinical populations, including children with intellectual disability, traumatic brain injury, ADHD, and autism and Asperger's disorder as previously defined by DMS-IV (Saklofske, Weiss, Raiford, & Prifitera, 2006; Strauss, Sherman, & Spreen, 2006). However, the GAI should not be used as a substitute for FSIQ solely because the WMI or the PSI is low, as working memory and processing speed represent important aspects of general cognitive ability.

Vocabulary Acquisition Index

The VAI is a WPPSI-IV ancillary index score derived from the Receptive Vocabulary and Picture Naming subtests. It is intended to provide a measure of vocabulary development. When combined with other sources of information such as parent and teacher report and behavioral observations, low scores on the VAI may warrant further evaluation with a speech–language pathologist.

WISC-V Complementary Scales

Naming Speed Literacy

Naming Speed Literacy requires the examinee to name objects, letters, or numbers as quickly as possible within a specified time limit. There are three different conditions: (1) Color–Object Naming, in which the examinee is required to say the name and color of an object (e.g., "red cat"); (2) Size–Color–Object Naming, in which the size of the object must also be named (e.g., "big green cat"), and (3) Letter–Number Naming, which requires the examinee to name letters and numbers. Naming Speed Literacy is a rapid naming task intended to measure storage and retrieval fluency and naming facility (Flanagan & Alfonso, 2017). It is not intended as a measure of intelligence, but rather a complementary subtest that can assist in the identification of cognitive weaknesses associated with academic learning. As such, similar tasks have been related to the development of reading and spelling skills, as well as learning disabilities, ADHD, and autism spectrum disorder (Crews & D'Amato, 2009; Korkman, Kirk, & Kemp, 2007; Powell, Stainthorp, Stuart, Garwood, & Quinlan, 2007; Weiss et al., 2016; Willburger, Fussenegger, Moll, Wood, & Landerl, 2008).

Naming Speed Quantity

Naming Speed Quantity requires the examinee to name the number of squares inside a larger box (one item varies the number of boxes from one to four, and another from one to five). The task measures storage and retrieval fluency and naming facility (Flanagan, Alfonso, & Ortiz, 2012). It is intended to complement Naming Speed Literacy in instances where math weaknesses are suspected, as tasks similar to Naming Speed Quantity have been shown to be more closely related to mathematics skills and specific learning disorders in mathematics than have letter–number or object-naming tasks (Pauly et al., 2011; van der Sluis, de Jong, & van der Leij, 2004; Weiss et al., 2016; Willburger et al., 2008).

Immediate Symbol Translation

Immediate Symbol Translation is intended to assist in the identification of cognitive weaknesses that may be having an impact on academic learning. For this subtest, the examinee is shown a series of symbols and taught told that each symbol is associated with a word, after which he or she is asked to "read" sentences made out of the symbols. New symbol–word associations are taught as the task progresses, and the sentences increase in length and complexity. Immediate Symbol Translation measures verbal–visual associative memory, storage and retrieval fluency and accuracy, and immediate recall (Flanagan & Alfonso, 2017; Weiss et al., 2016). These tasks are related to decoding skills, word-reading accuracy and fluency, and reading comprehension, as well as math calculation and reasoning skills (Floyd, Evans, & McGrew, 2003; Floyd, Keith, Taub, & McGrew, 2007; Hulme, Goetz, Gooch, Adams, & Snowling, 2007; Litt, de Jong, van Bergen, & Nation, 2013). As might be expected, they are sensitive to dyslexia as long as the examinee is required to respond verbally (Gang & Siegel, 2002; Litt & Nation, 2014).

Delayed Symbol Translation

Delayed Symbol Translation is administered 20–30 minutes after Immediate Symbol Translation and requires the examinee to translate the symbols into sentences from memory. No more symbol–word associations are taught as part of the delayed subtest. Tasks similar to Delayed Symbol Translation measure verbal–visual associative memory, storage and retrieval fluency and accuracy, and delayed recall (Flanagan & Alfonso, 2017).

Recognition Symbol Translation

On Recognition Symbol Translation, the examinee views one of the previously learned symbols and selects the word that corresponds to it from a list read aloud by the examiner. Performance on Recognition Symbol Translation can be compared to Delayed Symbol Translation to compare the ability to encode the symbol–word associations with the ability to retrieve them (e.g., intact recognition with impaired delayed recall suggests a weakness in retrieval). This subtest measures verbal–visual associative memory, storage and retrieval fluency and accuracy, and delayed recognition (Flanagan & Alfonso, 2017; Weiss et al., 2016).

Naming Speed Index

The NSI is derived from Naming Speed Literacy and Naming Speed Quantity. At a high level, it is intended to reflect the automaticity of naming as measured by a wide range of tasks (Wechsler, 2014b). In addition, it measures the ability to register visual stimuli and to retrieve verbal labels from long-term memory, working memory, visual processing speed, and oral–motor sequencing (Flanagan & Alfonso, 2017). The NSI is not a measure of intelligence, but rather an optional score that can enhance the assessment of examinees suspected of specific learning disabilities or other neurodevelopmental disorders.

Symbol Translation Index

The STI comprises all three Symbol Translation subtests and is a summary measure of visual–verbal associative memory across the different types of conditions each subtest represents (e.g., encoding, recall, recognition). It also measures auditory and visual processing, auditory discrimination, and attention to visual and auditory processing (Flanagan & Alfonso, 2017; A. S. Kaufman et al., 2016). Like the NSI, it is not intended to be a measure of intelligence, but rather is intended to enhance the assessment of examinees with specific learning disabilities, memory impairment, or other neurodevelopmental conditions.

Storage and Retrieval Index

The SRI is derived from the sum of standard scores of the NSI and STI. As such, it reflects the ability to accurately and efficiently store and retrieve auditory and visual information from long-term memory. High performance on this index may reflect well-developed capacity for learning and easy access to stored verbal knowledge. On the other hand, poor performance may reflect a number of things, including deficits in the encoding or retrieval of long-term memory stores, inattention, or visual or verbal processing weaknesses.

PSYCHOMETRIC PROPERTIES OF THE WISC-V AND WPPSI-IV

According to the criteria proposed by Flanagan and Alfonso (1995) and Bracken (1987), the WISC-V and the WPPSI-IV have outstanding psychometric properties.

Normative Samples

The WISC-V and the WPPSI-IV have excellent normative samples (Dumont & Willis, 2014; A. S. Kaufman et al., 2016). The sizes of the normative samples are 2,200 for the WISC-V and 1,700 for the WPPSI-IV, respectively. The sample size for most norming age groups is 200 cases. The normative samples are stratified to closely match contemporary U.S. census data for race/ethnicity, parent education level, and geographic region. Each age group contains 200 children, except for the oldest group at the upper end of the WPPSI-IV (i.e., 7:0–7:7), which is composed of 100 children.

Reliability

The WPPSI-IV and WISC-V composite scores have strong reliabilities (Wechsler, 2012b, 2014b). The overall internal-consistency reliability coefficients for the normative sample are in the .90s for all IQ and index scores except the WPPSI-IV VSI, which is .89. The PSI composites for both the WPPSI-IV and WISC-V are slightly below .90, but were calculated using test–retest methods because they are speeded tests. Test–retest typically yields lower reliability coefficients compared to internal-consistency methods. At the subtest level, the overall internal-consistency reliability coefficients of the normative sample are in the .80s or .90s for all of the WPPSI-IV subtests with the exceptions of Cancellation and Animal Coding (with test–retest reliability coefficients of .76 and .75, respectively. On the WISC-V, all subtests have internal-consistency reliability of above .80.

Overall, the reliability of the WPPSI-IV and the WISC-V for special group samples is consistent with reliability estimates for the normative samples (Wechsler, 2012b, 2014b). The test-retest stability coefficients of the WPPSI-IV and WISC-V FSIQ scores are .93 and .92, respectively. The test–retest coefficients of the index scores range from .82 to .94, with the exception of the WISC-V FRI, which has a test–retest reliability of .75. The subtest coefficients range from .71 to .90. Finally, the interscorer agreements of the WPPSI-IV and WISC-V subtests are all .96, even for the verbal subtests that require more subjective scoring techniques.

Validity

There is ample evidence to support the validity of the WISC-V and the WPPSI-IV. One of the largest changes introduced in these revisions was the five-factor index score test structure, consisting of Verbal Comprehension, Visual Spatial, Fluid Reasoning, Working Memory, and Processing Speed domains. Evidence supporting this model comes from the factor analyses of the WPPSI-IV and WISC-V normative samples contained in the test manuals (Wechsler, 2012b, 2014b), as well as studies demonstrating that the five-factor model had support similar to that for the four-factor model when applied to the WISC-IV and WAIS-IV (Benson et al., 2010; Keith et al., 2006; Weiss et al., 2013a, 2013b).

Taken together, results from these studies indicate that the latent traits measured by the Wechsler scales appear consistently across different ages, ethnicities, cultures, specific clinical populations, and sexes. Furthermore, they support the updated theoretical foundations of the Wechsler scales, as converging evidence suggests that the tests measure working memory, processing speed, and fluid reasoning, among other cognitive abilities recently identified as critical to the construct of intelligence.

In addition to the factor-analytic work supporting the construct validity of the WPPSI-IV and WISC-V, a multitude of evidence supports their utility as clinical tools. This is consistent with David Wechsler's original intent of developing an intelligence battery that was, above all else, a clinically useful instrument. Data collected during the standardization phase for both tests with a number of special groups (children with ADHD, autism spectrum disorder, learning disabilities, intellectual disability, etc.) demonstrate unique patterns of index score strengths and weaknesses relative to the normative samples (Wechsler, 2012b, 2014b). These results are corroborated by a number of independent samples that show similar patterns of performance (Calhoun & Mayes, 2005; Ghaziuddin & Mountain-Kimchi, 2004; Harrison, DeLisle, & Parker, 2008; Mayes & Calhoun, 2006; Rackley, Allen, Fuhrman, & Mayfield, 2012; Sweetland, Reina, & Tatti, 2006), though much of this evidence stems from previous versions of the tests, given their recent revisions. In addition, the Wechsler scales show significant utility for identification of specific learning disabilities (Flanagan, Ortiz, & Alfonso, 2013; Hale et al., 2008).

Finally, the Wechsler scales also correlate highly with other measures of intelligence. For example, the correlation between the WISC-V FSIQ and KABC-II Fluid–Crystallized Index (FCI) and Mental Processing Index (MPI) are .81 and .77, respectively (Wechsler, 2014b). Similarly, the correlation between the WPPSI-IV FSIQ and the DAS-II General Conceptual Ability (GCA) and Special Nonverbal Composite (SNC) scores are .81 and .75, respectively (Wechsler, 2012a). The magnitude of these correlations is high and provides evidence of concurrent validity, as the Wechsler scales appear to measure very similar constructs relative to other modern intelligence batteries. Similarly, the WPPSI-IV and WISC-V correlate highly with academic achievement as measured by the WIAT-III (discussed later in this chapter; Wechsler, 2012a, 2014a). Correlations between the WPPSI-IV FSIQ and WIAT-III index scores range from .50 to .75, and correlations between the WISC-V FSIQ and WIAT-III composites range from .58 to .81.

WIAT-III BACKGROUND AND HISTORY

The WIAT-III is a comprehensive, individually administered achievement test of listening, speaking, reading, writing, and mathematics skills. Both grade and age norms are provided for testing individuals who are in prekindergarten (PK) through grade 12 or ages 4:0 through 50:11 years. Separate norms are provided for fall, winter, and spring for grades PK–12. Administration time varies according to a number of factors, such as the grade and skill level of the examinee and the number of subtests administered; however, subtest administration time is typically between 1 and 15 minutes, depending on the subtest.

The original WIAT (Psychological Corporation, 1992) was designed to measure the academic achievement of students in kindergarten through high school, ages 5:0–19:11. The WIAT provided eight subtests to correspond to each of the areas of learning disability identification specified by the Education for All Handicapped Children Act of 1975 (P.L. 94-142) and was the first test of its kind to be linked with the Wechsler ability scales for conducting ability–achievement discrepancy analyses. Nine years later, the WIAT-II (Psychological Corporation, 2001) was published, with one new subtest (Pseudoword Decoding) and significant revisions to the existing subtests. Subsequently, updated scoring and normative materials were released in 2002 and 2005. The WIAT-II was designed for children, adolescents, college students, and adults ages 4:0 through 85:11 years. The WIAT-III retains updated versions of the subtests included in the previous editions and adds five new subtests: Early Reading Skills, Oral Reading Fluency, Math Fluency—Addition, Math Fluency—Subtraction, and Math Fluency—Multiplication. In addition, the former Written Expression subtest was split into three distinct subtests: Alphabet Writing Fluency, Sentence Composition, and Essay Composition. It is normed for individuals between the ages of 4:0 and 50:11 years.

WIAT-III SUBTESTS AND COMPOSITES

As shown in Table 9.1, the WIAT-III covers all 8 areas specified by the Individuals with Disabilities Education Improvement Act of 2004 (IDEA 2004), with 16 subtests and 8 composite scores (7 achievement area composites and 1 Total Achieve-

ment composite). With the exception of the three Math Fluency subtests, each subtest contributes to the Total Achievement composite to provide an estimate of overall academic achievement. An examiner may choose to administer as many or as few subtests as he or she deems appropriate for the purpose of the evaluation, the types of scores required, and the student's grade level. Figure 9.4 shows all WIAT-III composites and subtests.

Subtest Descriptions

Listening Comprehension, administered to examinees ages 4–50 (grades PK–12+), contains two components, Receptive Vocabulary and Oral Discourse Comprehension. For Receptive Vocabulary, the examinee points to the picture that best illustrates the meaning of each word he or she hears. For Oral Discourse Comprehension, the examinee listens to sentences and passages, and orally responds to comprehension questions.

Early Reading Skills, administered to examinees ages 4–9 (grades PK–3), requires the examinee to name letters, identify and generate rhyming words, identify words with the same beginning and ending sounds, blend sounds, match sounds with letters and letter blends, and match written words with pictures that illustrate their meaning.

Reading Comprehension, administered to examinees ages 6–50 (grades 1–12+), requires the examinee to read narrative and expository passages (either aloud or silently), and then orally respond to literal and inferential comprehension questions read aloud by the examiner.

Math Problem Solving, administered to examinees ages 4–50 (grades PK–12+), measures untimed math problem-solving skills in the areas of basic concepts, everyday applications, geometry, and algebra. The items require oral or pointing responses.

Alphabet Writing Fluency, administered to examinees ages 4–9 (grades PK–3), measures the ability to write letters of the alphabet within a 30-second time limit. The examinee may write letters in any order, in cursive or print, in uppercase or lowercase.

Sentence Composition, administered to examinees ages 6–50 (grades 1–12+), contains two components: Sentence Combining and Sentence Building. Sentence Combining requires the examinee to combine two or three sentences into one sentence that preserves the meaning of the original sentences. Sentence Building requires the examinee to write sentences that include a target word.

Word Reading, administered to examinees ages 6–50 (grades 1–12+), measures speed and accuracy

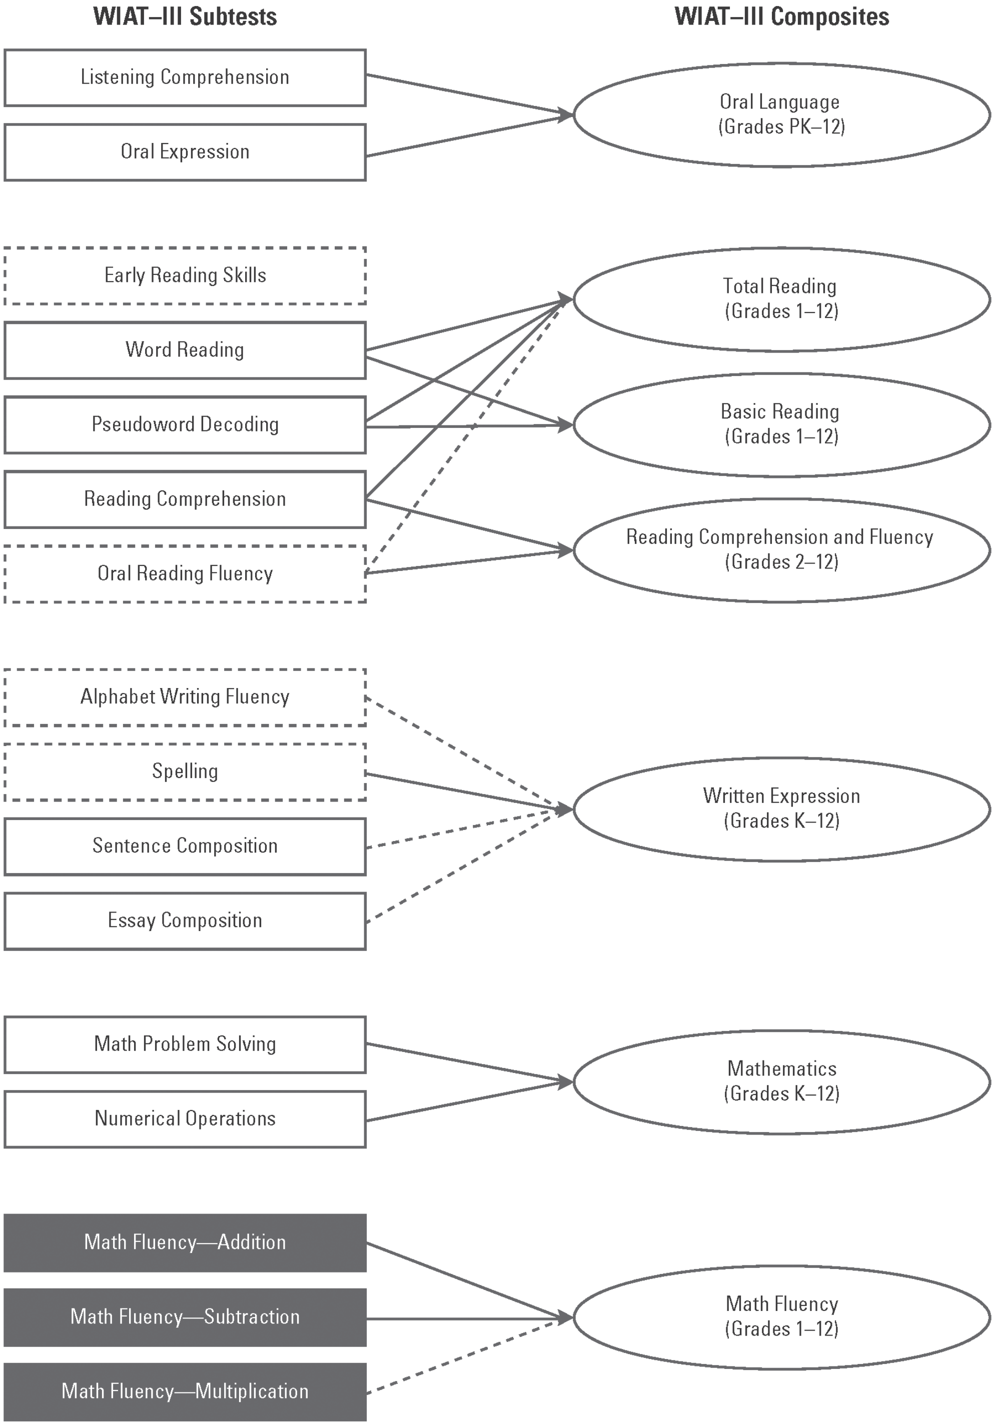

FIGURE 9.4. WIAT-III index scores and subtests. *Note.* A solid arrow indicates that the subtest contributes to the composite for all composite grade levels; a dashed arrow indicates that the subtest contributes to the composite for some, but not all, possible composite grade levels. The Early Reading Skills subtest *only* contributes to the Total Achievement composite. Boxes with dotted lines indicate that the subtest is included in the Total Achievement composite for some, but not all, possible grades. Subtests in shaded boxes do *not* contribute to the Total Achievement composite. Figures found in the Manual for the *Wechsler Individual Achievement Test®, Third Edition (WIAT®-III)*. of oral single-word reading. The examiner records the item reached at 30 seconds to obtain a supplemental measure of reading speed; however, the examinee continues reading the list of words without a time limit until the discontinue rule is met or the last item is read.

Essay Composition, administered to examinees ages 8–50 (grades 3–12+), measures spontaneous, compositional writing skills. The examinee is given 10 minutes to respond to one essay prompt.

Pseudoword Decoding, administered to examinees ages 6–50 (grades 1–12+), requires the examinee to read aloud from a list of pseudowords. As in the Word Reading subtest, the examiner records the item reached at 30 seconds to obtain a supplemental measure of reading speed; however, the examinee continues reading the list of words without a time limit until the discontinue rule is met or the last item is read.

Numerical Operations, administered to examinees ages 5–50 (grades K–12+), measures untimed, written math calculation skills in the areas of basic skills, basic operations with integers, geometry, algebra, and calculus.

Oral Expression, administered to examinees ages 4–50 (grades PK–12+), contains three components: Expressive Vocabulary, Oral Word Fluency, and Sentence Repetition. Expressive Vocabulary measures speaking vocabulary and word retrieval ability by requiring the examinee to say the word that best corresponds to a given picture and definition. Oral Word Fluency measures how quickly and easily the examinee can name things belonging to a given category within 60 seconds. Sentence Repetition measures oral syntactic knowledge and short-term memory by asking the examinee to repeat sentences verbatim.

Oral Reading Fluency, administered to examinees ages 6–50 (grades 1–12+), measures oral reading speed, accuracy, fluency, and prosody by requiring the examinee to read passages aloud. Fluency is calculated as the average number of words read correctly per minute. A qualitative scale is used to assess reading prosody.

Spelling, administered to examinees ages 5–50 (grades K–12+), requires the examinee to spell (write) letter sounds or words, depending on grade level. The examinee hears each letter sound within the context of a word, and each word within the context of a sentence.

Math Fluency—Addition, administered to examinees ages 6–50 (grades 1–12+), requires the examinee to solve written addition problems within a 60-second time limit. Math Fluency—Subtraction, administered to examinees ages 6–50 (grades 1–12+), requires the examinee to solve written subtraction problems within a 60-second time limit. Math Fluency—Multiplication, administered to examinees ages 8–50 (grades 3–12+), requires the examinee to solve written multiplication problems within a 60-second time limit.

PSYCHOMETRIC PROPERTIES OF THE WIAT-III

The normative sample of the WIAT-III meets or exceeds current practice recommendations, and the psychometric properties are generally strong (see Dumont & Willis, 2010).

Normative Samples

The WIAT-III was standardized on nationally stratified samples of 2,775 students in the grade-norm sample (grades PK–12), 1,826 students in the age-norm sample (ages 4:0–19:11), and 225 individuals in the adult age-norm sample (ages 20:0–50:11 years). The stratification of the normative samples matches recent U.S. census data closely on the following key demographic variables: grade/age, sex, race/ethnicity, parental educational level, and geographic region. Approximately 8% of the school-age normative samples included individuals with diagnosed clinical disorders, and approximately 2% were identified as academically gifted.

Reliability

The reliability coefficients for the school-age and adult samples are generally consistent. The average internal-consistency (split-half) reliability coefficients for the composite scores and for Math Problem Solving, Word Reading, Pseudoword Decoding, Numerical Operations, Spelling, Math Fluency—Subtraction, and Math Fluency—Multiplication (for the adult sample only) are in the .90s. The average split-half reliability coefficients for Listening Comprehension, Early Reading Skills (school-age sample only), Reading Comprehension, Sentence Composition, Essay Composition, Essay Composition: Grammar and Mechanics, and Oral Expression are predominantly in the .80s and .90s.

The WIAT-III composites and subtests also demonstrate strong test–retest stability coefficients. For the school-age sample, the average corrected stability coefficients are excellent (.87–.96) for the composite scores; excellent (.90–.94) for Reading Comprehension, Word Reading, Pseudoword Decoding, Oral Reading Fluency, Oral Reading Rate, and Spelling; good (.82–.89) for Early Reading Skills, Math Problem Solving, Essay Composition, Essay Composition: Grammar and Mechanics, Numerical Operations, Oral Expression, Oral Reading Accuracy, Math Fluency—Addition, Math Fluency—Subtraction, and Math Fluency—Multiplication; and adequate (.75, .79) for Listening Comprehension and Sentence Composition. Alphabet Writing Fluency is a speeded subtest with a restricted raw score range, so a lower average stability coefficient (.69) is expected. For the adult sample, the average corrected stability coefficients are excellent (.90–.97) for the composite scores; excellent (.90–.97) for Math Problem Solving, Word Reading, Pseudoword Decoding, Numerical Operations, Oral Expression, Oral Reading Fluency, Oral Reading Rate, Spelling, Math Fluency—Subtraction, and Math Fluency—Multiplication; good (.81–.87) for Listening Comprehension, Reading Comprehension, Sentence Composition, Essay Composition: Grammar and Mechanics, and Math Fluency—Addition; and adequate (.78, .74, respectively) for Essay Composition and Oral Reading Accuracy.

Validity

The validity of the WIAT-III has been demonstrated by using intercorrelation data, correlations with other measures, and clinical studies. The subtests that make up each composite are generally moderately correlated with one another and show expected relationships (e.g., strong correlations between Math Problem Solving and Numerical Operations, and between Word Reading and Pseudoword Decoding) and discriminant evidence of validity (e.g., the mathematics subtests correlate more highly with each other than with other subtests). Correlations among the composite scores range from .45 to .93, with stronger correlations among the reading composites, and weaker correlations between the Math Fluency composite and other composites. Construct validity was established by correlating the WIAT-III with other tests. Correlations with the WIAT-II indicate that the two tests measure similar constructs. The corrected correlations between the composite scores for the two tests ranged from .76 (Oral Language) to .93 (Total Achievement), and correlations between the common subtests ranged from .62 (Oral Expression) to .86 (Spelling). Consistent with expectations, the corrected correlations were high for subtests that are highly similar in content and structure, and relatively low for subtests in which content and structure were modified considerably for the WIAT-III.

Correlations between the WIAT-III and the Wechsler intelligence scales (WPPSI-IV, WISC-V, WAIS-IV, and WNV), and between the WIAT-III and the DAS-II, are consistent with expectations regarding typical correlations between cognitive ability and achievement measures. The correlations between the WIAT-III Total Achievement score and the overall cognitive ability scores for these measures range from .60 to .82. These correlations provide divergent evidence of validity, suggesting that the WIAT-III and the cognitive ability tests are measuring different constructs with varying degrees of overlap in the cognitive skills required.

To establish the validity and clinical utility of the WIAT-III, clinical studies were conducted with students identified as academically gifted and talented (GT), students with mild intellectual disability (ID), students with expressive language disorder (ELD), and students with specific learning disabilities in the areas of reading (SLD-R), written expression (SLD-W), and mathematics (SLD-M). Results showed expected patterns of performance in each study. Students identified as GT scored consistently higher than a matched control group across all subtests and composites except Early Reading Skills and Alphabet Writing Fluency. Students with mild ID scored significantly lower than a matched control group across all subtests and composites. Results from the ELD study confirmed that the oral language subtests and several other subtests and composites requiring expressive language and related skills reliably differentiated between students with ELD and their age-matched peers. Students with SLD-R (approximately 10% of whom were diagnosed with comorbid SLD-W) performed significantly lower than a matched control group on all reading-related subtests and composites, in addition to the Total Achievement composite, the Spelling subtest, and the Written Expression composites. Students with SLD-W (approximately 18% of whom were diagnosed with comorbid SLD-R) performed significantly lower than a matched control group on all writing-related subtests and composites (except the Alphabet Writing Fluency subtest) in addition to the Total Achievement composite and some reading-related subtests and composites. Students with LD-M performed significantly lower than a matched control group on all math-related subtests and composites. These results provide evidence that the WIAT-III reliably differentiates between students in these special groups and their age-matched peers.

ADMINISTRATION OPTIONS

The WISC-V, WPPSI-IV, and WIAT-III can be administered in paper-and-pencil format with traditional test kits, or digitally via the Q-interactive™ system. Q-interactive allows tests to be administered by using two tablets connected with Bluetooth. One tablet is used by the examiner to read instructions, record and score examinee responses, and send visual stimuli to the examinee's tablet. The examinee's tablet allows the test taker to view and respond to visual stimuli. The Q-interactive system differs from the well-known form of computer-administered testing found in education and the workplace, whereby the examinee self-guides the on-screen administration of items and responds by using a mouse or keyboard. Instead, it is specifically intended to enhance the types of testing in which the examinee interacts with a trained examiner who presents the test items, records and scores responses, and follows up as necessary. This facilitates the clinician's ability to establish rapport, observe qualitative aspects of performance such as problem solving style, and ensure that the examinee is demonstrating his or her best performance. An in depth review of how to use Q-interactive to administer the WISC-V, WPPSI-IV, and WIAT-III is outside the scope of this chapter, but refer to Wahlstrom, Daniel, Weiss, and Prifitera (2016) and Cayton, Wahlstrom, and Daniel (2012) for more detailed descriptions of the system. In addition, for an in-depth review of how to use Q-interactive to administer the WIAT-III, refer to Witholt, Breaux, and Lichtenberger (2016).

To date, all tests on Q-interactive are scored by using the original normative data collected via traditional paper-based administration methods. In place of renorming the Q-interactive versions of tests, studies have been conducted to establish the raw score equivalence of scores generated through paper- and digital-based administrations. The study methodologies vary, depending on test characteristics, but in all cases equivalence is defined a priori as a paper–digital format effect size less than or equal to 0.20, which is a little more than 0.5 scaled score point or 3 standard score points (Daniel, 2012a).

The goals of the Q-interactive equivalence program have shifted over time. Originally, all subtests placed on Q-interactive underwent an equivalence study. This included subtests of the WAIS-IV (Daniel, 2012a), the WISC-IV (Daniel, 2012b), and the Wechsler Memory Scale—Fourth Edition (WMS-IV) (Daniel, 2013a), among others. As these studies were completed, a collective knowledge of how test designs were affected by digital adaptation was acquired, and from then on the team only tested new designs that could potentially introduce an equivalence threat. For example, with the WIAT-III, the raw score equivalence of Oral Reading Fluency was assessed because it was the first time an examinee read paragraphs on the iPad screen. However, this was not done for Oral Word Fluency because it was identical to Delis–Kaplan Executive Function System (D-KEFS) Verbal Fluency—which was found equivalent in previous studies—in terms of how the items were administered and scored (Daniel, 2013b). All WISC-V subtests underwent an equivalence study in order to replicate the WISC-IV findings, with the exception of Coding, Symbol Search, and Cancellation (which at the time were completed in paper response booklets and thus were very unlikely to reveal format effects). In addition, WPPSI-IV subtests that required use of the client tablet were assessed for format effects because it was unknown whether the findings for school-age children could be applied to preschoolers on these types of tasks.

Overall, the equivalence study data indicate that there are few, if any, differences between subtests administered in paper versus digital formats. The WISC-IV study revealed that all subtests had a format effect size of 0.20 or lower (the selected threshold), with the exception of Matrix Reasoning and Picture Concepts, which had effect sizes of 0.27 and 0.21, respectively (Daniel, 2012b). When the WISC-IV study was replicated for the WISC-V, the effect sizes for Matrix Reasoning and Picture Concepts met the equivalence threshold (0.17 and 0.02, respectively), along with all of the other subtests assessed (Daniel, Wahlstrom, & Zhang, 2014). For the WPPSI-IV, it was found that the correspondence between the paper and digital formats of the Picture Memory subtest did not support equivalence (Drozdick, Getz, Raiford, & Zhang, 2016). As a result, the subtest is still administered by using a paper stimulus book, and the examiner uses the practitioner's device to record and score the examinee's responses. All other subtests met the equivalence threshold. On the WIAT-III, only Word Reading, Pseudoword Decoding, Sentence Repetition, and Oral Reading Fluency were assessed because they are the only subtests with unique response demands relative to subtests that had been previously found equivalent. The study did not reveal any effect of format (Daniel, 2013b).

These findings are not surprising, as equivalence is considered during all phases of subtest development on Q-interactive and is a major driver of design decisions on the system. For example, one question that clinicians often ask is this: Why, when a child selects the correct answer on WISC-V Matrix Reasoning or Visual Puzzles, does the selection flash rather than stay active on the screen? The reason is that some subtests, such as Visual Puzzles, require the examinee to select multiple answers that go together. In these subtests, there is a working memory component, whereby the examinee must hold stimuli in mind while considering whether they fit together. If responses could be selected and remain highlighted, would that reduce the working memory requirements and change slightly the difficulty of the task? The answer is unknown, but decisions were made to keep the experience in digital format as similar as possible to that in the paper format, in order to avoid potential equivalence threats such as this. For the same reason, physical manipulatives such as the Block Design blocks or WPPSI-IV Object Assembly puzzle pieces are used with Q-interactive, despite the fact that they could be redesigned as completely digital experiences.

There is one notable exception to the equivalence approach, which is the digital adaptation of WISC-V Coding and Symbol Search. These have been developed as completely digital subtests, in which the examinee responds by tapping the screen rather than writing in a response booklet. Figures 9.5 and 9.6 depict samples of the tasks. For Coding, the examinee views a box that contains a missing symbol, and uses a key at the top of the screen to select the correct symbol from among five responses at the bottom of the screen. For Symbol Search, the task's demands are similar to those in the paper format, but the child taps the correct response rather than crossing it out with a pencil. Because the changes to task demands were more drastic than those in other subtests adapted for Q-interactive, there was no assumption that the digital Coding and Symbol Search would be equivalent to the paper versions. Rather, the goal was to equate them to the paper norms, since the paper and digital versions are assumed to be measuring the same core constructs, as evidenced by a high correlation between the different formats. The first attempt at digital adaptation of Coding required the examinee to use a stylus to write the correct response in the box, which more closely represents the paper response processes. However, pilot data suggested that the correlations with the paper subtest were insufficiently low, and after consultation with child design experts the task was redesigned in its current form. The equating data collected on the revised digital formats of Coding and Symbol Search suggest impressive similarities to their paper counterparts, as the raw score correlations with the paper tasks are .88 for Coding and .85 for Symbol Search (Raiford et al., 2016). In addition, confirmatory factor analyses indicated that the goodness-of-fit statistics were similar, regardless of whether the digital or paper formats of Coding and Symbol Search were used in the model. Moreover, special group studies indi-

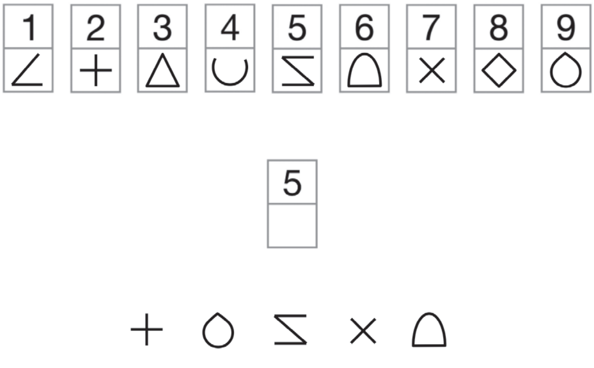

FIGURE 9.5. Example of an item from WISC-V Coding on Q-interactive.

FIGURE 9.6. Example of an item from WISC-V Symbol Search on Q-interactive.

cated similar patterns of performance across paper and digital subtests in individuals with intellectual disability, intellectual giftedness, specific learning disorders in math and in reading, ADHD, autism spectrum disorder with accompanying language impairment, and motor impairment. The finding that children with motor impairment performed similarly across paper and digital formats of Coding is especially important, given the reduction of graphomotor requirements in the digital format of the task. These results converge to indicate that the cognitive processes measured by traditional and digital formats of Coding and Symbol Search are very similar, and that administering the tasks in either format produces highly consistent results.

What are some considerations when practitioners are deciding whether to administer digital formats of the WISC-V, WPPSI-IV, or WIAT-III? One is how the testing experience will change for the test taker. Although the results of the equivalence studies suggest that raw scores do not change when a test is administered using a tablet device, many practitioners report that students are more engaged when interacting with technology (Daniel, 2013c). For the most part, this engagement is positive, as it suggests that scores are more likely to be valid because they aren't being negatively affected by boredom or fatigue. However, it may lead to new types of distractions for children who are inattentive and would rather do other things on the tablet than take a test. As always, the clinical skills used to manage behavior in traditional testing formats are important to keep an examinee motivated and on task.

Another consideration is that the test-taking experience with Q-interactive also changes significantly for the practitioner, and thus it is important to have appropriate training in the technology before using it for clinical cases. Basic familiarity with mobile technology is a must in order to feel comfortable during the testing session and provide the examinee with full attention. Finally, technology such as Q-interactive is accompanied by major changes in how test data are accessed, secured, and stored. Before using a system like Q-interactive, practitioners should understand their data privacy responsibilities as defined by the Health Insurance Portability and Accountability Act (HIPAA) and the Health Information Technology for Economic and Clinical Health Act (HITECH), as well as how the technology they use helps them comply with these requirements.

INTERPRETATION

The WPPSI-IV, WISC-V, and WIAT-III technical manuals provide basic instruction regarding their interpretation (Pearson, 2009; Wechsler, 2012a, 2014a). Leading clinicians and researchers have developed more in-depth and alternative interpretive strategies for these tests, all of which represent valid and useful approaches to test interpretation (Breaux & Lichtenberger, 2016; Flanagan & Kaufman, 2009; A. S. Kaufman et al., 2016; Raiford & Coalson, 2014; Sattler et al., 2016; Weiss et al., 2016). A detailed guide to interpretation is outside the scope of this chapter, and we refer the reader to these other outstanding volumes, as well as the tests' technical and interpretive manuals, for further information. Instead, we provide basic information illustrating how the WPPSI-IV, WISC-V, and WIAT-III can be utilized by practitioners. In addition, we include guidance for how these measures can be integrated within the context of learning disability evaluations. When reading this section, the reader is encouraged to keep in mind that psychological assessment is a complex problem-solving process (Prifitera, Weiss, & Saklofske, 1998), and test results should always be interpreted in conjunction with a thorough history and careful clinical observations of the individual.

Common Wechsler Scores

The WPPSI-IV and the WISC-V utilize two types of age-adjusted scores: scaled scores and standard scores (for all composite scores and for the WISC-V complementary subtests and process scores). For subtest scores, an examinee's raw scores are compared to others within his or her age group. The WIAT-III provides both age-based and grade-based subtest and composite standard scores, which are computed by comparing an examinee's raw scores to others within his or her age or grade group. These scores permit comparison of an individual's performance to that of others in his or her peer group; because they are based on a similar metric, they also allow for comparisons within and across Wechsler scales, as well as between Wechsler tests and other commonly used assessment batteries.

For those without formal training in psychometrics (examinees, parents, educators, etc.), scaled and standard scores are often difficult to understand. Thus the Wechsler scales provide a number of other metrics to help communicate test results, which include percentile ranks and age equivalents (and grade equivalents for the WIAT-III); both of these should be provided when appropriate on the WPPSI-IV, WISC-V, and WIAT-III. A *percentile rank* is the percentage of individuals within the examinee's age range obtaining scores below or equivalent to that of the examinee, whereas an *age equivalent* is the age of individuals who, on average, obtain the examinee's raw score. Composite scores always should be accompanied by a *confidence interval,* which is based on the scale's reliability and expresses the likelihood that an examinee's true score (i.e., the score he or she would obtain if there was no error in the test) falls within a specified range around the actual score that he or she obtained. The confidence interval is important because it communicates the error that is inherent in all psychological tests.

Levels of Performance

Wechsler standard scores can also be communicated by describing a range of performance within which each score falls, which correspond to the relationship of the examinee's score to that of his or her normative group. These qualitative descriptors are particularly useful when describing test results to individuals unfamiliar with quantitative test data. The traditional labels used to describe the different qualitative categories on Wechsler tests were revised with the WISC-V. The reasons are that (1) some of the traditional labels are confusing (e.g., *borderline*) or value-laden (e.g., *superior*), and (2) there is little consistency across various tests used by clinicians (Breaux & Lichtenberger, 2016; Raiford & Coalson, 2014).

Table 9.2 presents the qualitative descriptors used for the WISC-V, WPPSI-IV, and WIAT-III, which highlight the recent shift in terminology. These terms are not empirically based, which means that alternative labels can be used, depending on the reporting needs for an examinee. For example, as seen in Table 9.2, the WIAT-III descriptive categories are based on a 15-point scale, whereas the WISC-V and WPPSI-IV categories are based on a 10-point scale. Recently, an option to use the 10-point scale has been added to the WIAT-III scoring software on Q-global™, Pearson's scoring and reporting platform, and to Q-interactive.

The 15-point scale allows for finer differentiation at the high and low ends of the distribution, whereas the 10-point scale allows for finer differentiation in the middle of the distribution. When reporting on WIAT-III scores that were obtained as part of a broader evaluation including the WISC-V or WPPSI-IV, it may be helpful to use the 10-point scale for consistency, unless the examinee's achievement scores are at the tails of the distribution and would thus benefit from the greater differentiation yielded by the 15-point scale. Regardless of the scale used, it is recommended that *extremely high* and *very high* be used in place of *very superior* and *superior,* respectively.

Basic Interpretation of the Intelligence Scales (WISC-V and WPPSI-IV)

Reporting and Describing Index Scores

The FSIQ and index scores are much more reliable measures than the subtest scaled scores. In general, they are the first scores examined by practitioners.

The FSIQ is often used as the primary level of interpretation. Some controversy exists in the literature regarding the interpretability and clinical utility of the FSIQ in children, especially in clinical samples characterized by significant variation

TABLE 9.2. Qualitative Descriptions for the WISC-IV, WPPSI-IV, and WIAT-III

10-point scale (WISC-V and WPPSI-IV)			15-point scale (WIAT-III)	
Score range	WISC-V descriptive classification	WPPSI-IV descriptive classification	Score range	WIAT-III descriptive classification
130 and above	Extremely high	Very superior	146 and above	Very superior
120–129	Very high	Superior	131–146	Superior
110–119	High average	High average	116–130	Above average
90–109	Average	Average	85–115	Average
80–89	Low average	Low average	70–84	Below average
70–79	Very low	Very low	55–69	Low
69 and below	Extremely low	Extremely low	40–54	Very low

in index scores (e.g., see the 2007 special issue of *Applied Neuropsychology*, Volume 14, Issue 1). However, the FSIQ is the best single-point predictor of school achievement, work performance, and many other important life outcomes known to modern science (Gottfredson, 2008), and evidence suggests that FSIQ remains valid and predictive even in cases characterized by extreme index score discrepancies (Daniel, 2007; Watkins, Lei, & Canivez, 2007).

However, some previous interpretive approaches posit that the FSIQ is valid and interpretable only if no 23-point or greater discrepancy exists between the highest and lowest primary index scores. There is no evidence that there is a discrepancy or index score scatter (or subtest score scatter) beyond which the FSIQ becomes invalid and uninterpretable (see Flanagan & Alfonso, 2017, for a discussion). When great variability or discrepancy characterizes the primary index scores or the subtest scaled scores, the FSIQ alone is insufficient to describe a child's intellectual abilities. However, reliance on any single score is never recommended for describing a child's intellectual abilities or for identifying his or her strengths and needs. Also, not all subtests that contribute to the primary index scores are used to create the FSIQ; the FSIQ is derived from a subset of those primary subtests on the WISC-V and the WPPSI-IV.

Research indicates that the construct and predictive validity of the FSIQ are not affected by an index score discrepancy (Daniel, 2007). It is quite typical to have a discrepancy of greater than 23 points between two primary index scores: For the WISC-V, 56.6% of the normative sample (i.e., 1,246 of the 2,200 children) had such a discrepancy, and 52.5% of the special group study cases (261 of the 497 children from these groups) had such a discrepancy (Kaufman et al., 2016). Similar frequencies were found among the WPPSI-IV normative and special group study samples (Raiford & Coalson, 2014). Given the vast evidence in support of the predictive validity of *g* and the FSIQ (Daniel, 2007; Deary & Johnson, 2010; Deary, Strand, Smith, & Fernandes, 2007; Johnson, Deary, & Iacono, 2009; S. B. Kaufman et al., 2012), it is counterintuitive to assume that for almost 60% of children, the FSIQ is not valid due to such discrepancies. Identifying index score discrepancies can reveal rich clinical information about a child, which is why comprehensive assessment of these diverse cognitive domains is important. Furthermore, more specific domains of intellectual ability do not show the same broad degree of predictive validity as does *g* (Hartmann, Larsen, & Nyborg, 2009; Kotz, Watkins, & McDermott, 2008; Reeve & Charles, 2008). The FSIQ consistently provides essential, clinically rich information when practitioners are attempting to understand the expression of intelligent behavior in real-world settings (Jacobson, Delis, Hamilton, Bondi, & Salmon, 2004).

While interpretation should include consideration of the FSIQ, it should be augmented by examination of index-level results. This is important because index-level strengths and weaknesses can provide important insight into a child's functioning that cannot be obtained from the FSIQ alone. For example, many clinical disorders are characterized by unique patterns of cognitive strengths and weaknesses, though it should be noted that there is enough overlap of profile patterns across disorders to suggest caution against the use of profile patterns for diagnostic purposes in the absence of additional information.

Assessing Index-Level Strengths and Weaknesses

As just noted, analyzing index-level strengths and weaknesses is important because they often yield important clinical information and augment the interpretation of the FSIQ. A significant difference between a primary index score and an overall performance indicator (i.e., the mean of the primary index scores [MIS] or the FSIQ) suggests a strength or weakness in that specific cognitive area. Therefore, the next step is to compare the primary index scores to the overall performance indicator, which reduces the error rate resulting from multiple comparisons (e.g., doing pairwise comparisons between all primary index scores). This approach to interpretation is advocated by multiple researchers and within various interpretive approaches (Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Longman, 2005; Naglieri & Paolitto, 2005; Raiford & Coalson, 2014) and represents a significant advancement in the interpretive approach advocated for these measures. The preferred overall performance indicator is the MIS because it is based on a larger sample of behavior and is not subject to scaling, but is truly a mean indicator. However, there may be occasions where the MIS is unavailable (e.g., invalid subtests, choosing not to assess all five cognitive domains, choosing to administer only the FSIQ subtests and derive only the FSIQ, VCI, and FRI), so the FSIQ can be used in its place.

Determining whether the difference between a primary index score and the overall performance indicator is statistically significant is the first step in this level of interpretation; however, not all statistically significant differences are clinically meaningful. Some degree of cognitive variability is typical. Thus the significance and frequency of a discrepancy have different implications for test interpretation (Flanagan & Alfonso, 2017; A. S. Kaufman et al., 2016; Matarazzo & Herman, 1985; Payne & Jones, 1957; Raiford & Coalson, 2014; Silverstein, 1981; Weiss et al., 2016). The Wechsler scales provide base rate data for discrepancies to assist practitioners in determining the rarity of significant differences. Because the values differ by ability level, the base rate data are also provided by five ability levels. The base rates are provided by the direction of the discrepancy because the frequencies of score differences vary with the direction of the difference (Sattler et al., 2016). For instance, the percentage of the WISC-V normative sample with VCI scores greater than the MIS is not the same percentage of the normative sample with an MIS greater than the VCI. Clinically speaking, the direction of discrepancy is related to different patterns of cognitive strengths and weaknesses that may be unique to particular clinical disorders. As discussed, some statistically significant discrepancies are commonly found among individuals in the normative sample, whereas others are relatively rare.

As with the index-level strengths and weaknesses comparisons, the WISC-V provides critical value and base rate information relevant to index-level pairwise comparisons. Pairwise comparisons are best used to evaluate specific hypotheses in interpretation. Each primary index score is a summary of performance on two subtests. It is therefore important to evaluate the variability between the two subtest scaled scores that are used to derive each of the primary index scores being compared, to ensure clear interpretation of discrepancies between the index scores.

Examining Subtest-Level Variability

Composite scores are estimates of overall functioning in their respective areas and should always be evaluated within the context of the subtests that contribute to them (Flanagan & Kaufman, 2009; A. S. Kaufman et al., 2016; Raiford & Coalson, 2014). It is good practice to evaluate the level of score consistency or variability among subtest scaled scores before interpreting composite scores. In cases characterized by extreme subtest score variability, consideration of that variability augments interpretation of the composite scores and may yield a more complete picture of the child's performance. Subtest-level variability is best examined to inform composite score interpretation using (1) subtest-level strengths and weaknesses, and (2) pairwise subtest comparisons that are relevant to interpretation of index scores derived from only two subtests.

It is a good practice to conduct an analysis of subtest strengths and weaknesses when the subtest scaled scores appear variable. Such an analysis is usually hypothesis-driven and focused on certain cognitive domains associated with the referral question (Flanagan & Alfonso, 2017; A. S. Kaufman et al., 2016; Raiford & Coalson, 2014; Weiss et al., 2016). As at the index level, the subtest-level strengths-and-weaknesses analysis determines whether or not the difference between each primary subtest scaled score and the overall indicator of subtest performance is statistically significant and unusual. As with index-level strengths and weaknesses, there are two indicators of overall subtest performance: the mean of the primary subtest scaled scores (MSS-P) and the mean of the FSIQ subtest scaled scores (MSS-F).

For interpretation of the primary index scores, each of which consists of only two subtests, pairwise subtest-level comparisons are informative. For example, comparing subtest-level performance on Digit Span and Picture Span can provide information relevant to interpretation of the WMI, as well as potentially relevant to auditory and visual working memory performance. Such a comparison may also suggest that further subtest administration would be helpful. For example, if the difference between Digit Span and Picture Span is significant, administering Letter–Number Sequencing yields an Auditory Working Memory Index, and administering Spatial Span from the WISC-V Integrated provides a Visual Working Memory Index. (See Raiford, Chapter 11 this volume, for a complete overview of the use and interpretation of the WISC-V Integrated, which enhances interpretation by extending the information available about WISC-V performance.) As with other types of comparisons, the WISC-V provides critical value and base rate information relevant to subtest-level pairwise comparisons.

Interpretation of the WIAT-III

The interpretation of the WIAT-III follows the same basic outline as that of the WPPSI-IV and WISC-V. The practitioner should begin by interpreting the composite scores to determine if the scores are consistent with the Total Achievement composite and with the other composite scores. Next, he or she should interpret the individual subtest standard scores for more detailed information about the examinee's performance. Next, the practitioner should identify academic strengths and weaknesses by evaluating the pattern of composite and subtest scores. As with the Wechsler intelligence tests, both the statistical significance and base rate of score discrepancies should be considered to determine if differences are clinically meaningful.

Growth scale values (GSVs) and subtest skills analysis are two aspects of interpretation included in the WIAT-III but not the Wechsler intelligence scales. GSVs are provided at the subtest level and are intended for comparing performance across test sessions and measuring change over time. Unlike standard scores and percentile ranks, GSVs do not compare performance to a normative sample, but rather describe performance in absolute terms. Comparing GSVs over time indicates whether an examinee's skill level has changed relative to his or her own previous skill level, and this growth can be compared to the typical growth rate in the normative sample. The key advantage of GSVs is that they are sensitive to small changes over time; however, the practitioner must be careful not to overinterpret progress, as GSVs only represent growth in the limited range of academic skills measured by a given subtest. It is often useful to interpret GSVs within the context of the examinee's standard scores. For example, increased GSVs associated with increased standard scores indicate that the examinee is progressing at a faster rate than his or her peers are. Increased GSVs with consistent standard scores indicate that the examinee is developing additional academic skills but at a rate consistent with peers, whereas increased GSVs with lower standard scores indicate that academic skills are increasing but at a slower rate than peers' skills.

Subtest skills analysis data provide more in-depth information about the examinee's strengths and weaknesses, and assist in the formulation of intervention plans. There are two types of skills analysis within the WIAT-III: item-level and within-item-level. For item-level skills analysis, an item is assigned to a particular skill category; if that item is scored as incorrect, an error is marked for that particular category. Within-item-level skills analysis is used when a particular item may reflect multiple error categories, depending on the type of incorrect response that the examinee provides. In this case, the examiner is required to interpret the error and assign it to the relevant error category. Skills analysis is particularly useful in identifying nuanced skill weaknesses for students who exhibit average or below-average performance on a subtest. Importantly, an examinee's pattern of errors can be used to generate goal statements for intervention planning.

Integration of Cognitive Ability and Achievement Results for Learning Disability Evaluations

IDEA 2004 increases flexibility in determining the method to be used for learning disability identification. Analyses to support two of the more commonly used methods in the field are available for use with the WIAT-III and the WISC-V or WPPSI-IV: the ability–achievement discrepancy

(AAD) analysis and the pattern of strengths and weaknesses (PSW) discrepancy analysis. Both of these analyses require the integration of standardized achievement and ability measures, and the statistical information supporting them can be found in the WISC-V and WPPSI-IV technical and interpretive manuals and scoring software.

It should be noted at the outset that significant discrepancies as described by either the AAD or PSW approach are insufficient to diagnose a learning disorder, but they are often used as administrative criteria to determine eligibility for special education services in public school systems. Although they are important empirical sources of information, they must be interpreted as part of a comprehensive evaluation that includes a variety of other information (e.g., educational records, medical history, family history, social and emotional functioning).

AAD Analysis

An AAD is characterized by performance on an academic achievement test that is significantly lower than what would be expected, given an examinee's performance on a cognitive ability measure. While discrepancies of this sort sometimes indicate the presence of a learning disability, many other factors may cause academic achievement to be discordant with cognitive ability. For example, children who struggle with extreme inattention or anxiety may be at a disadvantage relative to peers with respect to knowledge acquisition. Similarly, bright and motivated children may compensate for their learning difficulties through the use of executive compensatory strategies, hard work, or external support. In other words, although the presence of an AAD indicates the child is not achieving at his or her potential, the reason for underachievement requires further investigation and cannot be inferred from the presence of a discrepancy alone. For this reason, AAD analyses should be accompanied by other sources of information (Berninger & O'Donnell, 2005; Shinn, 2007; Siegel, 2003) in the process of identifying a learning disability.

There are two methods for calculating AAD with the WIAT-III: the simple-difference method and the predicted-difference method. (Formulas to calculate simple-difference critical values and base rates, as well as those for the predicted-achievement method, can be found in Rust & Golombok, 1999.) The predicted-achievement method is typically preferred because it accounts for regression to the mean, and the correlations between the two tests used in the analysis. WIAT-III standard scores can be predicted from a number of cognitive batteries, including the WISC-V and WPPSI-IV. The FSIQ and a number of other index scores may be used to predict achievement scores.

PSW Analysis

IDEA 2004 allows clinicians to consider a child's "pattern of strengths and weaknesses" in determining eligibility for learning disability services. A PSW analysis may be conducted utilizing scores from the WIAT-III and the WISC-V or WPPSI-IV, based on the concordance–discordance model developed by Hale and Fiorello (2004). The PSW model is often preferred because it requires the identification of a relative processing weakness, which helps to clarify the factors underlying academic difficulties (e.g., a cognitive processing deficit as opposed to emotional factors or poor instruction). Doing so can facilitate differential diagnosis and treatment planning, which is often difficult, given that students with learning problems are a heterogeneous group (Hale et al., 2008).

PSW analyses can be completed digitally only, within Q-interactive (for digital administration) or the Q-global scoring system (for paper administration). Both systems conduct two score comparisons, each of which must be significantly different to meet the model's criteria for learning disability identification: (1) processing strength versus achievement weakness, and (2) processing strength versus processing weakness. In order to calculate the PSW analysis with the WIAT-III and either the WISC-V or WPPSI-IV, the following steps are necessary. First, the WIAT-III subtest or composite score that reflects the student's achievement weakness should be identified; the practitioner should check first to make sure that if a composite score is chosen, it is interpretable (i.e., subtest scores do not show significant scatter). Scores below 85 are typically chosen, though scores above 85 may be acceptable in some cases (e.g., gifted students). Second, the cognitive weakness is identified, once the practitioner has again made sure that the index is interpretable and theoretically related to the achievement weakness (see Hale et al., 2001; Hale, Fiorello, Bertin, & Sherman, 2003). Finally, a cognitive strength is identified that is interpretable and not related to the academic weakness identified in the first step. The manuals advise against the use of some index scores (e.g., WMI, PSI, AWMI, NSI) to identify cognitive strengths because they have lower *g* loadings and are therefore less consistent with the conceptualization of specific learning disability as representing unexpected underachievement in comparison to intellectual ability (Pearson, 2009; Wechsler, 2012a, 2014a).

Appendix 9.1 presents a case study that demonstrates how the WISC-V and WIAT-III can be integrated into a comprehensive evaluation. All personally identifiable information has been altered in the case study report to preserve the confidentiality of the examinee.

APPENDIX 9.1

Illustrative Case Study

Report date: 11/18/2017	Grade: 6
Examinee: Andy Ford	Ethnicity: Mixed
Age: 12 years, 6 months	Sex: Male
Date of birth: 5/13/05	Tests administered: WISC-V and WIAT-III (11/13/17)

REASON FOR REFERRAL

Andy is a 12-year-old male referred for evaluation at the recommendation of his pediatrician. He has a history of school underachievement, and the purpose of the current evaluation is to clarify the factors underlying his academic difficulties.

FAMILY HISTORY

Andy lives with his parents and two older sisters, with whom he has lived since birth. Andy comes from a culturally diverse family background; his father is European American, and his mother is Hispanic. His maternal grandmother is a first-generation Mexican immigrant. Andy's mother obtained her master's degree and is employed as a nurse. His father has a bachelor's degree and works in sales. No significant stressors were reported at home.

LANGUAGE DEVELOPMENT

Andy's dominant language is English, and his parents and siblings speak English at home. Andy's maternal grandmother, who lives nearby and sees Andy several times a month, speaks to him in Spanish. Andy's mother reported that Andy understands Spanish and speaks some Spanish to his grandmother, but prefers speaking in English in all settings. No history of speech or language delays was reported, although he spoke his first words and used short sentences slightly later than expected.

MEDICAL AND DEVELOPMENTAL HISTORY

Mrs. Ford reported that Andy was the product of a full-term gestation free of complications. With the exception of his language development, Andy met all major developmental milestones within normal limits. Medical history is significant for frequent ear infections at the age of 2 years, which were treated with the placement of pressure equalizer tubes. No other hospitalizations, surgeries, or chronic illnesses were reported. A recent physical exam revealed normal hearing and vision. Andy is not currently on medication.

EDUCATIONAL HISTORY

Andy is in the sixth grade, his first year in middle school. He attends a mainstream classroom and has never been evaluated for special education services. However, Mrs. Ford noted that he has generally struggled with reading and writing tasks, but formerly compensated for these difficulties by spending more time studying with his parents. As the coursework became more complex in middle school, Andy struggled to keep up in class and earned below-average grades in English language arts his first semester. He was assigned a small-group tutoring service and support from a classroom aide, neither of which was effective in improving his test scores.

Mrs. Ford reported that Andy is motivated to do well in school, but frustrated by his lack of success. His attendance record is excellent, and he has no reported disciplinary problems. Andy spends approximately 1 hour per night completing his homework. Mrs. Ford reported that Andy rarely forgets to bring assignments home or turn in completed work.

BEHAVIORAL OBSERVATIONS

Andy appeared alert and oriented. He seemed shy at the beginning of testing, but rapport was established quickly and maintained throughout testing. His speech was goal-directed and fluent, without errors of articulation, and his receptive language appeared adequate for testing purposes. Andy appeared cooperative and motivated on all tasks.

INTERPRETATION OF WISC-V RESULTS

Andy was administered all of the WISC-V subtests (see Tables 9.A.1 and 9.A.2 for his composite and subtest scores, respectively). Andy's general cognitive ability is within the average range of intellectual functioning, as measured by the Full Scale IQ (FSIQ). His overall thinking and reasoning abilities exceed those of approximately 27% of children his age (FSIQ = 91; 95% confidence interval = 86–97), indicating well-developed overall cognitive functioning. Another overall measure of cognitive ability, the Nonverbal Index (NVI), was examined due to Andy's lower performance on Verbal Comprehension subtests, because such a pattern may be related to academic achievement issues. The NVI was closer to the population average of 100 (NVI = 98, 45th percentile; 95% confidence interval = 92–104). A comparison of higher-order reasoning abilities and efficiency of cognitive processing indicated that these abilities are comparable (General Ability Index [GAI] = 91, 27th percentile; Cognitive Processing Index [CPI] = 94, 54th percentile).

Andy's verbal reasoning abilities, as measured by the Verbal Comprehension Index (VCI), are in the low average range and above those of approximately 14% of his peers (VCI = 84; 95% confidence interval = 78–93). The VCI is designed to measure verbal reasoning and concept formation. Andy performed comparably on the subtests contributing to the VCI, suggesting that these verbal cognitive abilities are similarly developed. An expanded measure of verbal reasoning, the Verbal (Expanded Crystallized) Index (VECI), measures broad verbal reasoning and includes knowledge

TABLE 9.A.1. Andy's WISC-V Composite Scores

Composite	Sum of scaled scores	Composite score	Percentile rank	95% confidence interval	Qualitative description
		Primary			
Verbal Comprehension Index (VCI)	14	84	14	78–93	Low average
Visual Spatial Index (VSI)	18	94	34	87–102	Average

[a] Subtests that contribute to the Full Scale IQ.

[b] Subtests that do not contribute to the primary index score but can be substituted into the Full Scale IQ for that index.

about words, the world at large, and social situations. His performance on the VECI was also in the low average range relative to other children his age.

Andy's low average performance on the VCI was significantly lower than the mean of his primary index scores (MIS). This indicates that his skills in the areas of nonverbal reasoning, sustained attention, and effortful mental control are better developed than are his verbal reasoning skills, and these discrepancies suggest a weakness in complex verbal information processing. Fewer than 15% of children with overall cognitive skills similar to Andy's have a higher MIS relative to the VCI, indicating a relatively rare discrepancy that may be of clinical import.

Andy's visual–spatial skills, as measured by the Visual Spatial Index (VSI), are in the average range and above those of approximately 34% of his peers (VSI = 94; 95% confidence interval = 87–102). The VSI is designed to measure the ability to evaluate visual details and understand visual–spatial relationships. He performed similarly on subtests contributing to the VSI, suggesting that his skills in this domain are developing at a comparable rate.

Andy's nonverbal reasoning abilities, as measured by the Fluid Reasoning Index (FRI), are in the average range and above those of approximately 58% of his peers (FRI = 103; 95% confidence interval = 96–110). The FRI is designed to measure the ability to identify conceptual relationships between visual objects and use reasoning skills to apply rules to them. An expanded measure of reasoning, the Expanded Fluid Index (EFI,) provides a broader measure of his ability to detect underlying conceptual relations, extract important information, and use reasoning to identify and apply rules. His performance on the EFI is also in the average range.

Andy's average performance on the FRI was significantly higher than the mean of his primary index scores (MIS), suggesting a strength in nonverbal reasoning relative to verbal reasoning, visual–spatial skills, sustained attention and effortful mental control, and processing speed. Andy also displayed variable performance on subtests contributing to the FRI, as his score on Figure Weights was higher than his mean score on the 10 primary index scores (scaled score = 12). Figure Weights measures quantitative and inductive reasoning, as well as mental flexibility and set shifting. His performance indicates a strength in this area that was demonstrated by less than 10% of the normative sample, suggesting a clinically important result.

Andy's abilities to sustain attention, concentrate, and exert mental control, as measured by the Working Memory Index (WMI), are in the average range. He performed better than approximately 50% of his same-age peers in this area (WMI = 100; 95% confidence interval = 92–108). These results suggest that relative to other children his age, Andy demonstrates the mental control and attentional skills necessary to facilitate learning and support more complex information processing. Andy performed comparably on the Working Memory subtests that contribute to the WMI. His Auditory Working Memory Index (AWMI), which provides a purer measure of auditory working memory, is in the low average range.

Andy's abilities to process simple or routine visual material without making errors, as measured by the Processing Speed Index (PSI), are in the average range compared to those of his peers. He performed better than approximately 30% of children his age in this area (PSI = 92; 95% confidence interval = 84–102). Learning often involves both routine and complex information processing, and Andy's performance on the PSI suggests that he demonstrates the basic processing abilities necessary to acquire new information.

Rapid automatic naming involves recognizing and recalling overlearned information, like letters and numbers or quantities, as efficiently as possible. Overall, Andy's rapid automatic naming speed is in the very low range relative to other children his age (Naming Speed Index [NSI] = 78, 7th percentile; 95% confidence interval = 72–89). He recognizes, recalls, and recites letters and numbers far more slowly than other young people his age. This skill is related to and predictive of reading ability. His ability to rapidly recognize and name quantities is more efficient and close to average. Rapid quantity recognition is related to math skills, because working with these basic building blocks of overlearned information is involved in solving math problems.

Andy's visual–verbal associative memory, or the ability to form new associations between symbols and meanings, is in the low average range relative to other young people his age (Symbol Translation Index [STI] = 82, 12th percentile; 95% confidence interval = 76–90). This type of memory is especially relevant to learning to read, write, and do math, because all of these skills involve learning systems of symbols that are assigned meanings. His performance suggests uniform abilities when he is recalling associations learned within the past few seconds or minutes, or when trying to recall them or recognize them half an hour later.

In summary, Andy demonstrates overall cognitive skills in the average range. His scores on nonverbal reasoning, sustained attention, mental control, and ability to process simple or routine information were average. His verbal reasoning skills were low average. He exhibited a relative strength in his nonverbal reasoning skills and a relative weakness in his verbal reasoning skills relative to visual–spatial skills, sustained attention and mental control, and processing speed. He has particular weaknesses in rapid automatized naming and visual–verbal associative memory, which are commonly observed in conjunction with specific learning disabilities in the areas of reading and written expression.

INTERPRETATION OF WIAT-III RESULTS

Given Andy's history of difficulties in reading and writing, he was administered subtests of word recognition and decoding, reading comprehension, and written expression. To evaluate a possible area of strength, a subtest of math problem solving was administered. Results were interpreted by using age-based norms.

Andy's WIAT-III results are presented in Table 9.A.3. Andy demonstrated overall reading skills in the below-average range, performing better than approximately 9% of his peers (Basic Reading = 80; 95% confidence interval = 76–84). His ability to read single words aloud was below average relative to his peers. He correctly read 33 words, which is better than approximately 6% of children his age (Word Reading = 77; 95% confidence interval = 72–82). His pseudoword decoding skills (i.e., the ability to sound out made up words) were below average (Pseudoword Decoding = 82; 95% confidence interval = 77–87). He was able to sound out 20 pseudowords correctly. An evaluation of the skills analysis data for Word Reading and Pseudoword Decoding revealed specific weaknesses in recognizing more advanced vowel types (e.g., vowel digraphs and diphthongs), consonant blends, and common suffixes. Finally, Andy's reading comprehension was average (Reading Comprehension = 100; 95% confidence interval = 88–112). His ability to read passages and provide oral responses to open-ended comprehension questions was better than 47% of his peers.

Andy was administered two subtests of written expression. His ability to spell single words read aloud by the examiner was at the low end of average and better than 23% of his peers (Spelling = 89; 95% confidence interval = 83–95). A skills analysis revealed particular difficulty in spelling irregular vowels and certain suffixes (e.g., *-ous, -ious*), suggesting lower skills in orthography relative to phonology. His written productivity, theme development, and text organization were also at the low end of average and better than approximately 19% of children his age (Essay Composition = 87; 95% confidence interval 77–97). His one-paragraph essay included a simple introduction, two transition words, and two clearly stated reasons; however, he did not include elaborations or a conclusion.

Finally, Andy's math problem-solving skills were average (Math Problem Solving = 108; 95% confidence interval = 100–116). His ability to complete math calculations quickly and accurately, as well as solve word problems, was better than 70% of his peers.

Overall, the results of Andy's academic testing reveal relative weaknesses in the areas of single-word recognition and decoding. Despite these weaknesses, Andy demonstrates average reading comprehension skills. Consistent with his average overall cognitive functioning and strength in fluid reasoning, he seems to utilize compensatory strategies and context cues effectively to circumvent his word recognition difficulties while reading in context. Andy's written expression skills were at the low end of average. His highest score was in the area of math problem solving, which represents a relative strength for Andy.

TABLE 9.A.3. Andy's WIAT-III Composite and Subtest Scores

Subtest/composite	Raw score	Standard score	95% confidence interval	Percentile rank	Grade equivalent	Age equivalent	Qualitative description
Reading Comprehension	33	100	88–112	50	6.7	12:4	
Math Problem Solving	56	108	100–116	70	10.4	15:0	
Essay Composition	[a]	87	77–97	19	4.0	9:0	
Spelling	27	89	83–95	23	5.2	10:4	
Basic Reading composite		80	76–84	9			Below average
Word Reading	33	77	72–82	6	2.9	8:4	
Pseudoword Decoding	20	82	77–87	12	2.5	7:8	

[a] This subtest has multiple raw scores.

ABILITY–ACHIEVEMENT COMPARISONS

Ability–Achievement Discrepancy

The predicted-difference method was utilized to assess for discrepancies between his predicted achievement (based on his WISC-V FSIQ) and actual achievement on the Basic Reading composite, as well as the Spelling and Essay Composition subtests. This analysis revealed that Andy's performance on the Basic Reading composite was significantly below what would be predicted from his FSIQ ($p < .01$). This level of discrepancy was evident in 10% of Andy's peers, a relatively rare occurrence. No discrepancies were revealed between Andy's cognitive functioning and written expression skills. This analysis suggests that relative to his overall cognitive functioning, Andy demonstrates significant underachievement in the area of basic reading skills, a necessary but insufficient condition for identifying a specific learning disability. To further evaluate the factors underlying his reading difficulties (e.g., a possible learning disability), an analysis of his pattern of strengths and weaknesses (PSW) was conducted.

PSW Analysis

Andy's score on the Basic Reading composite was used as the academic weakness in the PSW analysis. His NSI on the WISC-V was identified as his cognitive weakness, as naming speed is related to basic reading skills. Andy's FRI score was identified as his cognitive strength, as his skills in this area are average and significantly higher than the mean of his index scores, and fluid reasoning is not thought to be theoretically related to basic reading skills. This analysis revealed that Andy's academic and cognitive weaknesses were significantly lower than his cognitive strength ($p < .01$ for both the Basic Reading composite and the NSI compared to the FRI). Like the discrepancy analysis, the PSW results support the diagnosis of a specific learning disorder in reading with impairment in word recognition skills.

CONCLUSIONS AND RECOMMENDATIONS

Andy is a 12-year-old male with a history of difficulties in reading and spelling. The results of the current evaluation reveal overall cognitive skills in the average range, with his verbal comprehension, naming speed, and visual–verbal associative memory abilities underdeveloped relative to his fluid reasoning, visual–spatial, working memory, and processing speed abilities. He exhibits a relative strength in fluid reasoning. Andy's reading is below average and a relative weakness for him; his written expression skills are at the low end of average; and his math problem solving skills are average. Analyses reveal a pattern of strengths and weaknesses consistent with a specific learning disorder in the area of basic reading: Andy's academic weakness (Basic Reading) and cognitive weakness (NSI) scores were significantly lower than his cognitive strength (FRI) score. These results are consistent with parent and teacher reports. Based on these findings, Andy meets criteria for special education services for a specific learning disability in the area of reading with impairment in word recognition skills.

Andy's present level of reading achievement, as well as the interventions already implemented, suggest that he would be likely to benefit from individualized instruction. Reading instruction should integrate reading and spelling to reinforce what is taught, and should incorporate single-word reading of both real words and nonwords. He may benefit most from instruction that is explicit and systematic, offering repetition and opportunities to practice and reinforce skills in a variety of contexts to develop automaticity. Specifically, Andy needs work in the areas of phoneme–grapheme relationships, sight words, and structural analysis. Given Andy's strength in fluid reasoning and math, he may enjoy opportunities to track and chart his progress over time. Decisions regarding classroom accommodations and modifications will be made in collaboration with Andy's parents and teachers.

CHAPTER 10

The Woodcock–Johnson IV Tests of Early Cognitive and Academic Development

Fredrick A. Schrank
Barbara J. Wendling

The Woodcock–Johnson IV (WJ IV) Tests of Early Cognitive and Academic Development (ECAD; Schrank, McGrew, & Mather, 2015) is a special-purpose early childhood battery of cognitive and academic skills tests that is co-normed with, and conceptually related to, the Woodcock–Johnson IV (WJ IV; Schrank, McGrew, & Mather, 2014a). The WJ IV includes the Woodcock–Johnson IV Tests of Cognitive Abilities (WJ IV COG; Schrank, McGrew, & Mather, 2014b), the Woodcock–Johnson IV Tests of Oral Language (WJ IV OL; Schrank, Mather, & McGrew, 2014b), and the Woodcock–Johnson IV Tests of Achievement (WJ IV ACH; Schrank, Mather, & McGrew, 2014a). We discuss these three batteries in Chapter 14 of this volume.

The ECAD measures emergent cognitive abilities and academic skills. It is designed primarily for use with children from 30 months through 7 years of age, although the battery is also appropriate for use with children ages 8 through 9 years who have cognitive-developmental delays or intellectual disability. In contrast, the WJ IV COG and WJ IV ACH tests are designed primarily for use with individuals of school age through adulthood, although there is some overlap in age ranges of the WJ IV batteries; for example, many of the WJ IV OL tests can also be used with young children. The ECAD stimulus materials are designed to be engaging and attractive to young children, and administration of the entire battery can be completed in less than an hour by an examiner using only one test easel and only one test record. Some of the tests are unique to the ECAD, while others are adapted and alternate forms of tests included in other parts of the WJ IV that have been widely used at the prekindergarten (PreK) through grade 1 levels.

The ECAD was developed in response to a need for a dedicated WJ IV battery of cognitive and academic skills tests to measure both the emergence and development of the different broad Cattell–Horn–Carroll (CHC) abilities at the early childhood level. CHC theory is especially helpful for determining if a child's cognitive abilities and academic skills are developing as expected: Identification of specific cognitive or academic delays at a young age can suggest a need for early intervention. The ECAD combines an individualized, age-appropriate, norm-referenced assessment with a criterion-referenced (authentic) interpretive model to target early learning needs and to suggest related instructional practices or intensive interventions.

ORGANIZATION OF THE ECAD

Figure 10.1 presents the Selective Testing Table for the ECAD. Tests 1 through 7 are the cognitive tests that make up the General Intellectual Ability—Early Development (GIA-EDev) cluster;

		General Intellectual Ability–Early Development	Early Academic Skills	Expressive Language
ECAD 1	Memory for Names	■		
ECAD 2	Sound Blending	■		
ECAD 3	Picture Vocabulary	■		■
ECAD 4	Verbal Analogies	■		
ECAD 5	Visual Closure	■		
ECAD 6	Sentence Repetition	■		■
ECAD 7	Rapid Picture Naming	■		
ECAD 8	Letter-Word Identification		■	
ECAD 9	Number Sense		■	
ECAD 10	Writing		■	

■ Tests required to create the cluster listed.

FIGURE 10.1. Selective Testing Table (tests and clusters) for the Woodcock–Johnson IV Tests of Early Cognitive and Academic Development (ECAD). From *Woodcock–Johnson IV*™ (*WJ IV*™). Copyright © The Riverside Publishing Company. All rights reserved. Used by permission of the publisher.

Tests 8 through 10 are the early academic tests that make up the Early Academic Skills cluster. In addition, Test 3: Picture Vocabulary and Test 6: Sentence Repetition constitute the Expressive Language cluster.

Each of the seven cognitive tests represents one of seven broad CHC abilities: long-term storage and retrieval (Glr), auditory processing (Ga), comprehension–knowledge (Gc), fluid reasoning (Gf), visual processing (Gv), short-term working memory (Gwm), and cognitive processing speed (Gs). The broad CHC ability of reading–writing (Grw) is represented by one test of reading and one test of writing. The broad CHC ability of quantitative knowledge (Gq) is represented by one early math knowledge test.

HOW TO ADMINISTER THE ECAD TESTS

Administration and scoring of the ECAD tests require knowledge of the exact administration and scoring procedures, as well as an understanding of the importance of adhering to standardized procedures. The ECAD comprehensive manual (Wendling, Mather, LaForte, McGrew, & Schrank, 2015) provides extensive information on administration and scoring. Additionally, the test book contains an abbreviated set of instructions for administering and scoring items on each test; these brief instructions are found on the introductory page of the test (the first printed page after the tabbed page). Additional instructions may appear on the test pages, such as in boxes with special instructions.

For most purposes, examiners should begin testing with Test 1: Memory for Names. The format of this test provides the opportunity for a child to become engaged with attractive, storybook-like art, and the unusual, game-like names provide a verbal focus of attention. This test also provides a useful segue into the testing phase of an evaluation, as it requires only a pointing response from the child. Although tests can be administered in any order, most examiners administer the additional tests in sequential order, and discontinue testing at a point that provides the desired or required level of information. The cognitive tests (Tests 1–7) are administered to obtain an evaluation of any intraindividual differences among emergent cognitive abilities. An identified strength or weakness among the seven cognitive tests can provide insights into the relative development of different cognitive abilities.

Tests 8 through 10 are administered to determine a child's levels of early academic skills in reading, mathematics, and writing. An intra-achievement analysis can yield information about whether reading, math, or writing skills are better developed than the other academic areas. Many examiners routinely administer all 10 tests because of the depth of interpretive information obtained, including an overall comparison of early intellectual development to early academic skill acquisition.

Examiners will need to learn how to establish a basal and a ceiling level for several tests. Basal and ceiling criteria are included in the test book for each test requiring them. If an examinee fails to meet the basal criterion for any test, the examiner is directed to test backward until the examinee has met the basal criterion or until Item 1 has been administered. When stimuli are visible to the examinee, the examiner is required to test by complete pages. The complete page rule may impact the process of establishing a basal or a ceiling. For example, if the basal is not established on the first page administered, the examiner tests backward full page by full page until the basal is established or item 1 is administered. Conversely, if the ceiling appears to be reached on a page, the examiner must complete that page. If, in the process of completing the page, the examinee responds correctly to an item, testing must continue until the ceiling rule is met and the page is completed. Note that the basal rule is based on the lowest-numbered correct responses specified, and that the ceiling is based on the highest-numbered incorrect responses specified. For some tests, examinees begin with item 1 and test until they reach their ceiling level or time limit; these tests do not require a basal level. Test 1: Memory for Names has items arranged within sets; for this test, specific cutoff criteria are outlined in the test record, test book, and comprehensive manual.

Individual test items are scored during test administration. All tests use a 1 (correct) or 0 (incorrect) scoring rule for determining raw scores. Examiners will need to learn how to score items and calculate the raw score for each test. Generally, raw scores are determined by adding the number of correctly completed items to the number of unadministered test items below the basal. Scores for sample or practice items should not be included in calculating raw scores. The correct and incorrect keys in the test books are intended to be guides to demonstrate how certain responses are scored; not all possible or acceptable responses are included in the keys. Completion of the scoring procedure requires using the Woodcock–Johnson Online Scoring and Reporting System (Schrank & Dailey, 2014). Additionally, examiners may purchase and use the WJ IV Interpretation and Instructional Interventions Program (WIIIP; Schrank & Wendling, 2015b), an online option for generating narrative interpretive text and related interventions. The WIIIP simplifies the process of linking assessment to instruction by using ECAD test results to generate evidence-based interventions. These scoring and interpretive programs provide a number of different interpretive report options, profiles, and a full array of interpretive scores—including age- and grade-equivalent scores, relative proficiency indexes, and peer comparison scores (e.g., standard scores and percentile ranks).

Administration Time

As a general rule, experienced examiners require about 35 minutes to administer the seven cognitive tests and an additional 15 minutes to administer the three academic skills tests. Although there can be wide variation in the amount of time it takes to administer standardized tests to a young child, typically the entire ECAD can be administered in less than 1 hour, including the time needed for setting up the testing materials, establishing rapport, completing the identifying information on the test record, and calculating raw scores.

Testing Materials

Testing materials required for administration of the ECAD include the test book, test record, and response worksheet; the audio CD and appropriate audio equipment; pencils; and a stopwatch.

Summary of Key Administration and Scoring Points

Most tests use suggested starting points, basal and ceiling rules, and item response scores of 1 or 0. Table 10.1 summarizes the key administration and scoring points for each test.

SPECIAL ADMINISTRATION AND SCORING CONSIDERATIONS

Although the ECAD comprehensive manual and test book provide detailed rules for test administration, this section presents important reminders about tests that have special administration or scoring rules.

Test 1: Memory for Names

In Test 1: Memory for Names, when a child makes an error, the examiner must score the item 0 and follow the error correction procedure outlined in the test book. The final number correct is based on the number of correct responses the child obtained on the items administered before the cutoff criterion was met. At each potential cutoff point, the examiner tallies the number of cumulative correct responses to determine whether to continue or discontinue testing. In the score entry section of the test record, the examiner enters the total number correct and a letter corresponding to the set of items administered. To obtain estimated age and grade equivalents, the examiner locates the number of points in the appropriate column corresponding to the set of items administered.

Audio Tests

Two tests, Test 2: Sound Blending and Test 6: Sentence Repetition, require the use of an audio

TABLE 10.1. Summary of ECAD Test Administration and Scoring Rules

Test name	Item scoring rule	Sample items?	Basal/ceiling rules?[a]	Administration notes	Additional materials required for administration
Test 1: Memory for Names	1, 0	No	All begin with Introduction 1; ceiling determined by cutoffs	Give immediate corrective feedback when child makes an error. Scoring is based on items administered.	None
Test 2: Sound Blending	1, 0	Yes	All begin with item 1; ceiling is 6 highest incorrect		Audio
Test 3: Picture Vocabulary	1, 0	Yes	Yes; 6/6	Suggested starting points are available.	
Test 4: Verbal Analogies	1, 0	Yes	Yes; 6/6	Suggested starting points are available.	None
Test 5: Visual Closure	1, 0	Yes	All begin with item 1; ceiling is 6 highest incorrect		None
Test 6: Sentence Repetition	1, 0	Yes	Yes; 5/5	Suggested starting points are available.	Audio
Test 7: Rapid Picture Naming	1, 0	Yes	No; 2-minute time limit	All begin with sample items, then proceed to Item 1.	Stopwatch: Timed test
Test 8: Letter–Word Identification	1, 0	No	Yes; 5/5	Suggested starting points are available; word must be pronounced smoothly to receive credit.	None
Test 9: Number Sense	1, 0	No	Yes; 5/5	Suggested starting points are available.	None
Test 10: Writing	1, 0	No	Yes; 6/6	Suggested starting points are available.	Response worksheet

[a] May be modified by complete-page rule.

recording. The audio recording is used to ensure standardized presentation of these tasks. The audio equipment used must have a good speaker, be in good working order, and produce a faithful, clear reproduction of the test items. Using headphones is recommended, as they were used in the standardization. An examiner can wear a monaural earphone or wear only one headphone over one ear to monitor the audio recording while an examinee is also listening through his or her headphones. The examiner should not repeat or replay any item unless the directions permit it (e.g., on sample items). In some cases, a young child may need to be administered this test via live voice. If presenting the items orally, the examiner should say the words or sentences in an even voice, exactly as presented on the audio recording.

Timed Test

Test 7: Rapid Picture Naming has a 2-minute time limit. Administering this test requires using a stopwatch or a watch with a second hand. Because this is a test of cognitive processing speed, if a child uses a synonym or a word that is similar in meaning for the pictured item, the item should be scored as correct.

Response Worksheet

Administration of Test 10: Writing requires the examiner to use the response worksheet. Directions for using the response worksheet are provided in the test book.

Test Session Observations Checklist

To help document general testing observations, each test record includes a brief, seven-category behavior rating scale on the first page. The categories include levels of conversational proficiency, cooperation, level of activity, attention and concentration, self-confidence, care in responding, and response to difficult tasks. Each category has a range of possible responses, in order to help identify whether the behavior is typical or atypical for the age of the child being assessed. This checklist should be completed at the end of the testing session.

BASIC TECHNICAL INFORMATION

Following is a summary of reliability and validity information for the ECAD. For more complete information, readers should consult the ECAD's comprehensive manual (Wendling et al., 2015).

Median reliability coefficients for the ECAD tests are reported in Table 10.2. With the exception of the one timed test, coefficients of stability are reported as median internal-consistency (r_{11}) and median standard error of measurement (*SEM*) values. For the timed test, Test 7: Rapid Picture Naming, reliabilities were calculated using the split-half procedure. The median reliability for 7 of the 10 tests met or exceeded .80, with the other 3 exceeding .90. The 3 tests with median reliabilities below .80 demonstrated higher reliabilities at specific ages. For example, Test 3: Picture Vocabulary's median reliability is .74, but it has reliabilities of .94 at ages 2 through 4.

TABLE 10.2. ECAD Median Test Reliability Statistics

Test	Median r_{11}	Median *SEM* (SS)
Test 1: Memory for Names	.97	2.60
Test 2: Sound Blending	.84	4.74
Test 3: Picture Vocabulary	.74	7.79
Test 4: Verbal Analogies	.80	6.18
Test 5: Visual Closure	.77	7.19
Test 6: Sentence Repetition	.86	5.61
Test 7: Rapid Picture Naming	.86	5.81
Test 8: Letter–Word Identification	.96	2.60
Test 9: Number Sense	.79	6.87
Test 10: Writing	.91	4.50

Note. r_{11}, internal-consistency reliability. Split-half procedure used on Test 7.

Table 10.3 contains the median cluster reliability coefficients (r_{cc}) and median standard errors of measurement for obtained cluster standard scores, or *SEM* (SS), as calculated via Mosier's (1943) formula. Of the three ECAD clusters, the GIA-EDev cluster and the Early Academic Skills cluster exceed the commonly referenced professional standard of .90 for decision-making purposes. The exception is the Expressive Language cluster, with a median reliability of .89. It is of interest to note that the reliability of this cluster exceeds .90 at ages 2 through 4. Although the test reliabilities support use and interpretation of the test-level scores as single indicators of an ability, the ECAD clusters are preferred for most decision-making purposes because of their higher reliabilities.

Table 10.4 contains a summary of correlations for the ECAD clusters with other measures of cognitive abilities, including the Wechsler Preschool and Primary Scale of Intelligence—Third Edition (WPPSI-III; Wechsler, 2002), the Wechsler Preschool and Primary Scale of Intelligence—Fourth Edition (WPPSI-IV; Wechsler, 2012), and the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007). The correlations in Table 10.4 provide validity evidence for the ECAD GIA-EDev cluster as a measure of general intelligence and as an indicator of verbal abilities. There is also evidence, based on the high correlation (.91) with the DAS-II School Readiness cluster, that the ECAD

TABLE 10.3. ECAD Median Cluster Reliability Statistics

Cluster	Median r_{cc}	Median *SEM* (SS)
General Intellectual Ability—Early Development (GIA-EDev)	.95	3.35
Early Academic Skills	.96	2.60
Expressive Language	.89	4.97

TABLE 10.4. Correlations for ECAD Clusters and Other Measures of Cognitive Abilities

Other measure	GIA-EDev	Expressive Language	Early Academic Skills
Wechsler Preschool and Primary Scale of Intelligence—Third Edition (WPPSI-III)			
Full Scale IQ	.75	.72	—
Verbal IQ	.82	.81	—
General Learning Quotient	.80	.81	—
Wechsler Preschool and Primary Scale of Intelligence—Fourth Edition (WPPSI-IV)			
Full Scale IQ	.78	.62	—
Verbal Comprehension Index	.77	.72	—
Visual Spatial Index	.77	.51	—
Differential Ability Scales—Second Edition (DAS-II)			
General Conceptual Ability	.87	.71	.90
Verbal Ability	.79	.73	.81
Nonverbal Reasoning Ability	.70	.56	.74
Spatial Ability	.69	.43	.79
School Readiness	.82	.71	.91
Working Memory	.79	.72	.84
Processing Speed	.68	.58	.66

Early Academic Skills cluster is a strong indicator of general school readiness.

Table 10.5 contains a summary of correlations for selected ECAD tests and clusters with other measures of oral language, including the Clinical Evaluation of Language Fundamentals—Fourth Edition (CELF-4; Semel, Wiig, & Secord, 2003), the Peabody Picture Vocabulary Test, Fourth Edition (PPVT-4; Dunn & Dunn, 2007), the Comprehensive Assessment of Spoken Language (CASL; Carrow-Woolfolk, 1999), the Oral and Written Language Scales: Listening/Comprehension/Oral Expression (OWLS; Carrow-Woolfolk, 1995), and the WJ IV OL (Schrank, Mather, & McGrew, 2014b). The ECAD Expressive Language cluster shows moderate to strong correlations with all the CELF-4 composites and the total PPVT-4 score, and moderate correlations with the CASL Core Composite and the OWLS Oral composite. Correlations with the WJ IV OL clusters may be high because the tests are parallel forms. Overall, these results support the validity of the ECAD Expressive Language cluster and several of the tests as valid measures of general oral language abilities.

Table 10.6 contains a summary of correlations for selected ECAD tests and clusters with measures from the WJ IV ACH (Schrank, Mather, & McGrew, 2014a) for ages 6 through 8. Other age groups are reported in the ECAD comprehensive manual. Again, some of the correlations may be high because some tests are parallel forms. For example, Letter–Word Identification is in both tests and is in the ECAD's Early Academic Skills cluster, as well as the WJ IV ACH's Brief Achievement and Reading clusters. Although the item content is not identical, the tasks are essentially the same. The ECAD tests shown in Table 10.6 correlate more strongly with their respective domain-specific WJ IV ACH clusters. For example, Test 9: Number Sense correlates more highly with Mathematics than with any of the other WJ IV ACH clusters reported. In addition, Number Sense does not share any content with the WJ IV ACH Mathematics cluster. These correlations support the use of the ECAD tests and Early Academic Skills cluster as valid measures of early achievement in reading, math, and writing.

A summary of correlations between ECAD and other early childhood developmental measures are reported in Table 10.7. These measures include the Battelle Developmental Inventory, Second Edition (BDI-2; Newborg, 2005) and the Riverside Early Assessments of Learning IDEA Observational Version (REAL IDEA-OV; Bracken, 2013). The relationship between the ECAD cognitive tests (Tests 1–7) and two clusters (GIA-EDev and Expressive Language) and the BDI-2 Communication and Cognitive domains are reported. Not surprisingly, the GIA-EDev cluster and the BDI-2

TABLE 10.5. Correlations for Select ECAD Measures and Other Measures of Oral Language Abilities

Other measure	Expressive Language cluster	Test 2: Sound Blending	Test 3: Picture Vocabulary	Test 6: Sentence Repetition
Clinical Evaluation of Language Fundamentals—Fourth Edition (CELF-4)				
Core Language	.82	.58	.70	.74
Receptive Language	.74	.40	.70	.61
Expressive Language	.81	.54	.69	.73
Language Content	.76	.47	.78	.55
Language Structure	.81	.53	.71	.71
Working Memory	.68	.50	.54	.64
Peabody Picture Vocabulary Test, Fourth Edition (PPVT-4)	.79	.39	.75	.65
Comprehensive Assessment of Spoken Language (CASL): Core Composite	.52	—	.58	.53
Oral and Written Language Scales: Listening/Comprehension/Oral Expression (OWLS)				
Oral Composite	.50	—	.57	.52
Woodcock–Johnson Tests of Oral Language (WJ IV OL)				
Broad Oral Language	.79	.41	.85	.55
Listening Comprehension	.70	.41	.64	.55
Phonetic Coding	.36	.80	.29	.32

Cognitive domain had the highest correlation (.79), but there was also a strong correlation between GIA-EDev and the BDI-2 Communication domain (.75). This finding provides evidence to support the use of the ECAD GIA-EDev cluster as a valid measure of cognitive ability in developmental assessments with young children. Although the REAL IDEA-OV is an observational assessment scored as examiner ratings, the correlations with the ECAD were moderate to strong. In particular, the highest correlations were between GIA-EDev and the Cognitive domain (.80), the Communication domain (.82), and the Academic domain (.83). The ECAD's Expressive Language cluster had the strongest correlations with those same three domains: Cognitive (.78), Communication (.80), and Academic (.80). The pattern of correlations in Table 10.7 suggests that the ECAD is a valid measure of early cognitive abilities, expressive language skills, and preacademic skills.

TABLE 10.6. Correlations for Select ECAD Measures and WJ IV ACH Measures, Ages 6–8

	ECAD clusters and tests			
WJ IV ACH clusters	Early Academic Skills cluster	Test 8: Letter–Word Identification	Test 9: Number Sense	Test 10: Writing
Brief Achievement	.98	.94	.69	.93
Reading	.93	.96	.60	.83
Written Language	.91	.87	.60	.89
Mathematics	.81	.70	.79	.71
Phoneme–Grapheme Knowledge	.82	.81	.57	.75
Academic Knowledge	.59	.51	.61	.50

The information presented in Tables 10.2 through 10.7 provides a summary of the evidence supporting the ECAD's use as a measure of cognitive abilities, expressive language, and early academic skills during early childhood. The ECAD is a reliable and valid measure for evaluating children's abilities (Carney, 2017; Wright, 2017) .

INTERPRETATION

The ECAD can be interpreted at the test and cluster levels, depending on the purposes of an evaluation. The broad and narrow abilities described in contemporary CHC theory provide the basic interpretive architecture and the validity of the tests and clusters. Interpretation is based on extensive psychometric data and analyses provided by McGrew, LaForte and Schrank (2014), as well as related research outside the WJ IV literature that provides support for our interpretation of the emergent cognitive processes and developmental skills required for performance on each test. In addition to CHC theory, an analysis of task demands helps provide links to interventions or accommodations that may be helpful in many situations for developing a targeted educational plan, based in part on the trajectory of a child's early cognitive and academic development.

The ECAD tests and clusters are described in this section. Table 10.8 identifies the broad and narrow cognitive abilities measured by each test in the ECAD; it also includes brief test descriptions. The ECAD tests are organized into clusters for interpretive purposes; these clusters are outlined in Table 10.9. The ECAD's methodology for determining developmental levels is described. The remainder of the chapter describes the variation and discrepancy procedures that can be used to compare scores, determine a developmental profile of abilities, and assist in diagnostic decision making.

General Intellectual Ability—Early Development

The GIA-EDev score is a special-purpose measure of overall cognitive development that is based on seven tests, each representing a broad CHC factor. When combined and differentially weighted, the overall score measures psychometric *g* or general intellectual ability. In addition, each of the seven tests measures the emergence and developmental progression of a specific broad cognitive ability. Tests were selected for inclusion in the GIA-EDev score to best measure each of the seven broad CHC factors in the most developmentally appropriate format. The seven tests represent the following CHC constructs: long-term storage and

TABLE 10.8. ECAD Tests, CHC Broad and Narrow Abilities Measured, and Brief Test Descriptions

Test name	Primary broad CHC ability *Narrow ability*	Brief test description
Test 1: Memory for Names	Long-term storage and retrieval (Glr) *Associative memory* (MA)	Measures auditory–visual paired associate encoding in the learning phase, visual identification in the response phase.
Test 2: Sound Blending	Auditory processing (Ga) *Phonetic coding* (PC)	Assesses the ability to synthesize speech sounds into a whole word.
Test 3: Picture Vocabulary	Comprehension–knowledge (Gc) *Language development* (LD)	Evaluates general vocabulary knowledge through object recognition.
Test 4: Verbal Analogies	Fluid reasoning (Gf) *General sequential reasoning* (RG) *Induction* (I) Comprehension–knowledge (Gc) *Language development* (LD) *General (verbal) information* (KO)	Measures the ability to reason by using relationships between words.
Test 5: Visual Closure	Visual processing (Gv) *Closure speed* (CZ)	Assesses the ability to identify an object from an incomplete or masked visual representation.
Test 6: Sentence Repetition	Short-term working memory (Gwm) *Memory span* (MS) Comprehension–knowledge (Gc) *Listening ability* (LS)	Evaluates ability to listen to and repeat sentences presented orally.
Test 7: Rapid Picture Naming	Cognitive processing speed (Gs) *Naming facility* (NA) *Speed of lexical access* (LA)	Measures the speed/fluency of retrieval and oral production of recognized objects.
Test 8: Letter–Word Identification	Reading–writing ability (Grw) *Reading decoding* (RD)	Assesses skill in identifying printed letters and words.
Test 9: Number Sense	Quantitative knowledge (Gq) *Mathematics achievement* (A3) Fluid reasoning (Gf) *Quantitative reasoning* (RQ)	Evaluates understanding of numbers, number vocabulary, concepts, and relationships required to compare, judge, estimate size, quantity, position, or volume.
Test 10: Writing	Reading–writing ability (Grw) *Spelling ability* (SG)	Measures prewriting skills and details of letter and word forms.

TABLE 10.9. ECAD Clusters and Brief Cluster Descriptions

Cluster	Brief cluster description
General Intellectual Ability—Early Development (GIA-EDev)	Measures psychometric *g* as distilled from a broad spectrum of emergent cognitive abilities and functions, including auditory–visual paired associate encoding; phonological coding; knowledge of object names; analogic verbal reasoning; ability to identify and name an object when presented with only limited visual cues; listening and oral expression abilities; speed and fluency of retrieval and oral production of object names.
Expressive Language	Assesses single-word and sentence-level oral language skills.
Early Academic Skills	Evaluates emergent reading, mathematics, and writing skills.

retrieval (Glr), auditory processing (Ga), comprehension–knowledge (Gc), fluid reasoning (Gf), visual processing (Gv), short-term working memory (Gwm), and cognitive processing speed (Gs).

In the ECAD, CHC theory provides a foundation for interpretation of test results and is especially useful for determining whether different cognitive abilities and academic skills are developing as expected. Related research (much of it from outside the WJ IV literature) provides support to interpretation of the CHC constructs that the GIA-EDev cluster measures. Finally, all tests selected for inclusion in the ECAD have relevance for educational programming and intensive intervention. Table 10.10 includes a summary of suggested educational enrichment goals or individually targeted interventions related to developmental delays identified on the ECAD tests. As noted earlier, the GIA-EDev cluster includes the following: Test 1: Memory for Names; Test 2: Sound Blending; Test 3: Picture Vocabulary; Test 4: Verbal Analogies; Test 5: Visual Closure; Test 6: Sentence Repetition; and Test 7: Rapid Picture Naming.

TABLE 10.10. Examples of Educational Enrichment Goals or Targeted Interventions Related to Limitations in Performance on ECAD Tests

Test	Brief intervention, strategy, or accommodation
Test 1: Memory for Names	Active learning environments; picture matching games with oral elaboration; verbal associations; overlearning; mnemonics.
Test 2: Sound Blending	Language-rich environments; increased exposure to words and word sounds; early exposure to sounds, music, and rhythms; reading aloud to a child; opportunities to explore and manipulate word sounds; nursery rhymes and songs with rhyming words; explicit, systematic instruction in phonics; practice with blending sounds into words.
Test 3: Picture Vocabulary	Language- and experience-rich environments; vocabulary-intensive curriculum; explicit teaching of key vocabulary words; frequent exposure and practice with words; reading aloud to a child; text talks; picture books.
Test 4: Verbal Analogies	Vocabulary-rich learning activities; planned activities that promote thinking; use of words that describe relationships; similarities and differences; reading aloud to a child; dialogic and interactive book-reading techniques; inclusion in adult conversations.
Test 5: Visual Closure	Visual discrimination games; use of words describing the visual–spatial characteristics of objects; building blocks, log and block building sets, puzzles; dot-to-dot drawings; pegboards; visual matching games.
Test 6: Sentence Repetition	Songs, games, nursery rhymes, and musical instruments to develp auditory memory span; modeling of correct language use; use of increasingly complex syntactic forms in everyday conversations; oral rehearsal of information to be remembered.
Test 7: Rapid Picture Naming	Picture-naming activities; repetitive practice; serial naming; repeated reading.
Test 8: Letter–Word Identification	Reading to a young child; oral production of sound representations of words; matching games with letter-like symbols; direct and fully guided instruction; explicit, systematic, synthetic phonics programs; integrated word phonology, orthography, and morphology approaches; increased exposure to printed words; word recognition strategies (word walls, flow lists); systematic literacy programs.
Test 9: Number Sense	Number awareness; early number concepts; number vocabulary; manipulatives and board games; use of number words; counting skills; adding and subtracting with number line; direct instruction; guided practice.
Test 10: Writing	Prewriting play activities; tracing letters and saying letter names; integrated word phonology, orthography, and morphology programs of instruction; frequent writing practice; teaching spelling of common irregular words; saying letter sounds when spelling; explicit instruction in six syllable types.

Test 1: Memory for Names

In CHC theory, Memory for Names measures the narrow ability of associative memory, an aspect of long-term storage and retrieval (Glr). This test measures a developmentally important way in which semantic memories (Tulving, 1972, 1985) are created: the association of words with pictured objects. The controlled memory consolidation format utilized in task performance represents an important link between working memory and long-term memory. This link is critically important for education; it is the gateway between information to be learned and learned information (Schrank, Decker, & Garruto, 2016).

Memory for Names measures the ability to associate unfamiliar auditory and visual stimuli, encode the association as a semantic memory, and subsequently reidentify the paired visual association upon presentation of a verbal cue. Colorful, storybook-like art enhances the attractiveness of this learning task for young children. The stimulus presentation phase of this task employs a directed, spotlight-attention paired-associate encoding procedure that prepares the child to encode a stimulus (Brefczynski & DeYoe, 1999; Gazzaniga, Irvy, & Mangun, 1998; Klingberg, 2009; Sengpiel & Hubener, 1999). The response phase of this task measures whether consolidation of semantic memory has occurred in the learning phase. The test's error correction procedure utilizes a controlled-learning format that corrects any faulty hypothesis and provides the opportunity for additional spotlight-attention encoding, from which the examiner may glean qualitative information about the level of repetition required for paired-associate consolidation of semantic (meaning-based) representations into long-term memory.

The controlled-learning procedure employed in Memory for Names provides a cue to the intervention known as *active learning* (Marzano, Pickering, & Pollock, 2001). Active learning is especially important in early education because it facilitates the creation of meaning-based codes that can be used to relate new information or task requirements to previously acquired knowledge. Varying the learning tasks, incorporating emotions and novelty, and fostering creativity are ways to promote active learning in early education. See Table 10.10.

Test 2: Sound Blending

Sound Blending measures the ability to blend sounds into words, an important prerequisite to reading competence (Schrank & Wendling, 2015a). Blending sounds to create words is a key aspect of phonological coding, a narrow auditory processing (Ga) ability. A young child may have low scores on this test for several reasons, such as poor phonological awareness, English as a second language, articulation difficulties, weak memory, or inadequate instruction. However, with appropriate instruction, blending skills can be developed.

For preschool children with limitations or delays in sound-blending ability, an environment rich in words and the sounds that make up words is particularly important for language development. Increased exposure to words may help develop a greater sensitivity to the sound patterns within words (Biemiller & Boote, 2006; Carlisle & Fleming, 2003; Dickinson & Tabors, 2001; McDowell, Lonigan, & Goldstein, 2007; Missall, Reschly, & Betts, 2007; Poe, Burchinal, & Roberts, 2004; Roth, Speece, & Cooper, 2002). For children in the early primary grades, interventions include explicit, systematic instruction in phonics (Ehri, 1998; Jenkins & O'Connor, 2002; National Reading Panel, 2000; Snow, Burns, & Griffin, 1998; Stanovich, 1994; Torgesen, 1997; Torgesen et al., 1999), including practice blending sounds into words (Adams, 1990). See Table 10.10.

Test 3: Picture Vocabulary

Picture Vocabulary measures vocabulary, verbal ability, and background knowledge, all aspects of the narrow ability of language development (LD) and the broad ability of comprehension–knowledge (Gc). Picture Vocabulary is primarily a single-word expressive vocabulary task that requires the cognitive processes of object recognition, lexical access, and lexical retrieval. A child may have difficulty with this test due to limited knowledge of word meanings, word retrieval difficulties, English as a second language, limited experiences and opportunities, or cultural differences (Mather & Wendling, 2015). Observing performance and analyzing errors may help determine if poor performance is a result of retrieval difficulties or limited vocabulary. When an error is related to the correct response, it may indicate a retrieval or word-finding problem. Although scored as incorrect, this type of error indicates some level of object knowledge. For example, an individual may not be able to provide the exact name of an object, but can describe an appropriate function or attribute. An error that is not directly associated with the correct response may indicate a weakness in vocabulary knowledge.

Early interventions for the development of vocabulary knowledge include creating a language- and experience-rich environment (Gunn, Simmons, & Kame'enui, 1995; Hart & Risley, 2003), explicit teaching of key vocabulary words (Beck & McKeown, 2001; Graves, Juel, & Graves, 2004; Nagy, 2005; National Reading Panel, 2000), frequent exposure and practice with words (Gunn et al., 1995; Hart & Risley, 2003), reading aloud to the child (Adams, 1990), and text talks (structured dialogue about a text that has been read) (Beck & McKeown, 2001). See Table 10.10.

Test 4: Verbal Analogies

Verbal Analogies measures the ability to reason by using relationships between words, an aspect of fluid reasoning (Gf). As an early development task, this test taps the emergence of reasoning ability as the child applies his or her knowledge of the relationship between the words in the first part of each item to induce and say a fourth word that completes the analogy (an aspect of general sequential reasoning [RG]). Each item requires induction (I) of the structure for the first part of each analogy and then mapping (or projecting) that structure onto the second part (Gentner & Markham, 1997). Forming verbal analogies involves determining general principles from specific examples and establishing a connection between previously unrelated pieces of information (Bunge, Mackey, & Whitaker, 2009). As a young child matures and cognition progresses, language development (LD) increases, and comprehension–knowledge (Gc; particularly general verbal knowledge [KO]) facilitates verbal analogy solutions. In reciprocal fashion, increased word, object, and concept knowledge facilitates increased analogical reasoning ability (Goswami, 1989).

Analogical thought is an important cognitive process through which learning occurs (Goswami, 1989). Children as young as 36 months are able to utilize verbal analogical reasoning if they are familiar with the words and objects included in the analogy (Goswami, 1989). Analogies are often used to teach and learn new words; concepts are developed by association (analogous relationships) with prior knowledge (Gentner, 1983). Vocabulary-rich learning activities can increase a child's level of word knowledge (Beck & McKeown, 2001; Graves et al., 2004; National Reading Panel, 2000), which is required for reasoning with words. In the course of everyday conversations with a child, parents, teachers, and caregivers should be encouraged to increase their use of words that describe abstract relationships, such as similarities and differences (Engle et al., 2011; Goldin-Meadow et al., 2014; Marulis & Neuman, 2010; Roberts & Kaiser, 2011). Parents or caregivers should be encouraged to include the child in adult conversations, using high-level vocabulary words (Nisbett, 2009).

Test 5: Visual Closure

Visual Closure measures the ability to identify an object from an incomplete or masked visual representation. Recognition occurs when the incomplete picture matches a representation in semantic memory. In CHC theory, this is called closure ability (CZ), a narrow aspect of visual processing (Gv)—specifically, the ability to identify an object by name when provided only with a limited portion of a pen-and-ink drawing of the object. The attention to detail that is required to identify objects from limited, but key, features is an important developmental task that precedes the ability to decode and assign meaning to printed text.

Young children who have difficulty with the Visual Closure test may benefit from interventions that are designed to develop the ability to discriminate visual features and/or match visual information with object names (Greenleaf & Wells-Papanek, 2005). Parents, caregivers, and teachers of a young child with limitations in closure ability should be encouraged to increase use of words that describe the visual–spatial features of objects as part of everyday conversations with the child, and to spend more time with the child doing hands-on activities and playing games that facilitate conversations about visual–spatial features of objects. Building blocks, log and block building sets, and puzzles are useful for this purpose (Engle et al., 2011; Goldin-Meadow et al., 2014; Marulis & Neuman, 2010; Roberts & Kaiser, 2011).

Test 6: Sentence Repetition

Sentence Repetition measures auditory memory span (MS), a narrow ability of short-term working memory (Gwm). An expressive language task that requires listening ability (LS), this test requires the ability to encode and maintain verbal information in primary memory and then accurately reproduce it in sequence. Test performance is aided by semantic knowledge (word meaning), an aspect of comprehension–knowledge (Gc). A child may obtain low scores on this test for several reasons, such as limited attention, poor memory, or limited oral language (Mather & Wendling, 2015). Evaluators should encourage teachers, parents, and caregivers to model correct language use, monitor the child's understanding of sentence structure, and use increasingly complex syntactic forms in everyday conversations with the child (Engle et al., 2011; Goldin-Meadow et al., 2014; Marulis & Neuman, 2010; Roberts & Kaiser, 2011).

Test 7: Rapid Picture Naming

Rapid Picture Naming measures the speed or fluency of recognition, retrieval, and oral production of names of pictured objects (naming facility; NA). In CHC theory, this test is primarily a measure of cognitive processing speed (Gs) at the preschool level (McGrew et al., 2014), but speed of lexical access (LA) or retrieval ability (Gr) in the school years.

Evaluators should compare performance on Rapid Picture Naming to performance on Test 3: Picture Vocabulary. If limited proficiency on this test is a function of lack of knowledge of object names (i.e., if a child also does poorly on Picture Vocabulary), then a foundational and primary instructional goal would be to increase use of object names in conversations with the child (Engle et al., 2011; Goldin-Meadow et al., 2014; Marulis & Neuman, 2010; Roberts & Kaiser, 2011). Pictures can be used to help stimulate production and fluency with names of objects (Nickels & Best, 1996). The most widely cited intervention for limited proficiency in speeded object naming is serial naming training, or game-like activities that encourage naming speed (Bowers, Golden, Kennedy, & Young, 1994; Bowers & Wolf, 1993; Conrad & Levy, 2007; Hayward, Das, & Janzen, 2007; Kirby, Georgiou, Martinussen, & Parrila, 2010; Logan, Schatschneider, & Wagner, 2009; Nelson, Benner, & Gonzalez, 2005; Nelson, Stage, Epstein, & Pierce, 2005; Sternberg & Wagner, 1982).

Early Academic Skills

The Early Academic Skills cluster is an aggregate measure of emergent or developing reading, math, and writing skills. The Early Academic Skills cluster can also be useful as a screening measure for any delay in the development of early academic skills. This cluster includes Test 8: Letter–Word Identification, Test 9: Number Sense; and Test 10: Writing.

Test 8: Letter–Word Identification

Letter–Word Identification measures reading readiness skills and the development of reading decoding ability (RD), a narrow aspect of reading–writing ability (Grw) in CHC theory. This test requires a child to identify or read isolated letters and words orally. The child does not need to know the meaning of the words. In Letter–Word Identification, recognized letters and words are accessed from the child's mental lexicon (i.e., his or her store of word knowledge) and recoded phonologically as the sounds the letters or letter combinations make.

Although there are many intervention approaches for limited reading readiness or reading ability, delays in development of letter and word identification skills can be addressed through a highly structured and intensive program of direct and fully guided instruction (Chambers, Cheung, Slavin, Smith, & Laurenzano, 2010; Englemann, 1968; Miller & Dyer, 1975; Salaway, 2008), including explicit, systematic, synthetic phonics programs (Jenkins & O'Connor, 2002; National Reading Panel, 2000; Stanovich, 1994; Torgesen, 1997). Integrated word phonology, orthography, and morphology approaches are frequently recommended (Carlisle & Stone, 2005; Moats, 2005; Venezky, 1970, 1999).

Test 9: Number Sense

Number Sense measures a child's understanding of numbers and their relationships to other numbers, as well as the vocabulary and concepts necessary to compare, judge, and estimate size, quantity, position, or volume. This test measures a critical developmental familiarity with numbers and how to think with numbers; it employs a broad sampling of number development skills, such as number recognition, counting, sequencing, and understanding of magnitude and quantity estimation. In CHC theory, these skills are part of the broad ability of quantitative knowledge (Gq) and the narrow ability of mathematics achievement (A3). The test also taps fluid reasoning (Gf), specifically quantitative reasoning (RQ).

Young children who perform poorly on Number Sense will benefit from well-designed activities to help develop an awareness of numbers, knowledge of the meaning of numbers, early number concepts, and related vocabulary (Baroody, Eiland, & Thompson, 2009; Chambers et al., 2010; Gelman & Gallistel, 1978; Gersten, Jordan, & Flojo, 2005; Griffin, 2002, 2004; Malofeeva, Day, Saco, Young, & Ciancio, 2004; National Research Council, 2009). Number sense skills can be developed with manipulatives and board games that require counting and which help develop a sense of numeric quantity, patterns, core mathematical concepts, and the relationships among numbers (Gersten et al., 2008; National Council of Teachers of Mathematics, 2000; Ramani & Siegler, 2005). Basic counting skills should be explicitly taught (Gersten et al., 2008). High-quality instruction, with guided practice, helps develop the ability to solve basic mathematics facts and executive mathematics procedures quickly and efficiently (Gersten et al., 2008).

Test 10: Writing

The Writing test measures prewriting skills and knowledge of the details of letter and word forms, and focuses on early pencil-and-paper writing skills. In CHC theory, this test assesses part of the broad reading–writing ability (Grw), with later items requiring spelling ability (SG). When a child progresses to writing words, the task involves mapping phonology onto orthographic representations of words. A careful analysis of errors can often result in specific instructional recommendations.

Remediation of difficulties in early writing skill development may require use of multisensory techniques, such as repeatedly tracing and saying letter names (Carreker, 2005). Multisensory techniques involving repeatedly tracing and saying the letters and words can also be used to build word-spelling skills, and may be especially helpful when irregular words are introduced (Fernald, 1943). Integrated word phonology, orthography, and morphology programs of instruction are often effective when the child is ready to learn to spell words (Carlisle & Stone, 2005; Moats, 2005; Templeton & Bear, 1992; Venezky, 1970, 1999).

Expressive Language

The Expressive Language cluster is a combined measure of single-word and sentence-level oral language skills. This cluster is intended as a screening measure for any delay in the development of expressive language abilities. This cluster includes Test 3: Picture Vocabulary and Test 6: Sentence Repetition.

SCORES, DEVELOPMENTAL LEVEL INDICATORS, AND SCORE COMPARISON PROCEDURES

The Woodcock–Johnson Online Scoring and Reporting Program (Schrank & Dailey, 2014, 2015) calculates all derived scores based on age norms. As in other WJ IV batteries, age equivalents, grade equivalents (if appropriate), *W* scores (a Rasch-based metric; Wendling et al., 2015), relative proficiency indexes (RPIs), standard scores, and percentile ranks may be elected for inclusion in a score report. The scores selected for inclusion in a report should be determined by the purposes of an evaluation. In addition, the ECAD includes descriptive terms to help determine levels of cognitive and academic development, including the presence and severity of any developmental delay.

Levels of Cognitive and Academic Development

The ECAD introduces a set of terms to describe a child's levels of cognitive and academic development. The cutoff scores for the terms are derived from the *W* difference (*W* Diff) values obtained by the child (defined as the difference between a child's *W* score and the median *W* score for the reference group in the norming sample; Wendling et al., 2015).

The ECAD's underlying scaling metric (the *W* scale) is a Rasch-based metric (Bond & Fox, 2007; Rasch, 1960/1980; Wright & Stone, 1979; Woodcock & Dahl, 1971) that provides the basis for a set of criterion-referenced labels tied directly to proficiency with the measured tasks (LaForte, McGrew, & Schrank, 2015). The ECAD levels of development can be compared and contrasted to other methods sometimes used for determining developmental delay: months delay, percentage delay, and standard deviation (*SD*) delay—each of which has measurement limitations. Because a calculation of months delay, percentage delay, or *SD* delay is not comparable at all ages during early childhood (in terms of ability difference required to determine a delay), the ECAD's levels can draw attention to developmental needs in some cases or ages when the other score metrics are insensitive to identification of a delay. The ECAD method may be particularly accurate for identifying the presence and severity of cognitive or academic delay during a critical window of time when early identification and targeted intervention can reduce or even eliminate a developmental delay (Baroody et al., 2009; Biemiller & Boote, 2006; Case & Griffin, 1990; Chambers et al., 2010; Dickinson & Tabors, 2001; Engle et al., 2011; Gersten et al., 2005; Goldin-Meadow et al., 2014; Griffin, 2002; Marulis & Neuman, 2010; Miller & Dyer, 1975; National Research Council, 2009; Poe et al., 2004; Roberts & Kaiser, 2011; Roth et al., 2002; Salaway, 2008; Wasik, Bond, & Hindman, 2006; Whitehurst et al., 1994).

Table 10.11 illustrates the six basic terms for levels of development, as well as two important blended-category terms (*age-appropriate to advanced* and *mildly delayed to age-appropriate*), which draw attention to task performance at or near a critical change in interpretation. The RPIs that are reported on the table of scores are also based on *W* Diff values and can be used to provide meaningful interpretations regarding a child's proficiency with cognitive and academic tasks.

Score Comparison Procedures

Scores from the ECAD can be compared with intracognitive and intra-achievement variations, as well as with an ability–achievement comparison procedure. These procedures can help determine the presence and severity of any intraindividual strengths and weaknesses or performance discrepancies.

Intracognitive Variation Procedure

The intracognitive variation allows examiners to analyze a child's cognitive test scores to explore relative strengths and weaknesses among developing cognitive abilities. For example, a child may have a strength in learning ability, as shown in Test 1: Memory for Names, but a weakness in background knowledge, as shown in Test 3: Picture Vocabulary. Any variations within cognitive development can help determine a child's present educational needs. Examiners can calculate intracognitive variations if Tests 1 through 7 have been administered.

Intra-Achievement Variation Procedure

The intra-achievement variation allows examiners to analyze a child's academic test scores and explore relative strengths and weaknesses among developing academic skills. For example, a child may have a strength in number awareness, but a weakness in early reading skills. Any variations within achievement can help determine a child's present educational needs. Examiners can calculate intra-achievement variations if Tests 8 through 10 have been administered.

Ability–Achievement Comparison Procedure

Because the GIA-EDev score is a broad-based measure of intellectual ability, it serves as a good predictor of academic development. This procedure allows an examiner to determine if a child's overall achievement level is commensurate with a child's overall cognitive ability. The GIA-EDev score is used to calculate predicted scores for expected achievement. The child's predicted achievement is then compared to his or her actual achievement. Children with predicted scores significantly higher than their actual achievement scores exhibit an

TABLE 10.11. ECAD Developmental Levels, *W* Diff Values, and Reported RPIs

Level of development	*W* Diff values	Reported RPIs
Very advanced	+31 and above	100/90
Advanced	+14 to +30	98/90 to 100/90
Age-appropriate to advanced	+7 to +13	95/90 to 98/90
Age-appropriate	–6 to +6	82/90 to 95/90
Mildly delayed to age-appropriate	–13 to –7	67/90 to 82/90
Mildly delayed	–30 to –14	24/90 to 67/90
Moderately delayed	–50 to –31	3/90 to 24/90
Extremely delayed	–51 and below	0/90 to 3/90

ability–achievement discrepancy in achievement, which can suggest a need for academic intervention.

SUMMARY AND IMPLICATIONS

The ECAD (Schrank et al., 2015) is a special-purpose WJ IV battery of 10 early cognitive and academic skills tests, contained within a single test easel, that measure the emergence and development of CHC abilities at the early childhood level (ages 3 through 9). Four of the ten tests are unique to the ECAD, while the other six are adapted and alternate forms of tests included in other parts of the WJ IV that are useful for assessment in preschool, kindergarten, and the early primary grades. The ECAD forms of the tests have greater item density, to help capture changes in growth and development at the preschool and early elementary ages.

In addition to providing a highly reliable CHC-theory-based evaluation of cognitive abilities, the ECAD can be used to identify any delay in the development of expressive language or early academic skills. Test-level information can provide early indicators of specific cognitive and early academic skills that might be targets for intervention, if a need is identified. Early intervention that specifically targets cognitive deficits or delays in emerging academic skills can foster learning readiness and enhance the probability of success for a child entering kindergarten or progressing to the early grades.

CHAPTER 11

The Wechsler Intelligence Scale for Children—Fifth Edition Integrated

Susan Engi Raiford

The Wechsler Intelligence Scale for Children—Fifth Edition Integrated (WISC-V Integrated; Wechsler & Kaplan, 2015) is a companion measure to the most widely used intelligence test for children in the world, the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014). It allows practitioners to learn more about the cognitive processes and test-taking behaviors that affect performance on the WISC-V and that also have an impact on school performance.

Because the WISC-V represents a substantial revision of this popular test, the WISC-V Integrated also reflects a good deal of change since the previous edition. Major modifications have been made to both the WISC-V content and structure to stay current with advances in the field of intellectual assessment. With updated content and structure, the WISC-V Integrated can be used to understand WISC-V results in greater detail at the item, subtest, and composite level. The test allows practitioners to weigh evidence that supports or refutes hypotheses about WISC-V results, and it informs accommodation, modification, and intervention recommendations.

The current chapter provides an overview of the WISC-V Integrated. It concludes with a section on interpretation. An appendix provides a clinical case example to illustrate how results can be used to understand WISC-V results; to understand problem-solving and learning issues; and to facilitate accommodation, modification, and intervention planning.

HISTORY AND THEORY

The *process approach* to cognitive assessment has its roots in ideas put forth by Heinz Werner (1937). Werner proposed that cognitive assessment involving careful and systematic observation of problem-solving strategies yields richer and more useful information than correct–incorrect scoring does. He suggested that cognitive task performance involves multiple, dynamic processes. Any of these processes may contribute individually or in combination with others to exert an influence on responses and performance. For example, a child may have difficulty with Block Design due to low motor skills, but another child's difficulties on the same task may be related to impaired visual–spatial processing. While both children may score similarly on Block Design, the poor performance can be traced back to two different origins.

Process approaches to assessment recognize that in completing any cognitive task, regardless of its complexity, a number of mental processes are involved. These processes can range from simple (e.g., sensing, perceiving, motor functioning) to

---

Portions of this chapter are adapted from *Essentials of WISC-V Integrated Assessment* (Raiford, 2017). Copyright © John Wiley & Sons, Inc. I express my thanks to John Wiley & Sons for granting permission to adapt this material.

more complex (e.g., reasoning, decision making; Kaufman, Raiford, & Coalson, 2016). A problem with any of these processes can result in difficulties with completing the overall task. The process approach aims to understand the reasons for low scores through identifying the cognitive processes that operate jointly on performance, breaking them down to more specific components in a stepwise fashion or altering the task in some manner, and testing hypotheses through employing the tasks that involve fewer or different cognitive processes. For example, the hypothesis that low motor skills result in a child's lower Block Design score could be more closely examined by presenting the completed design and multiple pictured sets of blocks in a stimulus book and asking the examinee to select the set of blocks that, when assembled, make the design.

There are many approaches to understanding the cognitive processes involved in performance on the Wechsler scales, beginning with an approach used by David Wechsler himself. He stated that "individuals attaining identical scores on intelligence tests cannot always be classified in the same way" (Wechsler, 1944, p. 12). His approach was somewhat psychoanalytic in nature, and described how information at the task and item levels could provide clues as to the nature of impairment.

Kaufman (1979, 1994) and Kaufman and Lichtenberger (1999, 2000, 2002) encouraged clinicians to adopt a process approach to interpretation of test results by analyzing input and output modalities (e.g., verbal input, visual output) as a means of better understanding the underlying causes of a child's pattern of strengths and weaknesses. This evolved into the *shared-abilities analysis* approach to interpretation of Wechsler intelligence scale performance. Ultimately, the approach was thought to be not specific enough and too loosely integrated with factor-analytic research to be clinically useful (Floyd & Kranzler, 2012).

Edith Kaplan and others at the Boston Veterans Administration Medical Center operationalized and refined Heinz Werner's original work; they termed their version the *Boston process approach*. They provided supporting evidence that this approach improved diagnostic and clinical utility in neuropsychological assessment, and that problem solving varied across various neurological conditions, even in the presence of similar scores (Kaplan, 1988).

The Wechsler Intelligence Scale for Children—Third Edition (WISC-III) as a Process Instrument (Kaplan, Fein, Kramer, Delis, & Morris, 1999) and the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV) Integrated (Wechsler et al., 2004) were the predecessors of the WISC-V Integrated. Therefore, the WISC-V is the third edition of the WISC to feature a process approach measure that complements interpretation of results.

Psychologists utilize the process approach to investigate the reasons for low scores, learn about cognitive strengths and weaknesses, and develop recommendations for learning accommodations. Studies suggest that the process approach is clinically useful for assessing a wide variety of neuropsychological and neurodevelopmental problems, such as autism spectrum disorder, attention-deficit/hyperactivity disorder (ADHD), traumatic brain injury, and specific learning disorders (Boxer, Jackson, & Kohlman, 2014; Halleland, Sorensen, Posserud, Haavik, & Lundervold, 2015; Hoffmann, Donders, & Thompson, 2000; Kramer, Knee, & Delis, 2000; Mayfield, Reyes, Mayfield, & Allen, 2014; McLean, Johnson, Zimak, Joseph, & Morrow, 2014).

THE WISC-V INTEGRATED TEST FRAMEWORK

The WISC-V Integrated yields subtest-level scaled scores and index scores. Figure 11.1 shows the cognitive domains represented by the WISC-V Integrated and their corresponding WISC-V subtests, the WISC-V Integrated index scores published in the test manual, and the subtests that contribute to each index score. Descriptions of the cognitive domains have been provided earlier in this volume (see Wahlstrom, Raiford, Breaux, Zhu, & Weiss, Chapter 9).

The WISC-V Integrated battery consists of 14 subtests. Children are administered only the subtests necessary to clarify and extend WISC-V results.

An *adaptation* subtest includes the same item content as the corresponding WISC-V subtest, but the mode of presentation, response method, or item administration has been modified. Eight subtests (i.e., Similarities Multiple Choice, Vocabulary Multiple Choice, Picture Vocabulary Multiple Choice, Information Multiple Choice, Comprehension Multiple Choice, Figure Weights Process Approach, Arithmetic Process Approach, and Written Arithmetic) are adaptations of WISC-V subtests. A *variation* subtest has item content that does not correspond to that on a WISC-V subtest. and the mode of presentation, response method, and/or administration procedures have been modified. Two subtests (i.e., Block Design Multiple Choice and Cancellation Abstract) are variations of the WISC-V subtests. Two subtests (i.e., Coding Recall and Coding Copy) are designed to clarify WISC-V Coding performance. Two subtests (i.e., Spatial Span and Sentence Recall) are included because they improve the breadth of working memory construct coverage in the WISC-V/WISC-V Integrated system.

Each composite score in the published test is derived from two subtests. The Visual Working Memory Index can be derived after summing the WISC-V Picture Span scaled score and the Spatial Span scaled score. No substitution is permitted in deriving these scores.

The cognitive domains corresponding to the subtests appear in the first column of Figure 11.1. Because several of the WISC-V Integrated subtests are adaptations or variations, some of the WISC-V subtests appear in the second column. The third column lists the WISC-V Integrated subtests, in most cases next to the corresponding WISC-V subtest for which it is an adaptation or variation. The subtests used to derive the two index scores appear in the shaded boxes in the second and third columns, and an arrow designates the index score to which they contribute.

SUBTESTS AND INDEX SCORES

Table 11.1 provides a description of all subtests and information on the constructs and abilities thought to be involved with each subtest.

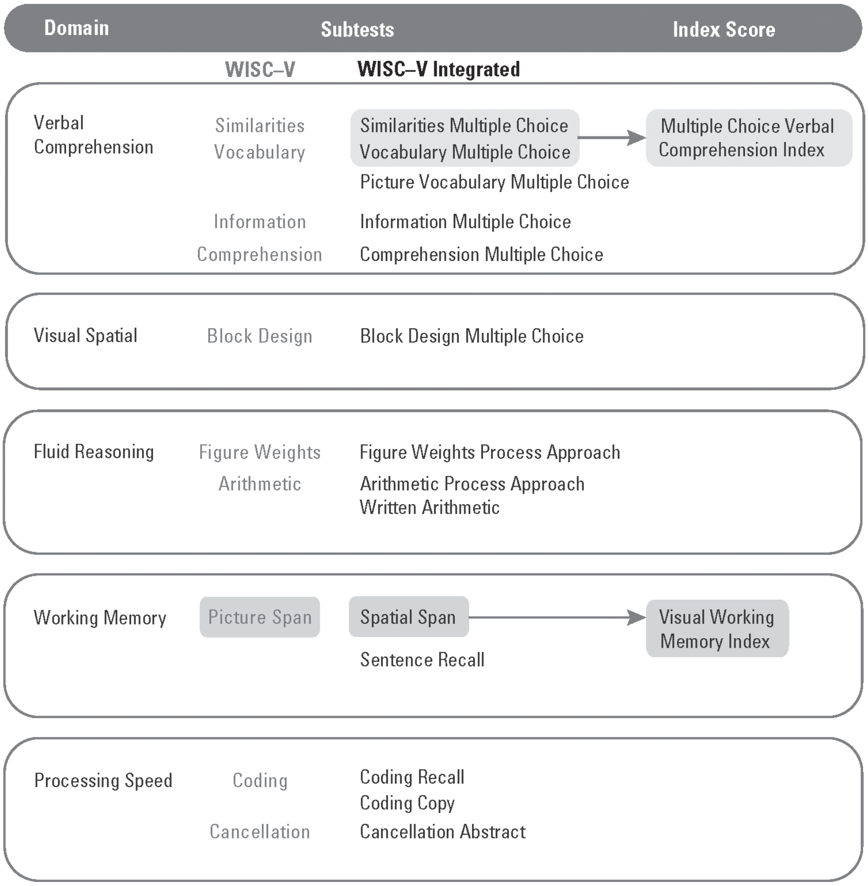

FIGURE 11.1. WISC-V Integrated test framework. Figures found in the manual for the *Wechsler Intelligence Scale for Children®, Fifth Edition Integrated (WISC®-V Integrated)*. Copyright © 2015 NCS Pearson, Inc. Reproduced with permission. All rights reserved.

TABLE 11.1. Subtest Descriptions, Constructs, and Abilities

Subtest	Description	Constructs and abilities
Similarities Multiple Choice	Multiple-choice adaptation (same items) of the WISC-V Similarities subtest. Each item and its response options are presented visually and read aloud. The child selects the response option that best represents how the common objects or concepts are similar.	Designed to measure: Verbal reasoning and concept formation. Decreased demands relative to WISC-V Similarities: Verbal expression and memory retrieval. Possibly increased demands relative to WISC-V Similarities: Receptive language skills, reading skills, decision-making skills, and working memory. Related to: Crystallized ability, associative and categorical thinking, Gf-I (induction), concept recognition and generation. May also involve: Auditory perception.
Vocabulary Multiple Choice	Multiple-choice adaptation (same items) of the WISC-V Vocabulary subtest. For picture items, the child views pictures and selects the best response from options read aloud. For verbal items, each item and its response options are presented visually and read aloud. The child selects the response option that best represents the definition of the word.	Designed to measure: Word knowledge, verbal concept formation, semantic memory. Decreased demands relative to WISC-V Vocabulary: Verbal expression and memory retrieval. Possibly increased demands relative to WISC-V Vocabulary: Receptive language skills, reading skills, decision-making skills, and working memory. Related to: Crystallized ability, Gc-VL (lexical knowledge), fund of knowledge, learning, verbal expression, long-term semantic memory, vocabulary development. May also involve: Auditory perception, auditory comprehension, abstract thinking, receptive vocabulary.
Picture Vocabulary Multiple Choice	Pictorial multiple-choice adaptation (same items) of the WISC-V Vocabulary subtest. The child views four pictures and selects the picture that best depicts the definition of the word that is read aloud.	Designed to measure: Word knowledge, verbal concept formation, receptive vocabulary. Decreased demands relative to WISC-V Vocabulary: Verbal expression, memory retrieval, receptive language. Possibly increased demands relative to WISC-V Vocabulary: Visual perception, decision-making skills, working memory. Related to: Crystallized ability, Gc-VL (lexical knowledge), fund of knowledge, learning, long-term memory, visual comprehension, visual–verbal association formation. May also involve: Visual perception, auditory comprehension.
Information Multiple Choice	Multiple-choice adaptation (same items) of the WISC-V Information subtest. Each item and its response options are presented visually and read aloud. The child selects the response option that best represents an understanding of the general knowledge topic.	Designed to measure: Acquisition, retention, and retrieval of general facts and knowledge. Decreased demands relative to WISC-V Information: Verbal expression and memory retrieval. Possibly increased demands relative to WISC-V Information: Receptive language skills, reading skills, decision-making skills, and working memory. Related to: Crystallized ability, Gc-K0 (general information), Glr (retention and retrieval of learned information). May also involve: Auditory perception, verbal expression.

(continued)

TABLE 11.1. *(continued)*

Subtest	Description	Constructs and abilities
Comprehension Multiple Choice	Multiple-choice adaptation (same items) of the WISC-V Comprehension subtest. Each item and its response options are presented visually and read aloud. The child selects the response option that best represents an understanding of the general principle or social situation.	Designed to measure: Verbal reasoning, verbal conceptualization, verbal comprehension, verbal expression, practical knowledge, judgment. Decreased demands relative to WISC-V Comprehension: Verbal expression and memory retrieval. Possibly increased demands relative to WISC-V Comprehension: Receptive language skills, reading skills, decision-making skills, and working memory. Related to: Crystallized ability (Gc), understanding of societal standards and conventional behavior, social judgment, Glr, common sense. May also involve: Auditory perception.
Block Design Multiple Choice	Multiple-choice variation (different items) of the WISC-V Block Design subtest. The child views a picture of a constructed block design and selects the pictured block set that produces a matching composition, within a specified time limit.	Designed to measure: Visual–spatial processing, analysis and synthesis of abstract visual stimuli, mental imaging. Decreased demands relative to WISC-V Block Design: Relaying response to motor channels, motor skills. Possibly increased demands relative to WISC-V Block Design: Decision-making skills, working memory. Related to: Gv-SR (spatial relations), Gv-Vz (visualization), Gv-CS (closure speed), mental rotation, nonverbal reasoning, visual perception, simultaneous processing, problem solving, cognitive flexibility, planning.
Figure Weights Process Approach[a]	Adaptation (same items) of the WISC-V Figure Weights subtest. The child is given additional time to respond. Within an extended time limit, the child is readministered Figure Weights items previously scored 0 points.	Designed to measure: Quantitative fluid reasoning/intelligence, inductive reasoning. Decreased demands relative to WISC-V Figure Weights: Speeded performance. Related to: Gf-I, Gf-RQ, simultaneous and successive processing, problem solving, cognitive flexibility. May also involve: Working memory, math problem solving, math computation.
Arithmetic Process Approach	Adaptation (same items) of the WISC-V Arithmetic subtest. Items 6–34 are presented in multiple modalities for the child to solve within a specified time limit. For Part A, Arithmetic items on which the child scored 0 points are presented visually and simultaneously read aloud. For Part B, the child is provided with pencil and paper, and is readministered the items scored 0 points in Part A.	Designed to measure: Quantitative, fluid, and logical reasoning, mental manipulation. Decreased demands relative to WISC-V Arithmetic: Attention, auditory working memory, short-term memory, auditory discrimination, auditory comprehension. Possibly increased demands relative to WISC-V Arithmetic: Reading, graphomotor skills. Related to: Gf-RQ, sequential processing, working memory, quantitative knowledge, applied computation, logical reasoning. May also involve: Auditory discrimination.
Written Arithmetic	Adaptation (same items) of the WISC-V Arithmetic subtest. The child is presented with the mathematical computations for Arithmetic items and uses paper and pencil to complete them.	Designed to measure: Numerical reasoning ability, acquired knowledge of mathematical calculations, math computation. Decreased demands relative to WISC-V Arithmetic: Attention, mental efficiency, verbal aspects of cognitive arithmetic, math problem solving.

(continued)

TABLE 11.1. *(continued)*

Subtest	Description	Constructs and abilities
Written Arithmetic *(continued)*		Possibly increased demands relative to WISC-V Arithmetic: Reading, graphomotor skills. Related to: Gf-RQ, sequential processing, working memory, quantitative knowledge, applied computation, logical reasoning, calculation skills, counting skills, math facts retrieval. May also involve: Working memory, knowledge of mathematical symbols and syntax, order-of-operations knowledge.
Spatial Span	Expands construct coverage of working memory. Spatial Span is composed of two tasks: Forward and Backward. For Spatial Span Forward, the child reproduces a sequence of tapped blocks. For Spatial Span Backward, the child reproduces a sequence of tapped blocks, in reverse order.	Designed to measure: Visual–spatial working memory. Related to: Gsm-MW (working memory capacity), Gsm-MS (memory span), Gv-MV (visual memory), attention and attentional capacity, simultaneous and successive processing, planning and metacognition, visual immediate memory, spatial locations, response inhibition. May also involve: Motor integration and programming, motor and self-regulation, cognitive flexibility, mental alertness, primacy effects, recency effects.
Sentence Recall[a]	Expands construct coverage of working memory. Sentence Recall items are composed of two tasks: a question task and a recall task. For the question task, the child responds either "Yes" or "No" to one or more simple questions. For the recall task, the child recalls the last word of each question, in the order presented.	Designed to measure: Auditory working memory with cognitive processing, working memory capacity. Related to: Storage during cognitive processing, reactivation of attention.
Coding Recall	Provides more information about performance on the WISC-V Coding subtest. Working within a specified time limit and without a key, the child attempts to remember the corresponding pairs from Coding in three formats: cued recall, free recall, and pairing.	Designed to measure: Incidental learning, associative memory. Decreased demands relative to WISC-V Coding: Graphomotor speed, timed performance. Possibly increased demands relative to WISC-V Coding: Associative memory. Related to: Short-term visual recall and recognition memory and learning ability. May also involve: Visual–motor skills, procedural learning.
Coding Copy	Provides more information about performance on the WISC-V Coding subtest. The child copies symbols within a specified time limit.	Designed to measure: Speed, fluency, and efficiency of processing; performance fluency, graphomotor speed, perceptual speed, visual–motor integration. Decreased demands relative to WISC-V Coding: Incidental learning, associative memory. Possibly increased demands relative to WISC-V Coding: Graphomotor speed. Related to: Selective and sustained attention, visual scanning and tracking, response inhibition. May also involve: Visual–motor skills.

(continued)

TABLE 11.1. *(continued)*

Subtest	Description	Constructs and abilities
Cancellation Abstract[a]	A variation of the WISC-V Cancellation subtest. Working within a specified time limit, the child scans two arrangements of shapes (one random, one structured) and marks target shapes.	Designed to measure: Processing speed; speed, fluency, and efficiency of processing; performance fluency. Decreased demands relative to WISC-V Cancellation: categorical knowledge, visual immediate memory. Possibly increased demands relative to WISC-V Coding: Response inhibition. Related to: Gs-P (perceptual speed), speed and efficiency, Gs-P (perceptual speed), simultaneous processing, planning and metacognition, speed and efficiency, selective and sustained attention, visual scanning and tracking, visual immediate memory, response inhibition. May also involve: Visual–motor skills.

[a] New subtest.

Multiple Choice Verbal Comprehension Index

The Multiple Choice Verbal Comprehension Index (MCVCI) is a new composite score that is designed to measure the same cognitive processes as the WISC-V Verbal Comprehension Index (VCI), but in a multiple-choice format to reduce expressive language requirements. It is derived from Similarities Multiple Choice and Vocabulary Multiple Choice, which are the multiple-choice adaptations of the subtests that contribute to the WISC-V VCI (i.e., Similarities and Vocabulary). The multiple-choice format reduces the demands on retrieval and expressive ability because correct responses are merely recognized to demonstrate acquired semantic knowledge.

Visual Working Memory Index

Picture Span from the WISC-V and Spatial Span are summed to derive the Visual Working Memory Index (VWMI). Contemporary working memory research indicates that domain-specific neuropsychological systems support auditory working memory versus visual–spatial working memory (Baddeley, 2012). The VWMI facilitates an expanded examination of a child's working memory abilities by providing a purer measure of visual working memory processes than the Working Memory Index (WMI), and by allowing examination of relative strength and weakness across the working memory system when compared with the Auditory Working Memory Index (AWMI).

PSYCHOMETRIC PROPERTIES

Normative Sample

The WISC-V Integrated normative sample consisted of 550 children, with 50 children (equal numbers male and female) in each of 11 age groups corresponding to those of the WISC-V normative sample. The normative sample was stratified to closely match 2014 U.S. census data for parental education level, race/ethnicity, and geographic region.

Reliability

The WISC-V Integrated composite scores have strong reliabilities (Wechsler & Kaplan, 2015). The overall internal-consistency reliability coefficients for the normative sample are .87 for the MCVCI and .90 for the VWMI. At the subtest level, the overall internal-consistency reliability coefficients of the normative sample are in the .80s or .90s, with the exceptions of Similarities Multiple Choice and Comprehension Multiple Choice (with coefficients of .79 and .77, respectively).

Overall, the reliability for special-group samples is consistent with reliability estimates for the normative sample (Wechsler & Kaplan, 2015). The test–retest stability coefficient of the MCVCI is .72, and that of the VWMI is .91. The subtest-level coefficients range from .69 to .86. Finally, the subtest-level interscorer agreement range is .98–.99.

Validity

The evidence to support the validity of the WISC-V Integrated is derived from its relations with the WISC-V and its intercorrelations. The subtests and index scores show moderate to high correlations with the WISC-V subtests and index scores from the same domain (Wechsler & Kaplan, 2015), the highest of which are with the WISC-V subtests and index scores from the same cognitive domain. These results indicate that the WISC-V Integrated subtests and index scores measure cognitive processes and abilities similar to those measured by the WISC-V, and that these cognitive processes and abilities are highly relevant to WISC-V performance. The subtest-level scores from each cognitive domain are generally moderately to highly correlated with other subtest-level scores in that domain. They show evidence of discriminant validity with subtests from other cognitive domains as well.

A great deal of evidence also supports the utility of the WISC-V Integrated as a clinical tool for understanding children's WISC-V performance, cognitive abilities, and problem solving. Studies conducted during the standardization stage with a number of special groups (e.g., children with intellectual disability, intellectual giftedness, ADHD, autism spectrum disorders, learning disabilities, traumatic brain injury, language disorders) demonstrate unique patterns of performance relative to the normative samples (Wechsler & Kaplan, 2015). These results are corroborated by a number of independent samples that show similar patterns of performance on the WISC-V and other measures of cognitive ability (see Wahlstrom et al., Chapter 9, this volume).

Moreover, the WISC-V Integrated correlates highly with academic achievement (Wechsler & Kaplan, 2015) as measured by the Wechsler Individual Achievement Test—Third Edition (WIAT-III) and the Kaufman Test of Educational Achievement, Third Edition (KTEA-3). Correlations of the index scores with achievement composites are generally in the .40s–.70s, and a great number of the WISC-V Integrated subtest-level scores have similar relationships with the achievement subtests and composites. These results indicate that the cognitive processes measured by the WISC-V Integrated are important to academic success. They also provide evidence of divergent validity (i.e., they suggest that the WISC-V Integrated and achievement tests measure different constructs, with varying degrees of overlap in the cognitive skills required).

INTERPRETATION

The WISC-V Integrated technical and interpretive manual (Wechsler & Kaplan, 2015) provides basic instruction regarding its interpretation. Clinicians and researchers have developed more in-depth and alternative interpretive strategies for the WISC-V Integrated (Raiford, 2017) and its predecessor, the WISC-IV Integrated (McCloskey, 2009; McCloskey & Maerlender, 2005). A detailed guide to interpretation is outside the scope of this chapter, and the reader is referred to these other works, as well as the technical and interpretive manual, for further information. Instead, basic information is provided to illustrate how the WISC-V Integrated can be utilized with the WISC-V to better understand low performance. The reader is cautioned that this is not a comprehensive review of interpretive strategies, and that test results should always be interpreted in conjunction with history, background, and careful clinical observations of the individual and corroborated with school-related information.

Scores and Levels of Performance

There are several types of scores available on the WISC-V Integrated, including age-adjusted scores, total raw scores, base rates for errors or other aspects of performance or observations, and percentile norms.

Age-Adjusted Scores

As the WISC-V does, the WISC-V Integrated utilizes two types of age-adjusted scores: scaled scores for subtest-level information, and standard scores for all composite scores. These are described in greater detail by Wahlstrom and colleagues in Chapter 9.

These scores permit comparison of the child's performance to his or her same-age peers and allow comparisons within the WISC-V Integrated and with the WISC-V and measures of achievement, memory, and other cognitive processes. To facilitate communication of results with parents and teachers, test results are communicated with percentile ranks (i.e., the percentage of children in the age group that obtain scores below or consistent with the child's performance). The index scores, like those on the WISC-V, should always be accompanied by a confidence interval. The index scores also utilize the same qualitative descriptors established for the WISC-V, as shown in Table 9.2 of this volume.

For most scores, comparisons can only take place at the scaled score level because interpretation must take into account performance relative to same-age peers. However, it is possible to conduct meaningful comparisons of WISC-V subtests with their corresponding adaptation subtests, as well as some of the WISC-V Integrated subtest-level scores, using both the scaled score and the raw score metrics.

Raw Scores

Subtest-Level Total Raw Scores

Total raw scores may be used to ascertain the effect of a modified presentation and/or response format on a given child's intraindividual performance. That is, comparisons at the raw score level answer the following question: How does changing the time given to respond, presentation method, or response format of a task affect the child's expression of a given ability? This information can be used to ascertain the benefit of those accommodations and modifications, and can inform recommendations for the same in the classroom. The scaled score metric comparison answers a different question. That is, what is the impact of the accommodation or modification on the child's performance relative to the impact on same-age peers' performance? This information provides a different take on the child's ability in that area, and also can clarify the need for accommodations or modifications in specific scenarios.

Base Rates and Percentile Norms

The WISC-V and the WISC-V Integrated contain a variety of other raw scores that are converted to base rates or percentile norms. They include longest span and sequence scores (e.g., the number of blocks recalled on the last Spatial Span Forward trial scored 1 point), error scores (e.g., the number of yes–no responses to Sentence Recall questions that were incorrect), and process observations (e.g., the number of times the examinee indicated not knowing the answer to an Information Multiple Choice item). It also provides percentile norms for the number of correct responses on the various tasks for Coding Recall.

Basic Interpretation

WISC-V interpretation generally proceeds from the global (e.g., Full Scale IQ) to the specific (e.g., index scores, subtest-level scores, item-level performance). The WISC-V Integrated can be used to clarify the child's WISC-V results at any point in the process.

Reporting and Describing Global Performance

All of the WISC-V interpretive systems recommend examining global performance first. Three global composite scores are available in the published WISC-V: the Full Scale IQ, the Nonverbal Index (NVI), and the General Ability Index (GAI). Each may be appropriate to describe overall intellectual ability, depending on the clinical situation and the purpose of the evaluation.

In some specific clinical situations, however, access to an alternate global score is useful. This is particularly important when issues related to language or motor impairment make it impossible to calculate a Full Scale IQ, NVI, or GAI. This occurs more frequently with the WISC-V than with its predecessors because all but one of the WISC-V composite scores do not allow substitution or proration. The sole exception is the Full Scale IQ, which allows only one substitution or proration—not enough to exclude all subtests that require verbal expression or all subtests that have motor requirements from the calculation.

Global Scores for Expressive Language Difficulties and/or Motor Impairment

Essentials of WISC-V Integrated Assessment (Raiford, 2017) provides several additional global composite scores that use combinations of WISC-V and WISC-V Integrated subtests to accommodate situations when expressive language, motor development, or both are concerns: the Nonexpressive Full Scale Score (NEFSS), the Nonmotor Full Scale Score (NMFSS); the Nonmotor Nonverbal Index (NMNVI), and the Nonmotor General Ability Index (NMGAI). The global composite scores are therefore expanded to seven options, which are listed in Table 11.2. Each score is listed with its abbreviation, subtest composition, and an example of potentially appropriate use. Interpretive details and the composite norms tables for these new scores are available in Raiford (2017).

For the NMFSS, it is notable that the complementary WISC-V Naming Speed Quantity subtest replaces Coding. Both Coding and Naming Speed Quantity involve cognitive speed and visual scanning. However, Coding involves encoding and rapidly using newly encoded associations and motor production, but Naming Speed Quantity involves rapid retrieval of frequently used long-term associative memories and expressive responses. To obtain the Naming Speed Quantity scaled score, the standard score must be converted to a scaled score from a standard score. The conversion can be completed automatically with the software that is included with the Raiford (2017) book.

Naming Speed Quantity was selected to contribute to the NMFSS for a number of reasons. First, if choosing between the two WISC-V Naming Speed subtests, Naming Speed Quantity has reduced language requirements relative to Naming Speed Literacy. Second, a review of the WISC-V technical and interpretive manual reveals that its clinical sensitivity is similar to that of Coding for many neurodevelopmental conditions commonly assessed with the WISC-V (i.e., intellectual disability, specific learning disorders, ADHD, autism spectrum disorder with language impairment, autism spectrum disorder without language impairment, and traumatic brain injury). Third, it has a superior *g* loading relative to Naming Speed Literacy (Raiford, 2017).

TABLE 11.2. Global Composite Scores in the WISC-V and WISC-V Integrated System and Examples of Potentially Appropriate Uses

Global composite score	Source	Subtest composition	Example of potentially appropriate use
Full Scale IQ	Wechsler (2014)	SI, VC, BD, MR, FW, DS, CD	Default global score
Nonexpressive Full Scale Score (NEFSS)	Raiford (2017)	SIMC,[a] VCMC,[a] BD, MR, FW, PS, CD	Expressive language issues, but ideal for crystallized ability to still contribute to the global score
Nonmotor Full Scale Score (NMFSS)	Raiford (2017)	SI, VC, BDMC,[a] MR, FW, DS, NSQ	Motor impairment
Nonverbal Index (NVI)	Wechsler (2014)	BD, VP, MR, FW, PS, CD	Language issues (expressive and mild receptive)
Nonmotor Nonverbal Index (NMNVI)	Raiford (2017)	BDMC,[a] VP, MR, FW, PS	Expressive issues accompanied by motor impairment
General Ability Index (GAI)	Wechsler (2014)	SI, VC, BD, MR, FW	Neurodevelopmental issue affecting working memory and/or processing speed performance
Nonmotor General Ability Index (NMGAI)	Raiford (2017)	SI, VC, BDMC,[a] MR, FW	Neurodevelopmental issue affecting working memory and/or processing speed performance, also accompanied by motor impairment

Note. Subtest abbreviations: SI, Similarities; VC, Vocabulary; BD, Block Design; MR, Matrix Reasoning; FW, Figure Weights; DS, Digit Span; CD, Coding; SIMC, Similarities Multiple Choice; VCMC, Vocabulary Multiple Choice; PS, Picture Span; BDMC, Block Design Multiple Choice; NSQ, Naming Speed Quantity.

[a] WISC-V Integrated subtest.

Reporting and Describing Index Scores

The published WISC-V Integrated index scores are useful when a more in-depth explanation of low scores is necessary. For example, if a child unexpectedly receives a low score on the WISC-V VCI, the MCVCI can be used to clarify whether the child merely performs more poorly than peers due to expressive issues or whether other weaknesses are implicated. As another instance, the VWMI can be used together with the WISC-V WMI and AWMI to provide a broader assessment of working memory. Table 11.3 lists the alternate index scores that correspond to primary index scores, and examples of their appropriate use.

Expanded Index Scores

The WISC-V and WISC-V Integrated system's expanded index scores may be used in various situations where a broader measure of the ability of interest would be helpful. For example, practitioners who assess intellectually gifted children, who perform comparisons with achievement scores in some states, or who complete evaluations for private school admissions have expressed interest in the expanded scores for their purposes. As another example, some practitioners utilize expanded index scores when there is a significant discrepancy between the two subtest scaled scores that contribute to the corresponding primary index score.

The names, sources, and examples of appropriate uses of each expanded index score are listed in Table 11.4. The appropriate uses listed are only examples; other clinical situations may also call for their use.

Index-Level Strengths and Weaknesses

It is crucial to ground interpretation of the index-level strengths and weaknesses in the context of index score interpretation, describing them in relation to the normative sample as well as to intrapersonal global performance. Kaufman and colleagues (2016) recommend using the Full Scale IQ for strengths-and-weaknesses comparisons even if another global composite score (i.e., the NVI or the GAI) is selected to represent overall ability. Even if another global score is selected, the authors suggest substituting the selected composite score for the Full Scale IQ score and performing the comparisons anyway because the correla-

Alternate index score	Alternate for:	Issue	Source	Examples of potentially appropriate uses
Multiple Choice Verbal Comprehension Index	Verbal Comprehension Index	Expressive	Wechsler and Kaplan (2015)	Measuring verbal comprehension in the presence of expressive language difficulties. Investigating the impact of reducing expressive and retrieval demands on the measure of verbal comprehension.
Nonmotor Visual Spatial Index	Visual Spatial Index	Motor	Raiford (2017)	Measuring visual–spatial processing in the presence of motor impairment. Investigate the impact of reducing motor demands and trial-and-error problem solving on the measure of visual–spatial ability.
Auditory Working Memory Index	Working Memory Index	Vision	Wechsler (2014)	Measuring working memory in the presence of visual impairment. Investigating the impact of eliminating visual requirements on the measure of working memory.
Visual Working Memory Index	Working Memory Index	Expressive	Wechsler and Kaplan (2015)	Measuring working memory in the presence of expressive language difficulties. Investigating the impact of eliminating expressive language demands on the measure of working memory.

TABLE 11.4. WISC-V and WISC-V Integrated Expanded Index Scores

Expanded index score	Source	Examples of appropriate use
Verbal (Expanded Crystallized) Index	Kaufman, Raiford, and Coalson (2016); Raiford, Drozdick, Zhang, and Zhou (2015)	• An expanded measure of crystallized ability is needed. • Intellectual giftedness. • Comparisons with achievement scores. • Evaluations for private school admissions. • Significant discrepancy between Similarities and Vocabulary (WISC-V VCI).
Nonexpressive (Expanded Crystallized) Index	Raiford (2017)	• An expanded measure of crystallized ability is needed in the presence of expressive language issues. • Intellectual giftedness in the presence of expressive language issues. • Comparisons with achievement scores in the presence of expressive language issues. • Evaluations for private school admissions in the presence of expressive language issues. • Significant discrepancy between Similarities Multiple Choice and Vocabulary Multiple Choice (WISC-V Integrated MCVCI).
Expanded Visual Spatial Index	Raiford (2017)	• An expanded measure of visual–spatial ability is needed. • Intellectual giftedness. • Comparisons with achievement scores. • Evaluations for private school admissions. • Significant discrepancy between Block Design and Visual Puzzles (WISC-V VSI).
Expanded Fluid Index	Kaufman, Raiford, and Coalson (2016); Raiford, Drozdick, Zhang, and Zhou (2015)	• An expanded measure of fluid reasoning ability is needed. • Intellectual giftedness. • Comparisons with achievement scores. • Evaluations for private school admissions. • Significant discrepancy between Matrix Reasoning and Figure Weights (WISC-V FRI).
Expanded Working Memory Index	Raiford (2017)	• An expanded measure of working memory ability is needed. • Strengths-and-weaknesses analysis for specific learning disability evaluation. • Significant discrepancy between Digit Span and Picture Span (WISC-V WMI). • Significant discrepancy between Digit Span and Letter–Number Sequencing (WISC-V AWMI). • Significant discrepancy between Picture Span and Spatial Span (WISC-V Integrated VWMI).
Expanded Auditory Working Memory Index	Raiford (2017)	• An expanded measure of auditory working memory ability is needed. • Strengths-and-weaknesses analysis for specific learning disability evaluation. • Significant discrepancy between Digit Span and Letter–Number Sequencing (WISC-V AWMI).
Expanded Processing Speed Index	Raiford (2017)	• An expanded measure of processing speed ability is needed. • Strengths-and-weaknesses analysis for specific learning disability evaluation. • Significant discrepancy between Coding and Symbol Search (WISC-V PSI).

tions of the Full Scale IQ with these other global scores is better than the Full Scale IQ retest stability value and only differ slightly from a prorated Full Scale IQ in terms of content. The Raiford (2017) book extends this approach to include the global scores created for children with expressive or motor difficulties provided in that book (e.g., NEFSS, NMFSS). There, I demonstrate that the correlations of those scores with the Full Scale IQ are comparable to those of the NVI and the GAI, and that their reliabilities and standard errors of measurement are comparable to those of the Full Scale IQ. I conclude that substituting any of those scores for the Full Scale IQ in strengths-and-weaknesses comparisons is likely to provide a good approximation.

It is typical to have some areas of strength and weakness across cognitive ability domains. A significant strength or weakness relative to an overall indicator of intellectual ability is a normal occurrence and should not be taken as a sign of pathology or abnormality. The Raiford (2017) book presents data demonstrating that such discrepancies are extremely common and occur in close to 90% of results, whether in clinical or nonclinical populations.

Composite-Level Pairwise Comparisons

A number of pairwise composite-level comparisons can clarify interpretation as framed within the process approach. These comparisons can elucidate the examinee's cognitive strengths and needs and reasons for poor WISC-V performance, as well as the potential effect of accommodations and modifications. The WISC-V Integrated provides critical values, base rates, and interpretive hypotheses relevant to three composite-level pairwise comparisons (i.e., VCI–MCVCI, WMI–VWMI, and AWMI–VWMI). The Raiford (2017) book provides additional composite score comparisons and similar information; the additional comparisons are listed in Table 11.5, along with the sources for each composite score. In that book, I also provide interpretive hypotheses for these comparisons, which can shed light on the impact

TABLE 11.5. WISC-V and WISC-V Integrated Composite Score Pairwise Comparisons

Score 1	Source	Score 2	Source
Full Scale IQ	Wechsler (2014)	Nonexpressive Full Scale Score	Raiford (2017)

of expressive or motor difficulties on WISC-V composite scores.

Examining Subtest-Level Performance

Pairwise subtest-level comparisons can inform interpretation of performance, particularly within the process approach. Such comparisons shed light on the reasons for poor WISC-V performance, as well as the potential effect of accommodations and modifications. The WISC-V Integrated provides critical value and base rate information relevant to subtest-level pairwise comparisons.

The pairs of subtest-level scores with meaningful comparisons are listed in Table 11.6. Each comparison is designated as meaningful, using a scaled score metric or both a scaled and raw score metric.

It is worth noting that comparisons of Picture Vocabulary Multiple Choice with Vocabulary and Vocabulary Multiple Choice should only be made at the scaled score or item level because Picture Vocabulary Multiple Choice is scored 0 or 1 at the

item level, whereas the others are scored 0, 1, or 2 at the item level. Total raw score comparisons may be made between Arithmetic and its adaptations, but Arithmetic has five picture items that do not appear on the corresponding adaptation scores. These must be taken into account when comparisons are made at the total raw score level. Detailed information relevant to interpreting subtest-level differences is offered in the Raiford (2017) book. A few illustrative examples extracted from that book appear in Table 11.7.

Examining Qualitative Aspects of Performance

Qualitative evaluation of WISC-V Integrated performance varies by cognitive domain and can take place at the scale, task, or item level. For example, such an evaluation can involve examining patterns of responses and performance across and within tasks, among items grouped by content, or across items with similar stimulus characteristics or response requirements.

TABLE 11.7. Sample Interpretive Hypotheses for Pairwise Comparisons of Various WISC-V and WISC-V Integrated Subtest Scores

Comparison	Interpretive hypotheses
Vocabulary and Vocabulary Multiple Choice	Vocabulary > Vocabulary Multiple Choice: • Expression of verbal concept formation and semantic knowledge not significantly influenced by expressive problems or retrieval deficits. • Difficulty inhibiting urge to respond to a partially correct response that is of lower quality than another option. • Working memory difficulties create issues with expression of verbal concept formation and semantic knowledge. Vocabulary < Vocabulary Multiple Choice: • Difficulty accessing or retrieving semantic knowledge when no external prompts or cues present. • Decision-making skills bolster expression of verbal concept formation and semantic knowledge. • Expressive language difficulties hamper expression of verbal concept formation and semantic knowledge.
Arithmetic and Arithmetic Process Approach Part A	Arithmetic > Arithmetic Process Approach Part A: • Working memory demands do not substantially reduce expression of quantitative reasoning skills. • Increasing reading demands hamper the expression of quantitative reasoning skills. • Listening comprehension demands do not constrain the expression of quantitative reasoning skills. Arithmetic < Arithmetic Process Approach Part A: • Reducing auditory working memory demands bolsters expression of quantitative reasoning skills. • The child was relatively more fatigued during Arithmetic, due to the additional items administered. • Simplifying sensory processing demands improves expression of quantitative reasoning skills. • Listening comprehension demands constrain the expression of quantitative reasoning skills.
Coding and Coding Copy	Coding > Coding Copy: • Graphomotor skills hamper the expression of processing speed ability. • Associative memory skills are relatively stronger than graphomotor skills (confirm by examining relative performance on Coding Recall). Coding < Coding Copy: • Associative memory skills reduce the expression of processing speed ability. • Graphomotor skills are relatively more well developed than associative memory skills (confirm by examining relative performance on Coding Recall).

Note. From Raiford (2017). Copyright © John Wiley & Sons, Inc. Adapted by permission.

Variability of performance may be due to issues with fatigue, distraction, inattention, persistence, motivation, receptive language, listening comprehension, reading, working memory, or decision-making skills. It could also be due to difficulties with a particular subject matter or area of knowledge. Common performance across subtests with similar types of content, stimulus, or response demands may indicate an area of weakness.

Each domain of the WISC-V and the WISC-V Integrated system provides unique opportunities to discover areas for remediation or growth. For example, the Raiford (2017) book provides grouping systems for error analysis of Verbal Comprehension subtest items that may be examined together to screen for weak content areas (e.g., human health, science, calendar information), as well as sets of Arithmetic, Arithmetic Process Approach, Written Arithmetic, Figure Weights, and Figure Weights Process Approach items that may be related to emerging math score weaknesses.

Appendix 11.1 presents a case study that demonstrates how the WISC-V, WISC-V Integrated, KTEA-3, NEPSY-II, California Verbal Learning Test for Children (CVLT-C), and Behavior Assessment System for Children, Third Edition (BASC-3) can be integrated into a comprehensive evaluation. All personally identifiable information has been altered in the case study report to preserve the confidentiality of the examinee.

APPENDIX 11.1

Illustrative Case Study

Name: Bill D.

School: B Elementary School

Date of birth: 8/25/2006

Age: 10 years, 10 months

Race/ethnicity: European American

Parents: Dennis and Ann D.

Date of testing: 7/1/2017

Date of report: 7/5/2017

REASON FOR REFERRAL

Mrs. D. requested an evaluation of Bill's cognitive strengths and weaknesses, as well as his emotional and behavioral functioning. Mrs. D. reported that Bill shows many signs of attention-deficit/hyperactivity disorder (ADHD). Bill says he has a hard time staying in his seat and paying attention. Specific questions to be answered:

- (Parents:) Does Bill have ADHD?
- (Parents:) What can we do to help Bill stay organized and on track at school?
- (School:) Are there issues that may require school accommodations?

ANSWERS TO REFERRAL QUESTIONS

Does Bill Have ADHD?

Yes. I have diagnosed Bill with ADHD, combined presentation. The diagnosis of this subtype means that he exhibits symptoms of both inattention and hyperactivity/impulsivity. Various educators, Mrs. D., and Bill report these symptoms, which are also observable in objective test results.

What Can We Do to Help Bill Stay Organized and on Track at School?

Pharmacotherapy (medication), working memory training, vigorous exercise, limiting screen time, executive function training, and parent support are all possible courses of action that are recommended to assist in improving school functioning; many of these will need to be implemented outside school. Numerous possible interventions are listed in the "Recommendations" section of this report. Because Bill attends a private parochial school, not all accommodations listed in the "Recommendations" section may be available or feasible.

Are There Issues That May Require School Accommodations?

Bill's diagnosis qualifies him to be recognized as having a disability in one of the categories designated under the Individuals with Disabilities Education Improvement Act of 2004, which governs free public school education: *other health impairment (ADHD)*.

Accommodations for these conditions, if available within the private school environment, are appropriate. Refer to the accommodations listed in the "Recommendations" section. Ultimately, the accommodation plan should be discussed and agreed upon in a follow-up meeting with parents, educators, and Bill himself.

EVALUATION METHODS AND PROCEDURES

Evaluation methods and procedures included the following:

- History and background review
- Parent interview
- Teacher interview
- Child interview
- Behavioral observations
- Review of group achievement testing results
- Psychological testing

Psychological tests administered were as follows (see "Complete Test Data" at the end of this report for full results):

- Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V)
- Wechsler Intelligence Scale for Children—Fifth Edition Integrated (WISC-V Integrated), selected subtests
- Kaufman Test of Educational Achievement, Third Edition (KTEA-3), selected subtests
- NEPSY: A Developmental Neuropsychological Assessment—Second Edition (NEPSY-II), selected subtests
- California Verbal Learning Test—Children's Version (CVLT-C)
- Clinical Evaluation of Language Fundamentals—Fifth Edition (CELF-5)
- Behavior Assessment System for Children, Third Edition (BASC-3):
    - Self-Report Form
    - Parent Rating Scales
    - Teacher Rating Scales

CURRENT SYMPTOMS

Bill's mother and teacher have observed that he shows many present signs of inattention. Both report consistent observations, as his mother helps him with schoolwork at home. He is off task when he is supposed to do homework or chores at home, has trouble completing such tasks, and appears disorganized. He avoids tasks that are effortful. He acts childish, loses track of what he is doing (e.g., because of noises), forgets what he is supposed to do, and lets his mind wander if an adult does not keep him on task. He reportedly has a short attention span, acts without thinking, listens to directions sporadically, and often does not listen carefully or pay attention when being spoken to. He has great trouble concentrating almost all the time and acts confused. He says he often gets in trouble for not paying attention. He is described by his mother and teacher as highly disorganized, with weak planning skills.

Bill has many behaviors consistent with hyperactivity. His teacher and mother report the following: He often interrupts, acts without thinking, is overly active, and fiddles with things. He disrupts other children's activities and schoolwork, has poor self-control, and is unable to slow down. He has difficulty waiting his turn, has trouble keeping his hands to himself, speaks out of turn, and has trouble staying seated during class. He is described as almost always being in motion. He acts out of control at times as well.

Bill shows some signs of social difficulties. He has some difficulty understanding certain social cues. For example, he sometimes becomes angry because he misinterprets lighthearted joking as a personal affront. However, he generally interacts well with the other boys in class and with adults. His classmates find him to be funny, and he uses humor as a method to make friends.

HISTORY OF PRESENTING PROBLEMS

Bill has never been formally evaluated for ADHD. His teacher says that Bill is easily sidetracked and does not focus on class activities. His mother works with him on homework and observes that Bill tries to avoid schoolwork in the evenings by diverting attention to martial arts or piano practice. He has attended his current private school since he was in prekindergarten at age 3. His teachers have consistently reported hyperactivity, but his parents have hoped that the issues would decrease with maturity. His mother reported that he is well liked at the school, despite some misunderstandings with others. His friends enjoy him for his sense of humor and imagination on the playground, although his teacher reports that sometimes their play degenerates into yelling, and that Bill cannot stand to lose at kickball and is sometimes a sore loser.

FAMILY HISTORY

Mrs. D. is a stay-at-home mother. Mr. D. is a sales manager. Mr. D. has a bachelor's degree in business, and his mother finished 3 years of college before becoming pregnant; she plans to finish her degree when Bill is able to drive. Bill has one brother, age 6. His 6-year-old brother also attends school at B Elementary and is in the first grade. Bill says he has a good relationship with his mother and father. His mother reports that apart from the difficulties with homework, getting Bill to finish chores can be challenging, but he is a sweet, loving boy.

MEDICAL/DEVELOPMENTAL HISTORY

Mrs. D. reported that her pregnancy with Bill was normal, but that he was born at 34½ weeks because her water broke early. The labor and delivery were unremarkable, but Bill spent 6 days in the NICU due to electrolyte imbalances and low bilirubin levels. He was released afterward and followed by his pediatrician for a short time, during which the issues resolved. No other health or medical concerns occurred after the birth.

Her mother reported that Bill always has been large and tall for his age. He likes sports and athletics, but she describes him as clumsy and easily frustrated (e.g., with waiting his turn or losing). Bill started walking late (at 19 months), but was saying simple words at 10 months and has normal language development. Bill was not toilet-trained until sometime after age 3.

Bill was previously diagnosed with developmental coordination disorder and fine and gross motor delays by the occupational therapist who assessed him 2 years ago. He underwent treatment for these issues and for a reflex (asymmetric tonic neck reflex) that was not integrated. He continues to attend occupational therapy once a week for fine and gross motor delays, and to work on his handwriting due to motor dysgraphia.

Bill is not presently prescribed any medications. His parents indicated that they are open to the possibility of medication to treat him if necessary. He has had recent vision and hearing screenings, which showed no abnormalities.

ACADEMIC HISTORY AND STATUS

When Bill was age 1½, he began to recognize numbers, letters, colors, and shapes. He began reading well at age 3.

Bill has just completed the fifth grade. Mrs. D. stated that his lowest grade this past year was a B– (80) in math, and that he reads far above grade level. His handwriting is somewhat messy. He has an excellent vocabulary and his spelling and grammar skills are above average. These reports were confirmed with review of school records. His group achievement scores indicate that he is functioning at or above grade level in all subjects.

Bill wants to be a school teacher and a martial arts instructor in the future. His parents anticipate that he will attend college after high school.

PATIENT'S STRENGTHS, COPING MECHANISMS, AND AVAILABLE SUPPORT SYSTEMS

Mrs. D. describes Bill as funny, smart, creative, caring, and kind toward others. His teacher describes him as a bright child with a great sense of humor who enjoys playing with the other children. She indicated that Bill likes to be with others and focuses well when he is in a one-on-one situation. She describes Bill as polite to adults and says he wants to do what is right.

MENTAL STATUS AND BEHAVIORAL OBSERVATIONS

Bill arrived on time and was oriented to person, place, time, and purpose of the testing. He was accompanied by Mrs. D. He was groomed neatly and dressed appropriately, and he was taller and heavier than his same-age peers. Activity level was higher than typical of other children his age, and eye contact was inconsistent. He turned away from testing on a number of occasions, and he sometimes attempted to change the subject by discussing comic books and sports and recounting movies he had recently seen. His speech revealed very strong vocabulary. His reported mood was "good," and his affect was generally mood-congruent. However, he became impatient and irritable after sitting for approximately 30 minutes; therefore, he was given multiple breaks.

Bill showed reactions to perceived success and failure, seeming happy and proud when he thought his performance was good, and irritated and impatient when he thought he was doing poorly. He asked if his answers were correct on multiple occasions. He verbally coached himself through several tasks involving visual stimuli. He required some corrective feedback and prompting, but quickly learned the rules of tasks and how they were performed when he was attentive. Given the effort and level of engagement Bill displayed in the session, the results of the assessment are likely to reflect accurate estimates of his cognitive functioning.

TEST RESULTS AND INTERPRETATION

Cognitive Functioning

Intellectual Ability

Bill's performance on cognitive measures suggests that his overall intellectual ability is in the very high range compared with that of other children his age. His Full Scale IQ is high average, but the Nonmotor General Ability Index, an indicator of ability that reduces the contribution of motor skills and of working memory and processing speed, indicates that Bill is functioning in the very high range. Given his known issues with motor functioning and attentional difficulties, this finding is not surprising. Because the Nonmotor General Ability Index eliminates motor production demands and minimizes the contribution of working memory and processing speed, the best estimate of his global ability is the Nonmotor General Ability Index. Results suggest relatively weaker working memory and motor production skills relative to higher-order reasoning. In the classroom, these weaknesses might be manifested as appearing to forget or failing to track complex information that is being presented; being slow to respond; having difficulty with tasks that require use of hands to manipulate objects; and messy handwriting.

In large studies, out of all the scores on cognitive tests, overall intellectual ability does the best job at predicting children's school success. However, it doesn't always tell us everything we need to know about a child's individual strengths and needs. An individual's cognitive picture is usually better and more deeply understood when narrower areas of ability are also considered.

Language

Speech

Bill responded readily to items that required expressive responses. He was articulate and highly verbal. He elaborated sufficiently.

Verbal Comprehension and General Verbal Knowledge

Bill's ability to access, apply, and express knowledge he has gained about words and their meanings and to reason with verbal material is in the extremely high range relative to that of other children his age, and is a personal strength relative to his other cognitive abilities. When acquired knowledge and social/practical knowledge are taken into account as well, Bill's verbal crystallized abilities are slightly lower (but still in the very high range). These results are not surprising, given reports of inattention in class and some social skill difficulties. Providing multiple choices for the social/practical knowledge questions, so that he was merely required to recognize the correct responses rather than to recall and express them, did not result in substantial improvement; he was able to respond slightly more accurately to just two more questions under these conditions.

Because he has very strong verbal skills and a well-developed vocabulary, teachers may expect him to perform other tasks more easily or grasp information more readily and quickly than he does in the classroom because of his inattention and hyperactivity.

Listening Comprehension

The kind of listening comprehension that students must do in school involves understanding relatively formal speech, rather than casual speech. Bill's listening comprehension abilities are average compared with those of other children his age. This finding suggests that Bill grasps the meaning of what is said in the classroom at a level that is typical of his peers. However, this skill is lower than expected relative to his intellectual abilities.

Associative Verbal Fluency

Bill's ability to call to mind and verbalize categorically associated information (associative verbal fluency) is high average relative to that of his same-age peers. However, when semantic constraints are applied (naming objects that begin with a specific letter rather than objects in a category), his verbal fluency is in the average range relative to other children his age. This decrease relative to his initial performance probably reflects the increased demands on executive functions and strategy inherent in the initial-letter condition.

Visual–Spatial Processing

Visual–spatial processing is the ability to evaluate visual details, to understand relationships of visual parts in space, and to use such information to assemble a geometric design that matches a model (either pictured or real). Sometimes the expression of this ability is tested through manipulation of real objects. Bill's visual–spatial processing ability is in the low average range compared with that of other children his age and is a personal weakness in relation to his other cognitive abilities. Reducing the influence of speedy performance on the task did not result in substantive improvement.

Bill frequently stopped attempting to solve problems requiring visual–spatial abilities, such as constructing a design with blocks or selecting pieces corresponding to a completed puzzle. However, his difficulty in this area was greater on a task involving physical (motor) manipulation of components of a construction, rather than mental imagery. This observation is not surprising because of his known motor skill delay. He is better able to quickly recognize correct solutions among multiple choices than to quickly construct them. His estimated visual–spatial ability is in the average range when motor production requirements are eliminated.

Reasoning and Problem Solving

Reasoning involves detecting and applying the underlying rules or relationships that define how objects or ideas are understood as a group or work together. Bill's visual reasoning ability is in the high average range compared with that of other children his age. He is better able to engage in proper reasoning and problem solving if tasks involve relationships among meaningful objects or verbal material rather than abstract shapes, and he has slightly lower performance on tasks that involve quantitative reasoning. It was noted that he had greater difficulty on problems requiring multiple operational steps or multiplication than on items merely requiring simple addition or subtraction.

Giving more time and allowing him to use pencil and paper, especially when math is involved in the problem solving, should help Bill to better express verbal quantitative reasoning relative to his own prior performance as well as in relation to his same-age peers. If the problem-solving load is reduced to requiring only simple responses to written math problems, his performance improves further.

Learning and Memory

Learning and memory were assessed to examine their role in, and implications for, Bill's future academic success. The two are closely related to each other and are very important to school achievement. Bill's performance on a broad measure of long-term storage and retrieval, which involves tasks requiring accurate and fluent retrieval of overlearned associations and accurate retrieval of new associations, is in the high average range.

Working Memory

Working memory is the ability to take in, keep, and manipulate information in one's awareness to get some type of output that can be expressed. Bill's working memory ability is in the low average range relative to that of other children his age, and is an intrapersonal weakness relative to his overall cognitive abilities. His auditory working memory (i.e., verbal stimuli and responses) is in the average range and is better than his visual working memory (i.e., visual stimuli and spatial locations), which is in the very low range. His working memory performance was consistent across items rather than variable, which suggests that his attention was consistent during these particular tasks.

Associative Memory

Bill's visual–verbal associative memory, or the ability to form new associations between symbols and meanings, is in the high average range relative to that of other young people Bill's age. His performance suggests uniform ability when he is recalling associations learned within the past few seconds or minutes, or when trying to recall or recognize them half an hour later.

Short-Term and Long-Term Auditory Memory

Relative to that of his peers, Bill's ability to encode and recall details of organized verbal material and lists of items from a few categories (short- and long-term auditory/verbal memory) is very high.

Short-Term and Long-Term Visual Memory

Bill's short- and long-term visual memory for visual abstract content and spatial locations is in the low average range.

Rapid Automatic Naming

Rapid automatic naming involves recognizing and recalling overlearned information, like letters and numbers or quantities, as efficiently as possible. Bill's ability to recognize, recall, and recite letters and numbers quickly is in the high average range relative to that of other children his age. His ability to rapidly recognize and name quantities is slightly less efficient, and is in the average range compared with that of others his age. Overall, his rapid automatic naming is in the high average range.

Cognitive Speed

Processing Speed

Processing speed is the ability to make speedy and accurate judgments about visual information and act on those judgments. Slow processing speed can lower academic performance, because information tends to be lost if it is not processed quickly. Bill's processing speed is in the high average range relative to other children his age. His score on a subtest that required him to quickly associate and write codes paired with numbers in a key was lower than his score on a task that required him to scan rows for symbols matching one of two target symbols. Results suggest that these difficulties are due to low graphomotor speed (the quickness with which one can reproduce symbols in written format) rather than weak associative memory for visual material.

Rapid Automatic Naming

Rapid automatic naming is also sometimes thought of as an aspect of cognitive speed and has been discussed above under "Learning and Memory."

Attention and Executive Functioning

Attention and executive functioning were evaluated to provide objective results to examine, along with the subjective reports (from Bill, his mother, and his educators) of Bill's issues with hyperactive and inattentive behavior. Objective findings show low cognitive flexibility and self-monitoring, low selective and sustained attention, and slowed responding when cognitive flexibility is required. These results are consistent with observations in the testing session and by educators and Bill himself. In other words, he has difficulty adapting to changing expectations.

Because Bill's attention and other executive functions are impaired, performance in other areas may improve after these issues are addressed.

Emotional and Behavioral Functioning

Bill has clinically significant attention and hyperactive/impulsive symptoms, according to subjective informants and objective test findings. These symptoms were also observed in the testing session. Bill's symptoms and test results are consistent with a diagnosis of ADHD, combined presentation (both inattentive and hyperactive/impulsive symptoms).

Social Perception and Skills

Because children with attention problems sometimes have deficits in social skills and perception, and informants indicate that Bill may be struggling in this area, this area was assessed. Objective testing results suggest that he has some difficulties reading others well and identifying emotional expressions in others (particularly misinterpreting facial expressions corresponding with neutral emotion, angry feelings, and disgust). These problems could lead to difficulties in the classroom or with peers.

For example, Bill may not distinguish nonverbal cues and facial expressions of teachers as readily as do his peers; if an instructor or his mother appears annoyed, he may not readily recognize that cue. He may also interpret neutral faces as conveying negative feelings or disapproval. In addition, he is likely to misinterpret nonverbal cues that most children his age comprehend; such cues are very valuable to provide ongoing feedback about performance and behaviors.

Bill's pragmatic language, or use of language for social purposes, was assessed through a measure completed by his mother as informant. He has some social communication deficits in the areas of awareness of voice pitch, loudness, and rhythm and their influence on meaning; and of reading and using body language. These difficulties are likely to interfere with his ability to respond appropriately on a consistent basis with peers and teachers.

SUMMARY AND DIAGNOSTIC IMPRESSIONS

Bill qualifies for a diagnosis of ADHD, combined presentation (both inattentive and hyperactive/impulsive type), moderate. Bill himself reports these symptoms, as do his educators and mother. These symptoms are sometimes observed in a one-on-one situation and are very apparent in the classroom. He has several of the symptoms of inattention required for this diagnosis. These problems cause him difficulty in the classroom and impair his academic and social functioning. Given his level of intelligence, he is likely to be capable of greater academic gains and social functioning if his ADHD is treated.

RECOMMENDATIONS

Medical and Physical Interventions

1. Medication to alleviate Bill's ADHD is strongly recommended. Medication could make an enormous difference in his school performance. Obtain an evaluation and share this report with the prescribing professional. (Provide referrals.)
2. The most effective treatments for ADHD combine medication with therapeutic approaches.
3. Physical exercise is critical, both for health and for reducing Bill's impulsive ADHD symptoms. The best approach is to combine medication and vigorous physical exercise. An hour a day at least 5 times per week is recommended.
4. Bill's screen time (smartphone, TV, computer, tablets) should be kept to a minimum unless it is required for school.

Therapy/Counseling/Training

1. Obtain executive function coaching for Bill. (Provide referrals.) This training is important to help him develop organizational skills that will be increasingly important in middle school. It is also important in order for his mother not to be the sole homework support; to preserve the mother–son relationship, Bill needs to learn strategies to be able to monitor and regulate his own homework completion.
2. Social skills groups or social language groups would probably be valuable in developing Bill's social communication skills. (Provide referrals.) Work with him on understanding figures of speech, turns of phrase, and humor. Idiom dictionaries are widely available on the Internet.
3. Obtain working memory training. Computer-based solutions for attention problems related to working memory are available that combine cognitive neuroscience with close professional support to deliver substantial and lasting benefits. The treatment includes easy-to-use software. It has been empirically shown to improve attention, working memory, and academic performance in multiple studies. The training occurs over a 5-week period. It includes pre-evaluation, daily training sessions (in the privacy of one's own home via computer), weekly coaching sessions via video chat or phone, and a wrap-up. I will provide the appropriate literature and information.

Home Interventions

1. Teach Bill to guide himself through problems and to verbally list steps to follow.
2. Instruct him in strategies to organize himself at home and in transitions between environment. In particular, teach use of lists and personal planners.
3. Communicate frequently with teachers about school activities, equipment needed, and homework. Use the school's app daily to monitor grades and assignments.
4. Teach memory aids, such as verbal mediation or rehearsal and mnemonic strategies, for use with schoolwork.

School Accommodations

1. Allow Bill additional time to complete school tests and standardized tests (50%).
2. Minimize distractions during learning activities, and consider preferential seating arrangements close to the teacher and away from visual distractions and movement (e.g., doors opening and closing, windows).
3. Closely monitor Bill's math performance. There are some indications that math may present challenges in the future. After Bill's ADHD is treated, obtain academic achievement assessment in the mathematics domain to better understand his math skills.
4. Explore options to allow Bill activity so that he can focus better when seated. These may include a seating disk, desk bands, a standing-desk option, an under-desk cycle, and/or fidget toys.
5. Bill's auditory working memory and auditory immediate and delayed memory are superior to his visual working memory and visual immediate and delayed memory. Presentation of information in an auditory format to supplement visual material may facilitate his learning. Provide copies of images, tables, or charts used in lecture or class. Use visual materials sparingly, especially if they are abstract. Meaningful visuals (e.g., pictures that can be semantically encoded) will be more helpful than abstract ones.

6. Have Bill repeat back the directions and parts of an assignment or task, or have a peer with verbal strengths do so in front of him if they are in a group situation, to confirm understanding.
7. Teach reading of visual displays, drawings, diagrams, and charts, and coach Bill in how to talk them through. Encourage use of puzzles and other spatial games and toys.
8. For in-class assignments, pair all students in the class and enlist them to ensure that they have completed all necessary steps for in-class assignments.
9. Provide a written schedule on the board daily, crossing off each portion of the day as it occurs.
10. Make redirection discreet, clear, and concise. Use quiet auditory redirection or discreet visual direction (e.g., move near Bill) if possible.
11. Provide Bill with teacher notes or outlines in advance of or during lectures.

Thank you for the opportunity to work with Bill and your family. Please let me know if I can be of further assistance.

COMPLETE TEST DATA

Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V) and WISC-V Integrated

Subtest Score Summary

Memory and Learning	Memory for Designs Immediate	6	
	Memory for Designs Delayed	6	
	Narrative Memory Free and Cued Recall Total	16	
	Narrative Memory Free Recall Total	15	
Language	Word Generation Semantic Total	13	
	Word Generation Initial Letter Total	10	

Note. Average scaled score is 10. About 68% of scores fall between 7 and 13. About 95% fall between 4 and 16. Percentile ranks less than or equal to 15% are considered unusual and potentially clinically relevant.

California Verbal Learning Test—Children's Version (CVLT-C)

Trials 1–5 Free Recall Total Correct: T score = 70; 95% confidence interval = 48–57.

Average T score is 50. About 68% of scores fall between 40 and 60. About 95% fall between 30 and 70.

Trial 1 Free Recall Total Correct: $z = 2.5$
Trial 5 Free Recall Total Correct: $z = 2.5$
Short-Delay Cued Recall Total Correct: $z = 2.0$
Long-Delay Free Recall Total Correct: $z = 1.5$
Long-Delay Cued Recall Total Correct: $z = 1.5$

Average z score is 0. About 68% of scores fall between –1 and 1. About 95% fall between –2 and 2.

Clinical Evaluation of Language Functioning—Fifth Edition (CELF–5), Pragmatics Activities Checklist

Pragmatics Profile scaled score: 6

Average scaled score is 10. About 68% of scores fall between 7 and 13. About 95% fall between 4 and 16.

Behavior Assessment System for Children, Third Edition (BASC-3)

Self-Report of Personality (Informant: Child), General Gender-Specific Norm Group

Composite Score Summary

Composite	*T* score	Percentile rank	90% confidence interval
School Problems	44	35	38–50
Internalizing Problems	50	50	47–53
Inattention/Hyperactivity	80	99	75–85
Emotional Symptoms Index	56	78	53–59
Personal Adjustment	50	50	45–55

Note. For this and all other BASC-3 tables, the average *T* score is 50. About 68% of scores fall between 40 and 59. About 95% fall between 30 and 69.

Scale Score Summary

CHAPTER 12

The Kaufman Assessment Battery for Children—Second Edition and KABC-II Normative Update

Lisa Whipple Drozdick
Jennie Kaufman Singer
Elizabeth O. Lichtenberger
James C. Kaufman
Alan S. Kaufman
Nadeen L. Kaufman

This chapter provides an overview of the Kaufman Assessment Battery for Children—Second Edition (KABC-II; A. S. Kaufman & Kaufman, 2004a) and describes the KABC-II Normative Update (KABC-II NU; A. S. Kaufman & Kaufman with Drozdick & Morrison, 2018). The presentation of the KABC-II and KABC-II NU covers the following topics: theory and structure, description of subtests, administration and scoring, psychometric properties, interpretation, and clinical applications. A description of the normative update sample is also included in the chapter, and a special section on the innovations in measures of cognitive assessment is provided for the KABC-II. An illustrative case report is presented in an appendix to the chapter, to exemplify the KABC-II in practice.

THEORY AND STRUCTURE

Structure and Organization

The KABC-II (A. S. Kaufman & Kaufman, 2004a) measures the processing and cognitive abilities of children and adolescents between the ages of 3 years, 0 months and 18 years, 11 months (3:0 and 18:11). Like the original Kaufman Assessment Battery for Children (K-ABC; A. S. Kaufman & Kaufman, 1983), the KABC-II is an individually administered, theory-based, clinical instrument that is used worldwide (e.g., Malda, van de Vijver, Srinivasan, Transler, & Sukumar, 2010; Vannetzel, 2010). It has been translated into multiple languages and adapted for use in numerous countries, such as France, Belgium, Italy, Germany, Austria, Switzerland, South Korea, and Japan (e.g., A. S. Kaufman & Kaufman, 2008; A. S. Kaufman, Kaufman, Melchers, & Melchers, 2014; A. S. Kaufman, Kaufman, & Publication Committee of Japanese Version of KABC-II, 2013). The KABC-II also provides examiners with a Nonverbal scale, composed of subtests that may be administered in pantomime and responded to motorically, to permit valid assessment of children who have hearing impairments, limited English proficiency, and so forth.

Starting with the original K-ABC, the Kaufman approach to assessment has become popular internationally. For example, in Germany, the K-ABC "has become 'the' assessment tool for preschoolers, and . . . is widely used in all areas of assessment, including child psychiatry and early remediation facilities" (P. Melchers, personal communication, October 29, 2003). The K-ABC and KABC-II likewise have been popular in Japan for two decades (Fujita et al., 2011; Ishikuma, Matsuda, Fujita, & Ueno, 2016; Ishikuma, Shinohara, & Nakao, 2007). And, notably, foreign versions of the

K-ABC and KABC-II are more than translations from one language to another, but incorporate cultural and societal differences as well. For example,

> When the Japanese version of the KABC-II was developed, preparation of the developmental stage was more challenging. Since there were no individualized achievement tests in Japan, the Japanese KABC-II was expanded to include achievement scales: Vocabulary, Reading, Writing, and Arithmetic (A. S. Kaufman et al., 2013). . . . When translating and adopting the foreign tests such as Wechsler tests and KABC-II for Japanese children, regardless of the degree of adaptation, we "create" the tests to be useful to understand the child's intelligence and find the best way to help the learning process for Japanese children. (T. Ishikuma, personal communication, December 20, 2016)

The KABC-II is grounded in a dual theoretical foundation: Luria's (1966, 1970, 1973) neuropsychological model, featuring three blocks or functional units, and the Cattell–Horn–Carroll (CHC) approach to categorizing specific cognitive abilities (Carroll, 1993; Flanagan, McGrew, & Ortiz, 2000; Horn & Noll, 1997; see also Schneider & McGrew, Chapter 3, this volume). The dual theoretical model has been seen as a notable strength of the KABC-II (Bain & Gray, 2008; Lichtenberger, 2005), but, interestingly, it has been perceived as both an asset and a limitation by a reviewer of the French KABC-II: Vannetzel (2010) states that

> the use of multifold perspectives is an essential point from the view of epistemology of the psychological assessment and of precision in terms of practice and level of formation. This plural paradigm, very risky in regards to the theoretical pertinence that it demands from the practitioner, illustrates rather well the "new world" in which psychometrics entered at the turn of the twenty-first century. (p. 233)

The KABC-II includes both Core and Expanded Batteries, with only the Core Battery needed to yield a child's scale profile. The KABC-II Expanded Battery offers supplementary subtests to increase the breadth of the constructs measured by the Core Battery and to follow up hypotheses. Administration time for the Core Battery takes about 30–70 minutes, depending on the child's age and whether the examiner administers the CHC model of the KABC-II or the Luria model. One of the features of the KABC-II is the flexibility it affords the examiner in determining the theoretical model to administer to each child.

When interpreted from the Luria model, the KABC-II focuses on mental processing, excludes acquired knowledge to the extent possible, and yields a global standard score called the Mental Processing Index (MPI) with a mean of 100 and a standard deviation (*SD*) of 15. The Luria model measures four domains: *sequential processing, simultaneous processing, learning ability*, and *planning ability*.

From the vantage point of the CHC model, the KABC-II Core Battery includes all scales in the Luria system, but they are interpreted from an alternative perspective; for example, the scale that measures sequential processing from the Luria perspective is seen as measuring the CHC ability of *short-term memory* (Gsm), and the scale that measures planning ability (Luria interpretation) aligns with Gf or *fluid reasoning* (CHC interpretation). The CHC model includes one extra scale that is *not* in the Luria model—namely, a measure of *crystallized ability* (Gc), which is labeled Knowledge/Gc. The global standard score yielded by the CHC model is labeled the Fluid–Crystallized Index (FCI), also with a mean of 100 and *SD* of 15.

Table 12.1 summarizes the dual-model approach, showing the Luria process and the corresponding CHC ability measured by each scale. The use of two theoretical models allows examiners to choose the model that best meets the needs of the child or adolescent being evaluated. The dual labels for the scales reflect the complexity of what the cognitive tasks measure and how their scores are interpreted. Examiners must select either the Luria or CHC model *before* they administer the test, thereby determining which global score should be used—the MPI (Luria model) or FCI (CHC model).

- The CHC model is the model of choice—except in cases where including measures of acquired knowledge (crystallized ability) is believed by the examiner to compromise the validity of the FCI. In those cases, the Luria-based global score (MPI) is preferred.
- The CHC model is given priority over the Luria model because we believe that knowledge/Gc is, in principle, an important aspect of cognitive functioning. Therefore, the CHC model (FCI) is preferred for children with known or suspected disabilities in reading, written expression, or mathematics; for children assessed for giftedness or intellectual disabilities; for children assessed for emotional or behavioral dis-

orders; and for children assessed for attentional disorders such as attention-deficit/hyperactivity disorder (ADHD).

- Situations in which the Luria model (MPI) is preferred include, but are not limited to, the following:
    - A child from a bilingual background.
    - A child from any nonmainstream cultural background that may have affected knowledge acquisition and verbal development.
    - A child with known or suspected language disorders, whether expressive, receptive, or mixed receptive–expressive.
    - A child with known or suspected autism.
    - An examiner with a firm commitment to the Luria processing approach who believes that acquired knowledge should be excluded from any global cognitive score (regardless of reason for referral).

This set of recommendations does not imply that we consider one model to be theoretically superior to the other. Both theories are equally important as foundations of the KABC-II. The CHC psychometric theory emphasizes specific cognitive abilities, whereas the Luria neuropsychological theory emphasizes *processes*—namely, the ways children process information when solving problems. Both approaches are valid for understanding how children learn and solve new problems, which is why each scale has two names, one from Luria theory and the other from CHC theory. Regardless of the model of the KABC-II that is *administered* (Luria or CHC), the way in which psychologists *interpret* the scales will undoubtedly be influenced by their theoretical preference.

On the original K-ABC, the Sequential and Simultaneous Processing scales were joined by a separate Achievement scale. That concept is continued with the Luria model of the KABC-II, although conventional kinds of achievement (reading, arithmetic) are excluded from the KABC-II Knowledge/Gc scale.

At age 3, only a global score is offered, either the MPI or FCI. For ages 4–18, the global scale is joined by an array of scales (see Table 12.1). The Planning/Gf scale is included only at ages 7–18 because a factor corresponding to the high-level set of abilities did not emerge for younger children. All KABC-II scales have a mean of 100 and *SD* of 15.

Theory: Luria and CHC

Luria (1970) perceived the brain's basic functions to be represented by three main blocks or functional systems, which are responsible for arousal and attention (block 1); the use of one's senses to analyze, code, and store information (block 2); and the application of executive functions for formulating plans and programming behavior (block 3). Within block 2, Luria (1966) distinguished between "two basic forms of integrative activity of the cerebral cortex" (p. 74), which he labeled *successive* and *simultaneous*. Despite Luria's interpretation of three blocks, each with separate functions, his focus was on *integration* among the blocks to be capable of complex behavior. Block 3

TABLE 12.1. The Dual Theoretical Foundations of the KABC-II

	Interpretation of scale from Luria theory	Interpretation of scale from CHC theory	Name of KABC-II scale
	Learning ability	Long-term storage and retrieval (Glr)	Learning/Glr
	Sequential processing	Short-term memory (Gsm)	Memory/Gsm
	Simultaneous processing	Visual processing (Gv)	Simultaneous/Gv
	Planning ability	Fluid reasoning (Gf)	Planning/Gf
	—	Crystallized ability (Gc)	Knowledge/Gc
Name of global score	Mental Processing Index (MPI)	Fluid–Crystallized Index (FCI)	

Note. Knowledge/Gc is included in the CHC system for the computation of the FCI, but it is excluded from the Luria system for the computation of the MPI. The Planning/Gf scale is for ages 7–18 only. All other scales are for ages 4–18. Only the MPI and FCI are offered for 3-year-olds.

is very closely related to the functions of block 1, as both blocks are concerned with overall efficiency of brain functions; part of the role of block 2 is to establish connections with block 3 (Reitan, 1988). Indeed, "integration of these systems constitutes the real key to understanding how the brain mediates complex behavior" (Reitan, 1988, p. 333; see also Naglieri & Otero, Chapter 6, this volume).

In the development of the KABC-II, the test authors emphasized the integration of the three blocks, not the measurement of each block in isolation. The block 1 arousal functions are key aspects of successful test performance on any cognitive task, but attention and concentration per se do not fit Kaufman and Kaufman's definition of high-level, complex, intelligent behavior. The Learning/Glr scale requires much sustained attention and concentration (block 1), but depends more on the integration of the three blocks than on any one in isolation. The Sequential/Gsm and Simultaneous/Gv scales are deliberately targeted to measure the block 2 successive and simultaneous functions, respectively, but again the test authors have striven for complexity. Luria (1966) defined the block 2 functions of analysis and storage of incoming stimuli via successive and simultaneous processing as *coding* functions, not problem-solving functions. But because block 2 is responsible for establishing connections with block 3, the KABC-II measures of simultaneous processing require not just the analysis, coding, and storage of incoming stimuli, but also the block 3 executive functioning processes for success. In addition, block 2 requires the integration of the incoming stimuli; hence subtests like Word Order and Rover require synthesis of auditory and visual stimuli. Planning/Gf is intended to measure Luria's block 3; again, however, success on these complex tasks requires not just executive functioning, but also focused attention (block 1) and the coding and storage of incoming stimuli (block 2).

The CHC model is a psychometric theory that rests on a large body of research, especially factor-analytic investigations, accumulated over decades. The CHC theory represents a data-driven theory, in contrast to Luria's clinically driven theory. CHC theory has two separate psychometric lineages: (1) Raymond Cattell's (1941) original Gf-Gc theory, which was expanded and refined by Horn (1968, 1985, 1989) to include an array of abilities (not just Gf and Gc); and (2) John Carroll's (1943, 1993) half-century of rigorous efforts to summarize and integrate the voluminous literature on the factor analysis of cognitive abilities. Ultimately, Horn and Carroll agreed to merge their separate but overlapping models into the unified CHC theory. This merger was accomplished in a personal communication to Richard Woodcock in July 1999; the specifics of CHC theory and its applications have been articulated by Dawn Flanagan, Kevin McGrew, and their colleagues (Flanagan et al., 2000; Flanagan & Ortiz, 2001; see also Schneider & McGrew, Chapter 3, this volume).

Both the Cattell–Horn and Carroll models essentially started from the same point: Spearman's (1904) *g* factor theory. Though they took different paths, they ended up with remarkably consistent conclusions about the spectrum of broad cognitive abilities. Cattell built upon Spearman's *g* to posit two kinds of *g: fluid intelligence* (Gf), the ability to solve novel problems by using reasoning (believed by Cattell to be largely a function of biological and neurological factors); and *crystallized intelligence* (Gc), a knowledge-based ability that is highly dependent on education and acculturation.

Almost from the beginning of his collaboration with Cattell, Horn believed that the psychometric data, as well as neurocognitive and developmental data, were suggesting more than just these two general abilities. Horn (1968) quickly identified four additional abilities; by the mid-1990s, his model included 9–10 *broad abilities* (Horn, 1989; Horn & Hofer, 1992; Horn & Noll, 1997). The initial dichotomy had grown, but not in a hierarchy. Horn retained the name of Gf-Gc theory, but the diverse broad abilities were treated as equals, not as part of any hierarchy.

Carroll (1993) developed a hierarchical theory based on his in-depth survey of factor-analytic studies composed of three levels or strata of abilities: *stratum III (general)*, a Spearman-like *g*, which Carroll considered to be a valid construct based on overwhelming evidence from factor analysis; *stratum II (broad)*, composed of eight broad factors that correspond reasonably closely to Horn's broad abilities; and *stratum I (narrow)*, composed of numerous fairly specific abilities, organized by the broad factor with which each is most closely associated (many relate to level of mastery, response speed, or rate of learning).

To Horn, the *g* construct had no place in his Gf-Gc theory; consequently, Carroll's stratum III is not usually considered part of CHC theory. Nonetheless, the KABC-II incorporates stratum III in its theoretical model because it corresponds to the global measure of general cognitive ability, the FCI. However, the *g* level is intended more as a practical than a theoretical construct. The

KABC-II scales correspond to 5 of the 10 broad abilities that make up CHC stratum II—Glr, Gsm, Gv, Gf, and Gc. The test authors chose not to include separate measures of Gq (*quantitative knowledge*) or Grw (*reading and writing*) because they believe that reading, writing, and mathematics fit in better with tests of academic achievement, like the Kaufman Test of Educational Achievement, Third Edition (KTEA-3; A. S. Kaufman & Kaufman, 2014); however, Gq is present in some KABC-II tasks. The Gq ability measured, though, is considered secondary to other abilities measured by these subtests.

The KABC-II assesses 15 of the approximately 70 CHC narrow abilities. Table 12.2 shows the relationship of the KABC-II scales and subtests to the three strata. For the KABC-II, the broad abilities are of primary importance for interpreting the child's cognitive profile. In developing the KABC-II, the test authors did not strive to develop "pure" tasks for measuring the five CHC broad abilities. In theory, for example, Gv tasks should exclude Gf or Gs. In practice, however, the goal of comprehensive tests of cognitive ability is to measure problem solving in different contexts and under different conditions, with complexity being necessary to assess high-level functioning. Consequently, the test authors constructed measures that featured a particular ability while incorporating aspects of other abilities. To illustrate, Rover is primarily a measure

TABLE 12.2. General (Stratum III), Broad (Stratum II), and Narrow (Stratum I) CHC Abilities Measured by the KABC-II

CHC ability	Measured on KABC-II by:
General ability (stratum III in Carroll's theory)	**Mental Processing Index (MPI)**—Luria model of KABC-II (excludes acquired knowledge), ages 3–18 **Fluid–Crystallized Index (FCI)**—CHC model of KABC-II (includes acquired knowledge), ages 3–18
Broad ability (stratum II in CHC theory)	
Long-term storage and retrieval (Glr)	**Learning/Glr Index** (ages 4–18)
Short-term memory (Gsm)	**Sequential/Gsm Index** (ages 4–18)
Visual processing (Gv)	**Simultaneous/Gv Index** (ages 4–18)
Fluid reasoning (Gf)	**Planning/Gf Index** (ages 7–18)
Crystallized ability (Gc)	**Knowledge/Gc Index** (ages 4–18)
Narrow ability (stratum I in CHC theory)	
Glr: Associative memory (MA)	*Atlantis, Rebus, Delayed Recall scale*
Glr: Learning abilities (L1)	*Delayed Recall scale*
Gsm: Memory span (MS)	*Word Order* (without color interference), *Number Recall, Hand Movements*
Gsm: Working memory (WM)	*Word Order* (with color interference)
Gv: Visual memory (MV)	*Face Recognition, Hand Movements*
Gv: Spatial relations (SR)	*Triangles*
Gv: Visualization (VZ)	*Triangles, Conceptual Thinking, Block Counting, Story Completion*
Gv: Spatial scanning (SS)	*Rover*
Gv: Closure speed (CS)	*Gestalt Closure*
Gf: Induction (I)	*Conceptual Thinking, Pattern Reasoning, Story Completion*
Gf: General sequential reasoning (RG)	*Rover, Riddles*
Gc: General information (K0)	*Verbal Knowledge, Story Completion*
Gc: Language development (LD)	*Riddles*
Gc: Lexical knowledge (VL)	*Riddles, Verbal Knowledge, Expressive Vocabulary*
Gq: Math achievement (A3)	*Rover, Block Counting*

Note. Gq, quantitative ability. KABC-II scales are in **bold**, and KABC-II subtests are in *italics*. All KABC-II subtests are included, both Core and supplementary. CHC stratum I categorizations are courtesy of D. P. Flanagan (personal communication, October 2, 2003).

of Gv because of its visualization component, but it also involves Gf; Story Completion emphasizes Gf, but Gc is also required to interpret the social situations that are depicted.

DESCRIPTION OF KABC-II SUBTESTS

Sequential/Gsm Scale

- *Word Order (Core for ages 3:0–18:11)*. The child touches a series of silhouettes of common objects in the same order as the examiner has said the names of the objects; more difficult items include an interference task (color naming) between the stimulus and response.
- *Number Recall (supplementary for ages 3:0–3:11; Core for ages 4:0–18:11)*. The child repeats a series of numbers in the same sequence as the examiner has said them, with series ranging in length from two to nine numbers; the numbers are single digits, except that 10 is used instead of 7 to ensure that all numbers are one syllable.
- *Hand Movements (supplementary for ages 4:0–18:11; Nonverbal scale for ages 4:0–18:11)*. The child copies the examiner's precise sequence of taps on the table with the fist, palm, or side of the hand.

Simultaneous/Gv Scale

- *Triangles (Core for ages 3:0–12:11; supplementary for ages 13:0–18:11; Nonverbal scale for ages 3:0–18:11)*. For most items, the child assembles several identical rubber triangles (blue on one side, yellow on the other) to match a picture of an abstract design; for easier items, the child assembles a different set of colorful rubber shapes to match a model constructed by the examiner.
- *Face Recognition (Core for ages 3:0–4:11; supplementary for ages 5:0–5:11; Nonverbal scale for ages 3:0–5:11)*. The child attends closely to photographs of one or two faces that are exposed briefly, and then selects the correct face or faces from a group photograph.
- *Conceptual Thinking (Core for ages 3:0–6:11; Nonverbal scale for ages 3:0–6:11)*. The child views a set of four or five pictures, and then identifies the one picture that does not belong with the others; some items present meaningful stimuli, and others use abstract stimuli.
- *Rover (Core for ages 6:0–18:11)*. The child moves a toy dog to a bone on a checkerboard-like grid that contains obstacles (rocks and weeds), and tries to find the "quickest" path—the one that takes the fewest moves.
- *Block Counting (supplementary for ages 5:0–12:11; Core for ages 13:0–18:11; Nonverbal scale for ages 7:0–18:11)*. The child counts the exact number of blocks in various pictures of stacks of blocks; the stacks are configured so that one or more blocks are hidden or partially hidden from view.
- *Gestalt Closure (supplementary for ages 3:0–18:11)*. The child mentally "fills in the gaps" in a partially completed "inkblot" drawing, and names (or describes) the object or action depicted in the drawing.

Planning/Gf Scale (Ages 7–18 Only)

- *Pattern Reasoning (Core for ages 7:0–18:11; Nonverbal scale for ages 5:0–18:11; Core for ages 5:0–6:11, but on the Simultaneous/Gv scale)*. The child is shown a series of stimuli that form a logical, linear pattern, but one stimulus is missing; the child completes the pattern by selecting the correct stimulus from an array of four to six options (most stimuli are abstract, geometric shapes, but some easy items use meaningful shapes).
- *Story Completion (Core for ages 7:0–18:11; Nonverbal scale for ages 6:0–18:11; supplementary for ages 6:0–6:11, but on the Simultaneous/Gv scale)*. The child is shown a row of pictures that tell a story, but some of the pictures are missing. The child is given a set of cards with pictures, selects the ones needed to complete the story, and places the cards with the missing pictures in their correct locations.

Learning/Glr Scale

- *Atlantis (Core for ages 3:0–18:11)*. The examiner teaches the child the nonsense names for fanciful pictures of fish, plants, and shells; the child demonstrates learning by pointing to each picture (out of an array of pictures) when it is named. Corrective feedback is provided for incorrect responses during the early learning trials.
- *Rebus (Core for ages 3:0–18:11)*. The examiner teaches the child the word or concept associated with each particular rebus (drawing), and the child then "reads" aloud phrases and sentences composed of these rebuses.

- *Delayed Recall (supplementary scale for ages 5:0–18:11)*. The child demonstrates delayed recall of paired associations learned about 20 minutes earlier during the Atlantis and Rebus subtests (this requires the examiner to administer the Atlantis—Delayed and Rebus—Delayed tasks).

Knowledge/Gc Scale (CHC Model Only)

- *Riddles (Core for ages 3:0–18:11)*. The examiner provides several characteristics of a concrete or abstract verbal concept, and the child has to point to a picture depicting the concept (early items) or name the concept (later items).
- *Expressive Vocabulary (Core for ages 3:0–6:11; supplementary for ages 7:0–18:11)*. The child provides the name of a pictured object.
- *Verbal Knowledge (supplementary for ages 3:0–6:11; Core for ages 7:0–18:11)*. The child selects from an array of six pictures the one that corresponds to a vocabulary word or answers a general information question read aloud by the examiner.

ADMINISTRATION AND SCORING

For the KABC-II, the Core Battery for the Luria model comprises five subtests for 3-year-olds, seven subtests for 4- and 5-year-olds, and eight subtests for 6- to 18-year-olds. The CHC Core Battery includes two additional subtests at each age, both measures of crystallized ability. Approximate average administration times for the Core Battery, by age, are given in Table 12.3. For the CHC test battery, the additional two Core subtests add about 10 minutes to the testing time for ages 3–6 and about 15 minutes for ages 7–18 years.

Examiners who choose to administer the entire Expanded Battery—all Core and supplementary subtests, the Delayed Recall scale, and all measures of crystallized ability—can expect to spend just under 60 minutes for 3- and 4-year-olds, about 90 minutes for ages 5 and 6, and about 100 minutes for ages 7–18. However, examiners who choose to administer supplementary subtests need not give all of the available subtests to a given child or adolescent—just the ones that are most pertinent to the reasons for referral.

TABLE 12.3. Average Administration Times (in Minutes) for the KABC-II Core Battery

Ages =	MPI (Luria model)	FCI (CHC model)
3–4	30	40
5	40	50
6	50	60
7–18	55	70

Sample and teaching items are included for all subtests, except those that measure acquired knowledge, to ensure that children understand what is expected of them to meet the demands of each subtest. Scoring of all subtests is objective. Even the Knowledge/Gc subtests require pointing or one-word responses rather than longer verbal responses, which often introduce subjectivity into the scoring process.

In their KABC-II review, Bain and Gray (2008) state that "generally, the KABC-II is easy to administer with practice and is inherently interesting for children, with several manipulative opportunities and brightly colored, well-designed stimuli. Some of the newly developed subtests are particularly attractive" (p. 100). They do note, however, that the numerous test materials "plus the manual make up a kit that is far from the lightest, most compact kit in the typical examiner's repertoire" (p. 100).

PSYCHOMETRIC PROPERTIES

The KABC-II is a psychometrically sound instrument. A brief review of the instrument's standardization sample, reliability, and validity is provided in this chapter. For a thorough description of the normative sample and reliability, stability, and validity data, see the KABC-II manual (A. S. Kaufman & Kaufman, 2004a) and *Essentials of KABC-II Assessment* (A. S. Kaufman, Lichtenberger, Fletcher-Janzen, & Kaufman, 2005).

Standardization Sample

The KABC-II standardization sample was composed of 3,025 children and adolescents. The sample matched the U.S. population on the stratification variables of gender, race/ethnicity, socioeconomic status (SES—parental education), region, and special education status. Each year of age between 3 and 18 was represented by 125–250 children, about equally divided between males and females, with most age groups consisting of exactly 200 children.

Reliability

KABC-II global scale (MPI and FCI) split-half reliability coefficients were in the mid-.90s for all age groups (only the value of .90 for the MPI at age 3 was below .94). The mean MPI coefficient was .95 for ages 3–6 and ages 7–18; the mean values for FCI were .96 (ages 3–6) and .97 (ages 7–18). Mean split-half reliability coefficients for the separate scales (e.g., Learning/Glr, Simultaneous/Gv) averaged .91–.92 for ages 3–6 and ranged from .88 to .93 (mean = .90) for ages 7–18. Similarly, the Nonverbal Index—the alternative global score for children and adolescents with hearing impairments, limited English proficiency, and the like—had an average coefficient of .90 for ages 3–6 and .92 for those ages 7–18. Mean split-half values for Core subtests across the age range were .82 (age 3), .84 (age 4), .86 (ages 5–6), and .85 (ages 7–18). Nearly all Core subtests had mean reliability coefficients of .80 or greater at ages 3–6 and 7–18. Stability data over an interval of about 1 month for three age groups (total *N* = 203) yielded coefficients of .86–.91 for the MPI and .90–.94 for the FCI. Stability coefficients for the separate scales averaged .81 for ages 3–6 (range = .74–.93), .80 for ages 7–12 (range = .76–.88), and .83 for ages 13–18 (range = .78–.95). Bain and Gray (2008) have concluded that "the reliability coefficients are consistently high" (p. 100).

Validity

Construct validity was given strong support by the results of confirmatory factor analysis (CFA). The CFA supported four factors for ages 4 and 5–6, and five factors for ages 7–12 and 13–18, with the factor structure supporting the scale structure for these broad age groups. The fit was excellent for all age groups; for ages 7–12 and 13–18, the five-factor solution provided a significantly better fit than the four-factor solution. In addition to the CFA evidence provided in the KABC-II manual, strong independent support for the theory-based structure of the KABC-II was provided in a reanalysis of standardization data for all age groups (Reynolds, Keith, Fine, Fisher, & Low, 2007), and for a new sample of 200 preschool children ages 4–5 years (Hunt, 2008; Morgan, Rothlisberg, McIntosh, & Hunt, 2009). In analyses of the KABC-II with preschool children, the authors found support for the four-factor structure of the KABC-II, but suggested that the data fit even better into a five-factor model, similar to the broad ability factors laid out for the older children (Potvin, Keith, Caemmerer, & Trundt, 2015). In addition, Reynolds and Keith (2007) demonstrated that the factor structure was invariant for high- and low-ability groups; Reynolds, Ridley, and Patel (2008) found invariant factor structure by gender for ages 6–18 years; and the construct validity of the KABC-II has also been demonstrated cross-culturally—for example, for 598 low-SES Kannada-speaking children ages 6–10 years in Bangalore, South India (Malda et al., 2010) and for children and adolescents tested in countries where the KABC-II has been translated and adapted (e.g., Fujita et al., 2011; A. S. Kaufman et al., 2013, 2014). Construct validity has also been demonstrated by ethnicity within the United States for 2001 white, black, and Hispanic children in grades 1–12 (Scheiber, 2016).

Correlation coefficients between the FCI and the Wechsler Intelligence Scale for Children (WISC; Wechsler, 1991, 2003, 2014) Full Scale IQ (FSIQ), corrected for the variability of the normative sample, were .81 for the WISC-V (N = 89, ages 6–16), .89 for the WISC-IV (*N* = 56, ages 7–16), and .77 for the WISC-III (*N* = 119, ages 8–13). The FCI also correlated .77 with the Woodcock–Johnson IV (WJ IV; Schrank, McGrew, & Mather, 2014) General Intellectual Ability (GIA) composite (*N* = 50, ages 7–18), .72 with the K-ABC Mental Processing Composite (MPC) for preschool children (*N* = 67), and .84 with the K-ABC MPC for school-age children (*N* = 48). Correlations with the MPI were generally slightly lower (by an average of .05).

Fletcher-Janzen (2003) conducted a correlational study with the WISC-IV for 30 Native American children from Taos, New Mexico, who were tested on the KABC-II at an average age of 7:8 (range = 5–14) and on the WISC-IV at an average age of 9:3. As shown in Table 12.4, the two KABC-II global scores correlated about .85 with the WISC-IV FSIQ. This strong relationship indicates that the KABC-II global scores and the WISC-IV global score measure the same construct; nevertheless, the KABC-II yielded global scores that were about 0.5 *SD* higher than the FSIQ for this Native American sample.

Correlations were obtained between the KABC-II and achievement on the Woodcock–Johnson III (WJ-III; Woodcock, McGrew, & Mather, 2001), the Wechsler Individual Achievement Test—Second Edition (WIAT-II; Psychological Corporation,

TABLE 12.4. Means, *SD*s, and Correlations between KABC-II and WISC-IV Global Scores for 30 Native American Children and Adolescents from Taos, New Mexico

KABC-II and WISC-IV global scores	Mean	*SD*	*r* with WISC-IV FSIQ	Mean difference	
				MPI vs. FSIQ	FCI vs. FSIQ
KABC-II					
Mental Processing Index (MPI)	95.1	13.3	.86	+8.4	—
Fluid–Crystallized Index (FCI)	94.1	12.5	.84	—	+7.4
WISC-IV					
Full Scale IQ (FSIQ)	86.7	12.3	—	—	—

Note. Children were tested first on the KABC-II (age range = 5–14, mean = 7:8) and second on the WISC-IV (age range = 6–15, mean = 9:3). Data from Fletcher-Janzen (2003).

2001), and the Peabody Individual Achievement Test—Revised/Normative Update (PIAT-R/NU; Markwardt, 1998) for six samples with a total *N* of 401. Coefficients between the FCI and total achievement for the six samples, corrected for the variability of the norms sample, ranged from .67 on the PIAT-R/NU for grades 1–4 to .87 on the WIAT-II for grades 6–10 (mean *r* = .75). For these same samples, the MPI correlated .63–.83 (mean *r* = .71). In addition, the KABC-II FCI correlated .75 (and the MPI correlated .71) with the Academic Skills Battery on the KTEA-3 Comprehensive Form for 99 individuals ages 4½ through 18 years (A. S. Kaufman & Kaufman, 2014, Table 2.15). Correlations with the KTEA-3 Academic Skills Battery were as follows: FCI = .75 (and MPI = .71) for ages 4½ –18 (*N* = 99) (A. S. Kaufman & Kaufman, 2014, Table 2.12).

KABC-II Normative Update

As noted at the start of this chapter, a normative update of the KABC-II was released in 2018. The published KABC-II was used with no changes to allow application of existing clinical research and interpretation guidelines to be applied to the new normative data. A normative sample of 700 children and adolescents ages 3 years, 0 months to 18 years, 11 months was collected in 2017. Each age year between the ages of 3 and 14 includes 50 children and adolescents, and ages 15–16 and 17–18 each include 50 adolescents. The sample was matched to the U.S. population on the stratification variables of gender, race/ethnicity, parent education level, and geographic region. Individuals in special education were included in the sample in a similar manner as described in the KABC-II. Psychometric information on the KABC-II Normative Update can be found in the KABC-II Normative Update supplemental manual (A. S. Kaufman et al., 2018).

Reliability

KABC-II NU global scale (MPI and FCI) split-half reliability coefficients were in the .90s for all age groups. The mean MPI coefficient was .96 for ages 3–6 and .97 for ages 7–18; the mean values for FCI were .97 (ages 3–6) and .98 (ages 7–18). Mean split-half reliability coefficients for the separate scales (e.g., Learning/Glr, Simultaneous/Gv) averaged .91–.98 for ages 3–6 and ranged from .91 to .97 for ages 7–18. Similarly, the Nonverbal Index had an average coefficient of .94 for ages 3–6 and .95 for ages 7–18. Mean split-half values for Core subtests across the age range were .86 (age 3), .90 (age 4), .91 (age 5), .88 (age 6), and .90 (ages 7–18).

Validity

Construct validity is based on the data reported previously for the KABC-II. In addition to the evidence provided for the KABC-II, correlation coefficients between the KABC-II NU FCI and the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; 2014) Full Scale IQ (FSIQ), corrected for the variability of the normative sample, was .72 (*N* = 79, ages 6–16). In addition, the KABC-II NU FCI correlated .74 (and the MPI correlated .68) with the Academic Skills Battery on the KTEA-3 Comprehensive Form for 99 individuals ages 4½ through 18 years.

INTERPRETATION

What the Global Scores Provide

KABC-II interpretation is focused on the scale profile; however, the global scores provide a general cognitive picture of a child's performance and provide a context in which the child's strengths and weaknesses can be determined. The MPI provides a measure of the child's general mental processing ability from a Lurian perspective, while the FCI provides a measure of general cognitive ability as defined in CHC theory. The differences in these approaches have been described earlier in this chapter.

When an examiner is interpreting the global scores, it is important to review the specific scales and subtests that constitute the global score. It is important to understand the index and subtest scatter that contributes to a global score when interpreting a global score such as the FCI or MPI. However, scatter among index and subtest scores is fairly common, with over half the original KABC-II normative sample exhibiting significant scatter (McGill, 2016). But despite the scatter among index and subtest scaled scores, there is strong psychometric support for global scores: They consistently demonstrate the highest reliability and stability estimates, as well as the highest predictive validity estimates, among all scores yielded by intelligence tests (Canivez, 2013). Therefore, while it is important to consider the scatter of scores contributing to global scores, global scores are interpretable even when significant scatter in scores is present (McGill, 2016). Also, a large-scale study of the Kaufman tests (KABC-II and KTEA-II) and the Woodcock–Johnson tests (WJ III), using structural equation modeling and CFA, demonstrated that the *g* that underlies cognitive batteries is essentially the same *g* that underlies achievement batteries (S. B. Kaufman, Reynolds, Liu, Kaufman, & McGrew, 2012); furthermore, Gf and *g* are virtually identical.

What the Scales Measure

Sequential/Gsm (Ages 4–18)

- *CHC interpretation*. Short-term memory (Gsm) is the ability to apprehend and hold information in immediate awareness briefly, and then use that information within a few seconds, before it is forgotten.
- *Luria interpretation*. Sequential processing is used to solve problems, where the emphasis is on the serial or temporal order of stimuli. For each problem, the input must be arranged in a strictly defined order to form a chain-like progression; each idea is linearly and temporally related only to the preceding one.

Simultaneous/Gv (Ages 4–18)

- *CHC interpretation*. Visual processing (Gv) is the ability to perceive, manipulate, and think with visual patterns and stimuli, and to mentally rotate objects in space.
- *Luria interpretation*. Simultaneous processing demands a Gestalt-like, frequently spatial, integration of stimuli. The input has to be synthesized simultaneously, so that the separate stimuli are integrated into a group or conceptualized as a whole.

Learning/Glr (Ages 4–18)

- *CHC interpretation*. Long-term storage and retrieval (Glr) is the ability both to store information in long-term memory and to retrieve that information fluently and efficiently. The emphasis of Glr is on the *efficiency* of the storage and retrieval, not on the specific nature of the information stored.
- *Luria interpretation*. Learning ability requires an integration of the processes associated with all three of Luria's functional units. The attentional requirements for the learning tasks are considerable, as focused, sustained, and selective attention are requisites for success. However, for effective paired-associate learning, children need to apply both of the block 2 processes, sequential and simultaneous. Block 3 planning abilities help them generate strategies for storing and retrieving the new learning.

Planning/Gf (Ages 7–18)

- *CHC interpretation*. Fluid reasoning (Gf) refers to a variety of mental operations that a person can use to solve a novel problem with adaptability and flexibility—operations such as drawing inferences and applying inductive or deductive reasoning. Verbal mediation also plays a key role in applying fluid reasoning effectively.
- *Luria interpretation*. Planning ability requires hypothesis generation, revising one's plan of action, monitoring and evaluating the best hypothesis for a given problem (decision making), flexibility, and impulse control. This set of high-level skills is associated with block 3 executive functioning.

Knowledge/Gc (Ages 4–18)—CHC Model Only

- *CHC interpretation.* Crystallized ability (Gc) reflects a person's specific knowledge acquired within a culture, as well as the person's ability to apply this knowledge effectively. Gc emphasizes the *breadth* and *depth* of the specific information that has been stored.

- *Luria interpretation.* The Knowledge/Gc scale is not included in the MPI, but may be administered as a supplement if an examiner seeks a measure of a child's acquired knowledge. From a Lurian perspective, Knowledge/Gc measures a person's knowledge base, developed over time by applying block 1, block 2, and block 3 processes to the acquisition of factual information and verbal concepts. Like Learning/Glr, this scale requires an integration of the key processes, but unlike learning ability, acquired knowledge emphasizes the *content* more than the *process*.

Gender Differences

Analysis of KABC-II standardization data explored gender differences at four different age ranges: 3–4 years, 5–6 years, 7–12 years, and 13–18 years. At ages 3–4, females significantly outperformed males on the MPI, FCI, and Nonverbal Index by about 5 points (0.33 *SD*), but there were no other significant differences on the global scales at any age level (J. C. Kaufman, 2003). Consistent with the literature on gender differences, females tended to score higher than males at preschool levels. Females scored significantly higher than males at ages 3 and 4 years by about 3–4 points, with significant differences emerging on Learning/Glr (0.27 *SD*) and Simultaneous/Gv (0.34 *SD*). Also consistent with previous findings, males scored significantly higher than females on the Simultaneous/Gv scale at ages 7–12 (0.24 *SD*) and 13–18 (0.29 *SD*). Females earned significantly higher scores than males at ages 5–6 on the Sequential/Gsm scale (0.22 *SD*) and at ages 13–18 on the Planning/Gf scale (0.13 *SD*).

In a subsequent study of gender differences on the KABC-II at ages 6–18 years, also based on standardization data, Reynolds and colleagues (2008) applied multigroup higher-order analysis of mean and covariance structures and of multiple-indicator/multiple-cause models. They found that males consistently demonstrated a significant mean advantage on the latent visual–spatial ability (Gv) factor, even when *g* was controlled for; the same finding held true for the latent crystallized ability (Gc) factor at all ages except 17–18. Females scored higher on the latent higher-order *g* factor at all ages, although the difference was significant at only two ages. No significant age × gender interaction effect was identified (Reynolds et al., 2008). In a study of 137 Mexican American children ages 7–12 years, Gomez (2008) found a slight superiority of males over females on the MPI. In general, in all studies, gender differences on the KABC-II are small; even when statistically significant, they tend to be small in effect size (McLean, 1995).

Ethnicity Differences

Because the original K-ABC yielded considerably smaller ethnic differences than conventional IQ tests did, it was especially important to determine the magnitude of ethnic differences for the substantially revised and reconceptualized KABC-II. On the original K-ABC, the mean MPC for African American children ages 5:0–12:6 was 93.7 (A. S. Kaufman & Kaufman, 1983, Table 4.35). On the KABC-II, the mean MPI for African American children ages 7–18 in the standardization sample (N = 315) was 94.8, and the mean FCI was 94.0. On the two new KABC-II scales, African American children ages 7–18 averaged 94.3 (Planning/Gf) and 98.6 (Learning/Glr). At ages 3–6, African American children averaged 98.2 on Learning/Glr.

When standard scores were adjusted for SES and gender, European Americans scored 4.4 points higher than African Americans at 7–12 years on the MPI—smaller than an adjusted difference of 8.6 points on WISC-III FSIQ at ages 6–11 (J. C. Kaufman, 2003), and smaller than the 6-point difference at ages 6–11 on the WISC-IV. At the 13- to 18-year level, European Americans scored 7.7 points higher than African Americans on the adjusted MPI (J. C. Kaufman, 2003)—substantially smaller than the 14.1-point discrepancy on adjusted WISC-III FSIQ for ages 12–16, and also smaller than the 11.8-point difference at ages 12–16 on the WISC-IV. Similar results are observed in comparison to the WISC-V. The mean WISC-V FSIQ, adjusted for sex and parent education level, for European Americans is 8.7 points higher than the mean for African Americans at ages 6–16. (WISC-III data are from Prifitera, Weiss, & Saklofske, 1998; WISC-IV data are from Prifitera, Weiss, Saklofske, & Rolfhus, 2005; WISC-V data are from A. S. Kaufman, Raiford, & Coalson, 2016.) The adjusted discrepancies of

6.2 points (ages 7–12) and 8.6 points (ages 13–18) on the FCI, which includes measures of acquired knowledge, were also smaller than WISC-III and WISC-IV FSIQ differences. The KABC-II thus seems to continue in the K-ABC tradition of yielding higher standard scores for African Americans than are typically yielded on other instruments. In addition, as shown earlier in Table 12.4, the mean MPI and FCI earned by the 30 Native American children in Taos are about 7–8 points higher than this sample's mean WISC-IV FSIQ (Fletcher-Janzen, 2003).

Further ethnicity analyses of KABC-II standardization data were conducted for the entire age range of 3–18 years, which included 1,861 European Americans, 545 Hispanics, 465 African Americans, 75 Asian Americans, and 68 Native Americans. When adjusted for SES and gender, mean MPIs were 101.7 for European Americans, 97.1 for Hispanics, 96.0 for African Americans, 103.4 for Asian Americans, and 97.6 for Native Americans. Mean adjusted FCIs were about 1 point lower than the mean MPIs for all groups except European Americans (who had a slightly higher FCI) (J. C. Kaufman, 2003).

Dale, McIntosh, Rothlisberg, Ward, and Bradley (2011) examined ethnic differences for 49 African American and 49 European American preschool children from a U.S. Midwestern city (mean age = 5 years), who were matched on age, sex, and level of parental education. African American and European American preschool children had similar patterns of highs and lows in their profiles of scores and performed comparably on the different scales. Differences on the FCI (European American mean = 97.1, African American mean = 95.6) were a trivial and nonsignificant 1.5 points, "the smallest gap seen in the literature" (Dale, 2009, p. viii).

In a different approach to evaluating ethnic bias, Scheiber (2016, 2017) focused on differential construct validity and differential predictive validity of the KABC-II indexes in white, black, and Hispanic children in grades 1–12 (total *N* = 2,001). As discussed earlier in regard to construct validity, Scheiber (2016) demonstrated that the KABC-II produced the same five factors (i.e., constructs) for each of the three ethnic groups, thereby providing evidence of its construct validity for these three groups of students. Scheiber (2017) used structural equation modeling to further evaluate the differential validity of the KABC-II in predicting academic achievement on the KTEA-II (A. S. Kaufman & Kaufman, 2004b) for the same 2,001 students. Again, she found a lack of predictive bias in the slopes (i.e., similar magnitude of predictive validity coefficients) for the three separate samples of students in grades 1–12. When examining the intercepts in these analyses, Scheiber (2017) found consistent *over*prediction of the achievement scores for Hispanic and black students (notably, *under*prediction of achievement would have indicated test bias; this did not occur for any of the separate KABC-II indexes such as Planning/Gf or for the FCI). It is unclear why most KABC-II indexes overpredicted achievement for ethnic minority children. Scheiber (2017) suggested that the causes might be related to institutional or societal variables that have prevented black and Hispanic students from achieving in school at the level predicted by their KABC-II indexes.

In a variant of the differential prediction approach, Scheiber and Kaufman (2015) investigated the three KABC-II global scores—the FCI, MPI, and Nonverbal Index—to determine which one was the least biased in terms of its predictive validity for the three ethnic groups studied in grades 1–4, 5–8, and 9–12. Whereas the MPI and the Nonverbal Index were specifically developed to promote fair assessment for children with language difficulties and for children from ethnic minority groups, the surprising result of Scheiber and Kaufman's (2015) differential predictive validity study was that the FCI proved to be the least biased of the three global indexes. These findings do not minimize the importance of using the MPI or Nonverbal Index in clinical circumstances that dictate the need for fair assessment for children with linguistic or cultural differences. However, the results of the study provide a reinforcement of the notion that for students in general, across a wide grade span, the FCI (even with its inclusion of Knowledge/Gc tasks) provides an unbiased measure of general cognitive ability as a predictor of achievement for ethnically diverse children and adolescents.

CLINICAL APPLICATIONS

Like the original K-ABC, the KABC-II was designed to be a clinical and psychological instrument, not merely a psychometric tool. It has a variety of clinical benefits and uses:

1. The identification of process integrities and deficits for assessment of individuals with specific learning disabilities.

2. The evaluation of individuals with known or suspected neurological disorders, when the KABC-II (and KABC-II NU) is used along with other tests as part of a comprehensive neuropsychological battery.
3. The integration of the individual's profile of KABC-II (and KABC-II NU) scores with clinical behaviors observed during the administration of each subtest (Fletcher-Janzen, 2003)—identified as Qualitative Indicators (QIs) on the KABC-II record form (see A. S. Kaufman & Kaufman, 2004a; A. S. Kaufman et al., 2005).
4. The selection of the MPI to promote the fair assessment of children and adolescents from African American, Hispanic, Native American, and Asian American backgrounds (an application that has empirical support, as summarized briefly in the previous section on "Ethnicity Differences" and in Table 12.4).
5. Evaluation of individuals with known or suspected ADHD, intellectual disabilities/developmental delays, speech–language difficulties, emotional/behavioral disorders, autism, reading/math disabilities, intellectual giftedness, and hearing impairment (KABC-II data on all of these clinical samples are presented and discussed in the KABC-II manual and KABC-II NU manual supplement).

We believe that whenever possible, clinical tests such as the KABC-II should be interpreted by the same person who administered them—an approach that enhances the clinical benefits of the instrument and its clinical applications. The main goal of any evaluation should be to *effect change* in the person who was referred. Extremely competent and well-trained examiners are needed to best accomplish that goal; we feel more confident in a report writer's ability to effect change and to derive clinical benefits from an administration of the KABC-II when the professional who interprets the test data and writes the case report has also administered the test and directly observed the individual's test behaviors.

INNOVATIONS IN MEASURES OF COGNITIVE ASSESSMENT

Several of the features described here for the KABC-II (and, therefore, for the KABC-II NU) are innovative in comparison to the Wechsler and Stanford–Binet tradition of intellectual assessment, which has century-old roots. However, some of these innovations are not unique to the KABC-II; rather, several of them are shared by other contemporary instruments, such as the WJ IV (Schrank et al., 2014), the Cognitive Assessment System—Second Edition (CAS-2; Naglieri, Das, & Goldstein, 2014), and the most recent revisions of the Wechsler scales (Wechsler, 2008, 2012, 2014).

Integrates Two Theoretical Approaches

As discussed previously, the KABC-II utilizes a dual theoretical approach—Luria's neuropsychological theory and CHC theory. This dual model permits alternative interpretations of the scales, based on the examiner's personal orientation or based on the specific individual being evaluated. One of the criticisms of the original K-ABC was that the mental processing scales were interpreted solely from the sequential–simultaneous perspective, despite the fact that alternative interpretations are feasible (Keith, 1985). The KABC-II addressed that criticism and provided a strong theoretical foundation for the test by building the test on a dual theoretical model. In their review of the KABC-II, Bain and Gray (2008) have praised the theoretical model:

> In terms of construct validity, Kaufman and Kaufman's efforts to combine the two theoretical models, the Luria model and the CHC model, into one instrument is particularly attractive to those of us who favored the use of the original K-ABC for younger children but found ourselves scrambling for variations on subtests measuring broad and narrow abilities for cross-battery assessment. (p. 100)

(For a comprehensive review of cross-battery assessment, see Flanagan et al., Chapter 27, this volume.)

Provides the Examiner with Optimal Flexibility

The two theoretical models that underlie the KABC-II not only provide alternative interpretations of the scales, but also give the examiner the flexibility to select the model (and hence the global score) that is better suited to the individual's background and reason for referral. As mentioned earlier, the CHC model is ordinarily the model of choice, but examiners can choose to administer the Luria model when excluding measures of acquired knowledge from the global score promotes fairer assessment of a child's general cognitive ability. The MPI that results is an especially pertinent global score, for example, for individuals who have a receptive or expressive language disability or who are from a bilingual background. This flexibility of choice permits fairer assessment for anyone referred for an evaluation. Note, however, that the results of differential predictive validity studies with large samples of typically developing white, black, and Hispanic students found that all three KABC-II global indexes are unbiased, with the lowest differences observed with the FCI—at least regarding the prediction of academic achievement (Scheiber & Kaufman, 2015).

The examiner's flexibility is enhanced as well by the inclusion of supplementary subtests for most scales, including a supplementary Delayed Recall scale to permit the evaluation of a child's recall of paired associations that were learned about 20 minutes earlier. Hand Movements is a supplementary Sequential/Gsm subtest for ages 4–18, and Gestalt Closure is a supplementary task across the entire 3–18 range. Supplementary subtests are not included in the computation of standard scores on any KABC-II scales, but they do permit the examiner to follow up hypotheses suggested by the profile of scores on the Core Battery, to generate new hypotheses, and to increase the breadth of measurement on the KABC-II constructs.

Promotes Fairer Assessment of Minority Children

As mentioned earlier, children and adolescents from minority backgrounds—African American, Hispanic, Asian American, and Native American—earned mean MPIs that were close to the normative mean of 100, even prior to adjustment for SES and gender. In addition, there is some evidence that the discrepancies between European Americans and African Americans are smaller on the KABC-II than on the WISC-IV, and that Native Americans score higher on the KABC-II than the WISC-IV (see Table 12.4). These data, as well as additional data (Dale et al., 2011; Scheiber, 2016, 2017), suggest that the KABC-II (and KABC-II NU), like the original K-ABC, will be useful for promoting fairer assessment of children and adolescents from minority backgrounds.

Offers a Separate Nonverbal Scale

Like the K-ABC, the KABC-II (and KABC-II NU) offers a reliable, separate Nonverbal scale composed of subtests that can be administered in pantomime and responded to nonverbally. This special global scale, for the entire 3–18 age range, permits valid assessment of children and adolescents with hearing impairments, moderate to severe speech–language disorders, limited English proficiency, and so forth.

Permits Direct Evaluation of a Child's Learning Ability

The KABC-II Learning/Glr scale allows direct measurement of a child's ability to learn new information under standardized conditions. These tasks also permit examiners to observe the child's ability to learn under different conditions; for example, Atlantis gives the child feedback after each error, but Rebus does not offer feedback. In addition, Rebus involves meaningful verbal labels for symbolic visual stimuli, whereas Atlantis involves nonsensical verbal labels for meaningful visual stimuli. When examiners choose to administer the supplementary Delayed Recall scale to children ages 5–18, they are then able to assess the children's ability to retain information that was taught earlier in the evaluation.

USE WITH THE KTEA-3

The KTEA-3 can be used in tandem with the KABC-II to identify skill deficits and potential process deficits in children with learning difficulties. (See Morrison, Singer, & Raiford, Chapter 29, this volume, for detailed info on the KTEA-3.) When an achievement measure like the KTEA-3 is linked with a cognitive measure like the KABC-II, examiners can efficiently collect in-depth data that can help them test hypotheses, formulate a diagnosis, and make decisions about eligibility, as well as bridge the gap between assessment and intervention. The KTEA-3 is linked to the KABC-II and provides a cohesive theoretical basis for interpreting a comprehensive assessment battery. This integration extends to interpreting the KABC-II and KABC-II NU cognitive scales in conjunction with students' patterns of errors on the KTEA-3 (e.g., Liu et al., 2017).

Thus, to glean information about a wide spectrum of abilities within the CHC framework, examiners can integrate findings from the KTEA 3 and KABC-II. As described earlier in the chapter, the KABC-II addresses five of the CHC broad abilities: short-term memory (Gsm), visual processing

(Gv), long-term storage and retrieval (Glr), fluid reasoning (Gf), and crystallized ability (Gc). The KTEA-3 Comprehensive Form measures three additional broad abilities: auditory processing (Ga), reading and writing (Grw), and quantitative knowledge (Gq). It also measures Glr narrow abilities that increase the breadth of the Glr narrow abilities measured by the KABC-II when the two batteries are administered together. Moreover, the KABC-II indirectly measures one of the Gq narrow abilities (i.e., mathematics achievement, by virtue of the fact that Rover and Block Counting each require a child to count). Publications by Flanagan and her colleagues describe CHC theory in depth, and provide more detail in test interpretation from that theoretical perspective (see, e.g., Flanagan, Ortiz, & Alfonso, 2013). Lichtenberger and Breaux (2010) provide a CHC-based analysis of each KABC-II subtest that outlines the narrow CHC abilities measured by these tasks. This analysis is summarized below.

CHC ABILITIES MEASURED BY KABC-II SUBTESTS

Long-Term Storage and Retrieval (Glr) Narrow Ability

Associative Memory

- KABC-II Atlantis
- KABC-II Rebus
- KABC-II Atlantis—Delayed
- KABC-II Rebus—Delayed

Learning Abilities

- KABC-II Atlantis—Delayed
- KABC-II Rebus—Delayed

Short-Term Memory (Gsm) Narrow Ability

Memory Span

- KABC-II Word Order (without color interference)
- KABC-II Number Recall
- KABC-II Hand Movements

Working Memory

- KABC-II Word Order (with color interference)

Visual Processing (Gv) Narrow Ability

Visual Memory

- KABC-II Face Recognition
- KABC-II Hand Movements

Spatial Relations

- KABC-II Triangles

Visualization

- KABC-II Triangles
- KABC-II Conceptual Thinking
- KABC-II Block Counting
- KABC-II Pattern Reasoning
- KABC-II Story Completion

Spatial Scanning

- KABC-II Rover

Closure Speed

- KABC-II Gestalt Closure

Fluid Reasoning (Gf) Narrow Ability

Induction

- KABC-II Conceptual Thinking
- KABC-II Pattern Reasoning
- KABC-II Story Completion

General Sequential Reasoning

- KABC-II Story Completion
- KABC-II Rover
- KABC-II Riddles

Note. Success on KABC-II Rebus is dependent to some extent on Fluid Reasoning.

Crystallized Ability (Gc) Narrow Ability

General Information

- KABC-II Verbal Knowledge (items that measure general information)
- KABC-II Story Completion

Language Development

- KABC-II Riddles

Lexical Knowledge

- KABC-II Riddles
- KABC-II Verbal Knowledge (items that measure vocabulary)
- KABC-II Expressive Vocabulary

Grammatical Sensitivity

Note. Success on KABC-II Rebus is dependent to some extent on Grammatical Sensitivity.

Auditory Processing (Ga) Narrow Ability

Phonetic Coding—Synthesis

Note. Deficits in certain Ga narrow abilities, such as Speech Sound Discrimination (US), may affect performance negatively on such tests as KABC-II Riddles, Word Order, and Number Recall.

Quantitative Knowledge (Gq) Narrow Ability

Mathematical Achievement

- KABC-II Rover
- KABC-II Block Counting

Appendix 12.1 presents a case study that demonstrates how the KABC-II can be integrated into a comprehensive evaluation. All personally identifiable information has been altered in the case study report to preserve the confidentiality of the examinee.

APPENDIX 12.1

Illustrative Case Study

Name: Jacob W.
Age: 5 years, 10 months
Grade in school: Kindergarten (spring semester)

REASON FOR REFERRAL

Jacob attends kindergarten at a private school. He was referred for an evaluation by his parents, Mr. and Mrs. W., and his teacher, Mrs. A., due to concerns about Jacob's current cognitive and motor abilities. Jacob has been struggling in school and is not progressing at the expected pace in his kindergarten class. In addition, Mrs. A. reports that some skills Jacob acquired early in the school year have markedly declined. Mrs. A has also observed fine and gross motor difficulties, and his parents confirm that he has always been clumsier and less coordinated than his peers. Both Jacob's parents and his teacher and school are seeking recommendations for ways to assist Jacob to be successful in the classroom.

EVALUATION PROCEDURES

- Collateral interview with parent, Mrs. W.
- Collateral interview with teacher, Mrs. A.
- Review of school records
- Behavior Assessment Scale for Children, Third Edition (BASC-3; Reynolds & Kamphaus, 2015), parent and teacher versions
- Delis Rating of Executive Function (DREF; Delis, 2012), parent and teacher versions
- Kaufman Assessment Battery for Children—Second Edition (KABC-II NU)
- Kaufman Test of Educational Achievement, Third Edition (KTEA-3), Form A
- NEPSY—Second Edition (NEPSY-II; Korkman, Kirk, & Kemp, 2007)
- Bruininks–Oseretsky Test of Motor Proficiency, Second Edition (BOT-2; Bruininks & Bruininks, 2005)

The KTEA-3 was administered on Q-interactive with a touch tablet (iPad).

BACKGROUND INFORMATION

Background information was obtained through separate interviews with Mrs. W. and with Mrs. A.

Family/Social History

Jacob lives with his mother, father, and two siblings. Mrs. W. reported that Jacob is a loving child who tends to "go with the flow" of the household. She also reported that he tends to be slow and takes his time to get ready in the morning, requiring frequent prompting to get going. Jacob's mother reports that he is "laid back" and relatively quiet. She indicated that he enjoys playing with his younger sister, but his sister tends to lead the play. When he doesn't want to do something, he will just sit still and not interact. However, he enjoys interacting with others and makes friends easily.

Mrs. W. noted that Jacob has problems with attention, and that previously it was a battle every evening to get him to complete homework assigned in kindergarten. He has difficulty with attention and working independently. He is easily distracted and loses track of what he is doing. When he is frustrated, he puts his hands on his head and doesn't continue. Usually after a short break, he will successfully continue with the task. He is working with a behavioral therapist weekly for 6 weeks, and this intervention has improved his behavior at home, with homework being completed more quickly and with less distress. Mrs. W. reported that the weekly intervention has also improved her relationship with Jacob because there is less stress and conflict in regard to schoolwork and behavior.

Jacob's mother also reported that he is very sensitive to others. He can get distressed over sad moments in shows he is watching, and he is very attuned to others' feelings. However, she reported that he recovers quickly from moments of distress and responds appropriately to support. There are no reports of educational, emotional, or social difficulties in Jacob's family members or relatives.

The interviewer noted in particular that when Mrs. W. was asked to indicate Jacob's strengths, she became emotional; she said that this is something that she never hears about Jacob. She indicated that reports from school are almost always negative, and that it was hard for her to think of his strengths. She was able to identify his mood and attitude as strengths, as well as his memory, comprehension, and social skills. The following day, a conference was held with the teacher about Jacob's mother's response, and it was agreed that daily communications could be changed to include more positive feedback to the family.

Medical/Developmental History

Jacob is small for his age, based on parental report. He was the result of a full-term, healthy pregnancy but did experience complications at birth. He had fluid in his lungs and spent 2 days in the NICU before he came home; there were no reports of anoxia, and his mother reported that there were no further complications. Jacob met most cognitive-developmental milestones as expected, although he was delayed in motor development. Although Jacob was an early talker, he speaks softly and mumbles at times. However, his mother reported that he has a large vocabulary and that he speaks and communicates well. She reported that his hearing and vision are within normal limits. Mrs. A. noted Jacob's quiet speech and confirmed his vocabulary and communication skills.

Jacob has a history of poor muscle tone. He has poor balance, and he is not as well developed motorically as his peers. For example, he cannot stand on one foot, and he runs with his arms in close to his body. Jacob's mother reports that he has been behind on motor development since birth. His teacher reported particular difficulty with eating and swallowing, and noted that Jacob eats finger foods by inserting his entire hand into his mouth. His mother reported that when he began eating, he frequently gagged and choked due to weak throat muscles. However, she stated that this has improved greatly, and that his swallowing and eating behavior is related to the foods he is eating. She cuts up his food into small pieces to accommodate his eating difficulties.

Educational History

Jacob started kindergarten in the fall and is currently in his sixth month of instruction. Mrs. A. reported that she has to frequently remind Jacob to focus and complete his work. She reported some regression of learned skills (e.g., spelling, months of the year) over the year. Jacob has not mastered his numbers and is not yet counting consistently above 20. She reported that reading fluency is also a problem, although she has seen some improvement in reading and spelling recently. In addition, he is slow in completing his work and takes longer to learn new material. Mrs. A. has placed Jacob at the front of the classroom to provide him with more support. She gives him instructions and has him repeat them back to her; often she repeats the instructions.

Jacob is working with a dyslexia therapist on his handwriting skills. His tracing and production of letters has improved, but reports indicate that he is not on grade level. Mrs. A. is recommending that he repeat kindergarten to allow him greater opportunity to learn and to catch up with his peers. His parents agree with this recommendation, but are concerned with his slower progress and with ways to help him.

Previous Test Results

Jacob completed a psychological evaluation through his local school district and had an evaluation with a developmental pediatrician. Parents reported that both evaluations showed that Jacob was in the average range. These prior reports were not available for this report.

BEHAVIORAL OBSERVATIONS

Classroom Observations

A classroom observation was conducted to observe Jacob in his classroom environment. At the beginning of the observation, he was sitting quietly at his desk. He had drawn over his paper instead of completing his work, and was now completing a “time out” while waiting his turn for individual reading instruction. He was observing everything in the room and fiddling with his papers, but he was not attempting to interact with other classmates or the teacher, or to get out of his seat and move around the classroom. He was dressed casually and wore a baseball cap. He had a friendly smile and made eye contact when introduced. During reading, he was very attentive to the teacher, but frequently had to be redirected to the reading task. His reading fluency was slow and did not increase when he was prompted; however, he was generally accurate in his reading, although he had more difficulty with blended word sounds. He utilized a finger-pointing technique to keep track of where he was on the page, and the teacher turned pages for him. Following reading, he went to a second center in the classroom, where he was required to use scissors. He had a loose gait and stumbled while moving between centers. He had mild difficulty with the scissors, and his cutting was imprecise. He placed all pieces of the paper he cut into a pile instead of sorting out the sections he needed to glue to his paper. He frequently looked to the teacher and his classmates for direction on what he should be doing.

Test Session Observations

Jacob was always happy and willing to participate in testing. Testing was completed in an empty, undecorated classroom, free from both visual and verbal distractions. He was talkative and repeatedly made conversation as he completed tasks. He frequently jumped from topic to topic and often reacted to stimuli on the tasks by relating them to his own experiences. For example, upon seeing a fish with headphones, he said, “He must be listening to music like I do.” He was hesitant to guess and often asked questions about the stimuli instead of answering the questions. He was concerned about his performance at times, asking if he got a question correct. However, he was more interested in completing the testing so he could go back to his friends.

Jacob was tested across four sessions, as he had difficulty maintaining performance beyond 45 minutes. He had difficulty maintaining attention to tasks and frequently asked to stop or do something else. However, he responded to redirection and prompting to continue on tasks. On lengthier tasks, he required frequent prompting to continue on the tasks. Several times when he stopped working, he stared blankly at the examiner or materials and had to be prompted to return to the task. When this occurred, he required the directions to be repeated before he completed an item. His pace throughout testing was fairly slow, and he frequently made mistakes. Jacob made a lot of self-corrections throughout testing, which increased the length of time it took to complete tasks, but did increase his accuracy.

TEST RESULTS AND INTERPRETATION

Behavior Reports

Jacob’s mother and teacher completed two behavioral rating scales assessing behavioral problems and executive functioning. The results are displayed in Table 12.A.1. Executive functioning is the general ability to plan, organize, and direct behavior. For most areas, the reports were very similar. Jacob exhibits difficulty with attention, executive functioning, working memory, and problem solving. The difficulties with attention and executive functioning are severely elevated both at home and school. In addition, Jacob exhibits normal levels of activity and impulsive behaviors in both environments. Similar behaviors are reported across environments as well, with the need for frequent prompting, difficulty following directions, and difficulty completing multiple tasks reported as the most stressful by both raters.

Jacob’s mother and teacher differed somewhat in their ratings of his behavior problems, with greater difficulty generally being reported in the classroom than at home. Jacob exhibits greater withdrawal symptoms (e.g., refuses to talk, prefers to play alone, isolates self from others) and greater social problems (e.g., poor adjustment to changes in routine, slow involvement in group activities) in the classroom. He demonstrates better adaptability and social skills at home, and his mother reported good resilience (e.g., recovers well from setbacks or changes).

TABLE 12.A.1. Jacob's Behavioral Rating Scores (Teacher and Parent Forms)

Scale/index	Teacher *T* score (percentile rank)	Parent *T* score (percentile rank)
BASC-3		
Hyperactivity	43 (30)	42 (24)
Aggression	43 (25)	41 (14)
Externalizing Problems	42 (25)	40 (14)
Anxiety	45 (37)	48 (50)
Depression	46 (41)	50 (58)
Somatization	*60 (88)*	37 (7)
Internalizing Problems	50 (58)	44 (28)
Attention Problems	*68 (96)*	*63 (89)*
Atypicality	59 (86)	45 (40)
Withdrawal	*64 (90)*	38 (8)
Behavioral Symptom Index	55 (73)	46 (38)
Adaptability	46 (37)	60 (84)
Social Skills	41 (23)	61 (87)
Functional Communication	*38 (14)*	54 (58)
Activities of Daily Living	—	40 (16)
Adaptive Skills	*40 (20)*	55 (64)
DREF		
Behavioral Functioning	50 (50)	48 (42)
Emotional Functioning	51 (54)	47 (38)
Executive Functioning	*78 (>99)*	*65 (93)*
Total Composite	*61 (86)*	54 (66)
Attention/Working Memory	*72 (99)*	*70 (98)*
Activity Level/Impulse Control	47 (38)	45 (31)
Compliance/Anger Management	52 (58)	54 (66)
Abstract Thinking/Problem Solving	*74 (99)*	*61 (86)*
Teacher top stressors		
Is off task when he is supposed to do classwork.		
Cannot do two or more tasks at the same time.		
Does not start classwork without extra prompting.		
Has trouble completing tasks like homework or class projects.		
Has trouble following directions.		
Parent top stressors		
Is off task when he is supposed to do homework or chores.		
Loses track of what he is supposed to do, due to noises or other things going on.		
Forgets what he is supposed to do.		
Cannot do two or more tasks at the same time.		
Has trouble following directions.		

Note. Italics indicate at-risk or clinically significant results.

In general, Jacob's behaviors at home and school fall into the normal or average range. However, attentional control was elevated on the BASC-3 both at home and at school. Moreover, his teacher and parent ratings on the DREF indicated severe elevations in attention/working memory and in executive functioning. The major stressors indicated by both his teacher and mother included being off task when he is supposed to be completing work/chores, having difficulty completing multiple tasks, and having trouble following directions.

Assessment of Cognitive Abilities

General cognitive ability refers to an individual's overall ability to reason, solve problems, and learn information in an efficient and timely manner. Jacob was administered the KABC-II NU, a comprehensive test of general cognitive abilities, to evaluate his overall level of functioning as well as provide a profile of cognitive abilities. The results are displayed in Table 12.A.2. He obtained a KABC-II NU Fluid–Crystallized Index (FCI) of 91 (95% confidence interval [CI] = 87–95), placing his general cognitive ability at the 27th percentile and classifying it in the average range.

Jacob's intellectual functioning is made up of a profile of specific cognitive abilities, which provides far greater information than a single overall score. Jacob's cognitive skills are in the average range for his age. His profile of scores on the KABC-II NU suggests some variability across specific cognitive abilities. Jacob's index scores ranged from 85 (16th percentile) to 104 (61st percentile). A closer review of his performance on the individual scales provides a better description of Jacob's abilities.

Jacob demonstrated a personal relative strength in crystallized ability, which reflects his breadth and depth of specific knowledge acquired within a culture, as well as his ability to apply this knowledge effectively. He obtained a Knowledge/Gc Index score of 104 (95% CI = 96–111; 61st percentile), which is also a measure of verbal ability and reflects Jacob's observed verbal skills. His strongest performance was observed on Riddles, a task requiring Jacob to listen to a series of verbal characteristics describing a concept, and then to point to or name the described concept. This task requires reasoning as well as knowledge of words and concepts.

Jacob's ability to learn new information, to store that information in long-term memory, and to retrieve it fluently and efficiently was average. He obtained a Learning/Glr scale score of 97 (95% CI = 94–100; 42nd percentile). His performance on two tasks requiring him to associate verbal labels with visual stimuli demonstrated good acquisition of and immediate recall of the information. However, his delayed recall of this learned information was in the lower extreme, with a Delayed Recall scale score of 66 (95% CI = 56–76; 1st percentile). On a task requiring him to recall verbal labels for visual stimuli, he was unable to produce any correct responses 20 minutes after learning the information. He did slightly better on a task requiring him to recognize and identify visual stimuli when provided with the verbal label.

Jacob demonstrated relative significant weaknesses in his ability to process visual and spatial information mentally and in his short-term memory abilities (when stimuli are presented in sequential fashion). His score of 85 (95% CI = 80–92; 16th percentile) on the Simultaneous/Gv scale reflects relatively lower ability to perceive, manipulate, and think with visual patterns and stimuli, and to mentally rotate objects in space. His weakest subtest performance was observed on a task requiring him to assemble plastic shapes or triangular blocks to match a picture of a design shown in a stimulus book. His relatively lower performance was influenced by his constructional abilities; however, most of his failures were due to misplaced shapes in his constructions. On tasks requiring reasoning utilizing visual stimuli, Jacob demonstrated slightly better performance.

Additionally, Jacob demonstrated a relative weakness in his short-term or working memory ability, which can be defined as the ability to take in information, hold it in immediate awareness briefly, and perform some mental manipulation or recall of that information within a few seconds. Jacob obtained a Sequential/Gsm Index score of 85 (95% CI = 79–93; 16th percentile). On a task requiring him to repeat a series of numbers, he had difficulty consistently recalling spans of greater than three digits. Interestingly, on the second task—which required him to listen to a series of words and then point to the correct pictures of the common objects named by the examiner—he also had difficulty recalling a span of longer than three words. Although short-term memory and visual processing were both relative weaknesses for Jacob, they were both in the average range for his age.

Assessment of Achievement

The KTEA-3 Comprehensive Form was administered to assess Jacob's current academic achieve-

TABLE 12.A.2. Jacob's Scores on Cognitive Testing

Index/scale	Index/standard score (mean = 100, *SD* = 15)	Subtest scaled score (mean = 10, *SD* = 3)	*T* score	Percentile rank
	KABC-II NU			
Sequential/Gsm	85			16
Simultaneous/Gv	85			16
Learning/Glr	97			42

Inhibition Total Errors				*11–25%*
Inhibition Self-Corrected Errors				*2–5%*
Inhibition Total Errors		6		*11–25%*
	BOT-2 (male norms)			
Fine Manual Control			*38*	*12*
Manual Coordination			*34*	6
Body Coordination			*36*	8
Strength and Agility			*37*	*10*
Total Motor Composite			*34*	6

Note. Italics indicate at-risk or clinically significant results.

ment. The results are displayed in Table 12.A.2. Jacob scored in the average range on the Academic Skills Battery, reflecting his overall achievement. There was significant variability in his composite scores, ranging from a standard score of 99 (95% CI = 93–105; 47th percentile) on the Reading Composite to a standard score of 78 (95% CI = 73–83; 7th percentile) on the Math Composite. His Math Composite was a both a normative and relative weakness for him. His Written Language Composite of 89 (95% CI = 84–95; 23rd percentile) included notable score variability in its subtests. Jacob obtained a significantly higher score on spelling words spoken by the examiner (Spelling standard score = 106; 82nd percentile) than on expressing himself in writing sentences (Written Expression standard score = 74; 4th percentile).

Reading

Jacob obtained his highest performance on the Reading Composite. The reading skills measured include letter–sound correspondence (phonics), word recognition, decoding, fluency, and comprehension. Jacob's overall reading skills were in the average range. In addition to the reading measures included in the Reading Composite, Jacob completed measures of Phonological Processing and Oral Fluency. Both phonological processing and rapid automatic naming have been found to be critical to academic achievement. Jacob's performance on Phonological Processing was average for his age range (standard score = 94; 34th percentile). However, his performance on fluency measures was in the low average to low range (Oral Fluency Composite = 65; 1st percentile). His performance on these tasks was consistent with teacher and parent reports of Jacob's slowness on tasks in the classroom and at home.

Math

Jacob's math computation and arithmetic skills, and his math problem-solving skills, were below average. His performance was comparable on both subtests (standard scores of 79–80), indicating difficulty in his ability to apply mathematical principles to real-life problems and to perform mathematical calculations accurately. Many of the errors made in math appeared to be related to poor understanding of math structure. For example, on problems such as 1 + 1, he would respond by writing 11.

Writing

As noted earlier, Jacob demonstrated variability in his performance across writing tasks. When he was completing the tasks, he utilized an adaptive pencil grasp. As he produced letters, he used incorrect letter formation on multiple letters and frequently identified a letter out loud that did not match the letter he was writing (e.g., he stated *b* and madet he *b* sound while writing the letter *d*). Several times during spelling, he began a word and wrote the second letter to the left of the first letter instead of to the right. He usually caught this and self-corrected to spelling left to right. However, once he wrote the entire word in reverse before noticing his error. His handwriting was mostly legible, but generally poor. His spelling ability was average, but many of the letters were poorly formed, and it took him a long time to write each letter.

Comprehension

Jacob's comprehension ability both from reading passages and orally presented information was average (Comprehension standard score = 105; 63rd percentile). His Listening Comprehension (standard score = 110; 75th percentile) was higher than his Reading Comprehension (standard score = 98; 45th percentile), although both scores were in the average range.

Assessment of Neuropsychological Abilities

Additional testing was completed to assess Jacob's cognitive skills. He completed several subtests of the NEPSY-II; the results are displayed in Table 12.A.2. On measures of attention, he was in the borderline range overall, but produced a high rate of omission errors (percentile rank = 6–10%) in comparison to a relatively low rate of commission errors (percentile rank = 51–75%). Omission errors are failures to respond when a response is required (e.g., indicative of inattention), while commission errors are responses when a response is not required (e.g., indicative of impulsivity or poor inhibition). On measures of inhibition, Jacob also demonstrated difficulty, although his performance on these tasks was influenced by slow responding time and a high rate of errors. However, it is important to note that he corrected most of his errors, which added to his slow time. This finding is consistent with his performance on the fluency measures on the KTEA-3. Jacob's performance on measures of language, visuospatial processing, and memory and learning was consistent with his performance on the KABC-II NU and KTEA-3. He demonstrated relatively intact language and learning abilities, but difficulties in visual–spatial processing.

Assessment of Motor Abilities

Motor functioning includes fine motor skills such as handwriting and tracing, as well as gross motor skills such as balance, coordination, and gait. Jacob's fine and gross motor abilities are below what is expected for his age (BOT-2 Total Motor Composite = 34; below average). Again, the results are displayed in Table 12.A.2. The majority of his scores fell into the below-average range on the BOT-2. He had a relatively better performance on the fine motor integration task, which required him to copy shapes. As he did on the written tasks on the KTEA-3, he utilized an immature pencil grasp.

DIAGNOSTIC IMPRESSIONS

The following *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition (DSM-5) diagnoses are well supported:

F90.0 Attention-deficit/hyperactivity disorder, predominantly inattentive presentation
F82 Developmental coordination disorder (need to rule out medical or neurological cause)

The following DSM-5 diagnosis is suggested:

F81.2 Specific learning disorder, with impairment in mathematics

SUMMARY

Jacob, a 5-year old attending kindergarten in a private school, was referred for an evaluation by his parents and teacher due to concerns about his inattention, difficulties in school, and motor difficulties. Jacob was cooperative with testing, but required multiple testing sessions to accommodate his difficulty in maintaining effort and attention. He demonstrated difficulty maintaining attention and focus on tasks both during the testing sessions and during a classroom observation.

Jacob demonstrated several behavioral strengths during the assessment. He exhibited a positive attitude and strong social skills, which are also reflected in his good relationships with his family and peers. In addition, he was receptive to feedback and returned to work when prompted without struggle or complaint. However, parent and teacher reports as well as clinical observations indicated significant difficulties with sustaining attention, initiating work, and completing tasks in a timely manner.

Jacob demonstrated several cognitive and academic strengths. His general cognitive ability was in the average range, as were all of his KABC-II NU index scores. He exhibited a relative strength in his verbal crystallized ability, and relative cognitive weaknesses in visual processing and short-term memory; however, all his scores fell within the average range with the exception of his Delayed Recall index score, which was low. Jacob demonstrated significant variability in his composite scores on the KTEA-3, with a significant strength in his reading abilities and a normative and relative weakness in his math abilities. Additionally, he demonstrated a relative strength on tests of reading and listening comprehension. Further cognitive testing demonstrated difficulties with attention and executive functioning, and supported the strengths and weaknesses observed on the KABC-II NU. Finally, Jacob demonstrated significant motor delays in relation to his peers. Nonetheless, he can improve his achievement if he is shown how to use his cognitive strengths to facilitate school learning.

RECOMMENDATIONS

Further Assessment and Reevaluation

- Given Jacob's young age and developing skills, it is highly recommended that he be reevaluated in a year, to track his progress and develop appropriate supports if needed.
- It is recommended that a full medical and neurological evaluation be completed, to rule out any underlying neurological or medical causes for Jacob's motor and attentional difficulties.
- An oral–motor swallowing evaluation by a speech–language pathologist to determine any need for intervention with swallowing is also recommended.
- An evaluation by an occupational or physical therapist is strongly recommended, to create a

specific treatment plan for developing Jacob's motor abilities and to establish appropriate targets for intervention.

General Recommendations

- Utilize Jacob's strengths to help him on more difficult tasks or tasks that require his cognitive weaknesses.
    - Allow spoken responding if written responses are not required.
    - If he has difficulty initiating a response, provide a cue or choices for him to demonstrate learning.
    - For tasks in which speed is not essential, allow him additional time to complete tasks.
    - For tasks that require time, reward improvements in performance accuracy or completion.

Executive Functioning

- Use a consistent behavior system at both school and home.
- Develop predictable routines (e.g., regular school schedule, homework at same time).
- Develop his executive skills through appropriate modeling, chaining, and practice:
    - Modeling:
        - Pair Jacob with a peer for tasks requiring multiple steps or complex steps.
        - Use a talk-aloud procedure to help Jacob plan steps.
    - Chaining:
        - Use checklists for completing tasks (visual or written) that have steps in sequential order. Have him review a full list and then work on the first step. When possible, review the first step before moving to the next step, so he begins to put the steps together. When there are more steps, always review the steps he has completed. As he is learning a new task, it will help him to repeatedly go through all the steps he needs to complete a task.
    - Practice:
        - Have Jacob talk through his tasks as he learns them; this will take advantage of his verbal abilities and allow him to put steps together.
        - Utilize a daily behavioral self-report card. Include only a few key behaviors on this card, and have him evaluate his performance on these. This way, he can begin to direct his behavior instead of being evaluated by others only.

Attention/Working Memory

- Reduce distractions in classroom and other working environments when possible during learning and testing times.
- Seat Jacob in a location that maximizes his ability to pay attention (nearest to teacher, near kids with good attention skills, away from visual distractions).
- Utilize multiple modalities to teach constructs (e.g., use both verbal and visual teaching when introducing new concepts).
- Break tasks into short segments, and provide visual cues for steps in multistep tasks. Use memory aids (e.g., pictorial graphic organizers) as reminders of the instructions or to guide the completion of an activity.
- Provide incentives for sustained attention.
    - Begin with requiring attention for short lengths of time, and then extend these as Jacob achieves his goals.
    - Use a high-interest activity to reinforce attention on a low-interest activity.
- Provide cues to signal off-task behavior and improve Jacob's self-awareness. Consider nonverbal cues (such as tapping a finger on a reminder card on his desk). As he progresses, these cues can be minimized.

Motor Skills

- Have Jacob continue working with the intervention specialist on handwriting and fine motor skills.
- Encourage activities that involve fine motor abilities, such as coloring, puzzles, cutting, and drawing.
- Encourage other activities that involve gross motor activities, such as playing catch, throwing a ball, or physical exercises.
- Jacob will take longer than most children to complete physical tasks, including those required for schoolwork (e.g., cutting with scissors, writing). He should be given additional time to complete these activities.

Mathematics

- Create math games out of everyday activities (e.g., "How many socks do I have?," weighing things, counting together)

- Look into elementary learning games online that teach basic skills.

Language and Literacy

- Reading fluency:
    - Have Jacob practice reading new or challenging words in isolation prior to reading them in text.
    - Have him orally read "phrase cards," and track the time needed to read them accurately.
    - Use the *neurological impress* method (paired reading, where the student and an adult read the same text almost simultaneously).
- Writing:
    - Continue working with Jacob on handwriting and letter formation skills to improve his writing fluency. Encourage proper letter formation, and only work on speed once letter formation is well established and legible.

John O. Willis

The late Colin D. Elliott (1937–2016) studied the ability profiles of children with learning disabilities (LDs) and the measurement of children's developmental stages in his work as an educational psychologist for 7 years, prior to his becoming a trainer of school psychologists for over 20 years at the University of Manchester in the United Kingdom. In 1983, he made a major contribution to the field of psychometric assessment in both his home country and the wider field with the publication of the British Ability Scales (BAS; Elliott, 1983a, 1983b). An American version followed, called the Differential Ability Scales (DAS; Elliott, 1990a, 1990b). The bright and attractive stimuli made the test engaging for children, while the selection of subtests and capacity to tailor testing to a child's age and ability level made it efficient for examiners to administer and score. New features from the DAS were incorporated into the second edition of the BAS (BAS II; Elliott, 1996), which in turn influenced the development of the current American version, the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007a, 2007b, 2007c, 2007d). A new version of the British version, the British Ability Scales 3 (BAS3; Elliott & Smith, 2012), has since been published.

Citing controversies and widespread popular misunderstandings in the definition of the terms *intelligence* and *IQ,* Elliott preferred to focus on ability and specific abilities in various cognitive domains. Elliott wrote:

> The DAS-II certainly produces a second-order composite score called the General Conceptual Ability score (GCA). However, *this is not a global composite score such as is found in other batteries.* It is not derived from a heterogeneous mix of all subtests, but is derived only from either six or four subtests that are the best measures of conceptual and reasoning abilities. (2007c, p. xiii; emphasis in original)

Therefore, the DAS-II was designed as a profile test that yields reliable and focused subtest and composite scores for various abilities and the higher-order General Conceptual Ability (GCA)

This chapter is a revision of Colin D. Elliott's chapter in the third edition of *Contemporary Intellectual Assessment* (Elliott, 2012). Shortly before his death, which was a tremendous loss to the fields of psychology and education as well as to his beloved family, his friends, and his many admirers, Dr. Elliott had, at the invitation of Dawn P. Flanagan, informally agreed to revise his previous chapter (in collaboration with Ron Dumont and John O. Willis) for the present edition. Much of this chapter was written by Dr. Elliott, and we have endeavored to follow both his style and his beliefs about assessment in the new material we have added.

composite, which is derived from only the subtests that are the best measures of higher-level conceptual and reasoning abilities; it is not an assortment of various cognitive abilities, as other tests' general composite scores are. Many of the features for which Elliott advocated have become more popular in other tests and have influenced the field of cognitive ability test construction. Although, sadly, Colin Elliott is no longer with us, his ideas and innovations live on—both in psychological tests influenced by his innovations in the five editions of the BAS and DAS, and in the daily practice of evaluators who have been educated and guided by the manuals for those tests.

STRUCTURE OF THE DAS-II

The DAS-II consists of 20 individually administered subtests divided into two overlapping batteries. The Early Years battery is normed for children ages 2 years, 6 months to 8 years, 11 months (2:6–8:11). The School-Age battery is normed for children ages 5:0–17:11. Thus the Early Years and School-Age batteries were co-normed on children ages 5:0–8:11. The overlap provides important advantages in terms of out-of-level testing because examiners assessing bright younger children or less able older ones are able to select a battery containing six tests that are appropriate for each child's ability and level of cognitive development.

This flexible design is rare, if not unique, among tests of cognitive abilities. The current Wechsler intelligence scales (Wechsler, 2008, 2012, 2014) offer slightly different instruments spanning the age range from 2:6 to 90, but examiners must use three separate test batteries with three different norming samples. The current edition of the Wechsler Preschool and Primary Scale of Intelligence (WPPSI-IV; Wechsler, 2012) covers the age range from 2:6 through 7:7 with seven subtests (five included in the Full Scale IQ) for ages 2:6 through 3:11, and 17 subtests (six for the Full Scale IQ) for ages 4:0 through 7:7. All of the subtests for younger children are included in the form for older children, and three of the Full Scale IQ subtests are the same for both age groups. However, like most tests with different subtests for different ages (and unlike the DAS-II), the WPPSI-IV does not provide norms that would allow a child older than 3:11 to take the younger version, or a child under age 4:0 to take the older version. The overlapping normative age ranges provided by the DAS-II norms constitute a tremendous asset for assessing low-scoring older children and high-scoring younger ones. Additional norms, permitting even greater ranges of our-of-level assessment can be found in Dumont, Willis, and Elliott (2009) and were being considered by Elliott for inclusion in the next edition of the DAS (C. D. Elliott, personal communication, May 15, 2014). The lack of norms beyond age 17:11 is a nuisance for examiners working with older high school students and adults. Elliott also hoped to extend the age range above age 17 in the next edition (C. D. Elliott, personal communication, May 15, 2015).

Six core subtests in each battery contribute a composite score: the GCA, focused on reasoning and conceptual abilities; a Special Nonverbal Composite (SNC); and three lower-level composite scores called *cluster scores*. All the core subtests are highly *g*-saturated.

In addition to the core subtests, up to 10 diagnostic subtests are available for children taking the Early Years battery, and up to eight are available for those taking the School-Age battery. These diagnostic subtests yield three additional cluster scores, and also measure other specific abilities that do not contribute to the composites.

The youngest children (ages 2:6–3:5) take a more limited range of subtests. This range is called the Early Years (Lower Level), and the 3:6–8:11 range is called the Early Years (Upper Level). The overall structure of the DAS-II is summarized in Table 13.1.

CLINICAL AND THEORETICAL UNDERPINNINGS

Users of cognitive ability tests typically compare an individual's performance and responses with those of a representative population sample of the same age as the person being tested. Paradoxically, however, while test scores are nearly always compared with the norm, the children, students, or adults whom users assess are often extremely atypical. The bread-and-butter work of a psychologist or psychological examiner involves individuals who are having difficulties or are failing to learn under normal conditions, or whose behavior gives cause for concern.

Because the individuals who are typically referred to psychologists manifestly have a huge range of individual special needs, the clinical priorities in the development of the DAS-II and its predecessors have been as follows:

TABLE 13.1. Number of DAS-II Subtests and Composites in Each Battery

Battery	Number of subtests	General composite	Cluster scores
Early Years (Lower Level), ages 2:6–3:5	4 core 3 diagnostic	1. GCA 2. SNC	*Core clusters* 1. Verbal 2. Nonverbal
Early Years (Upper Level), ages 3:6–8:11	6 core 10 diagnostic	1. GCA 2. SNC	*Core clusters* 1. Verbal 2. Nonverbal Reasoning 3. Spatial *Diagnostic clusters* 4. School Readiness 5. Working Memory 6. Processing Speed
School-Age, ages 5:0–17:11	6 core 8 diagnostic	1. GCA 2. SNC	*Core Clusters* 1. Verbal 2. Nonverbal Reasoning 3. Spatial Ability *Diagnostic clusters* 4. Working Memory 5. Processing Speed

Note. GCA, General Conceptual Ability; SNC, Special Nonverbal Composite.

1. Many children referred for psychological assessment have a history of problems with attending to adult instruction (e.g., distractibility or short attention span). For such children, test materials need to be varied and engaging, using different formats and types of tasks. A uniform approach to the administration of all subtests (e.g., using easels) has always been deliberately avoided in the DAS-II and its predecessors, in the interest of engaging children with variety.

2. Because many low-functioning children are likely to be assessed, there need to be plenty of test items that afford an opportunity for teaching and demonstrating what is required in each task. This is to ensure as far as possible that the children who are being assessed understand what they are supposed to be doing. Young children, and children with developmental disabilities and specific learning disabilities (SLDs), often have difficulty in warming up to a task and initially understanding the task requirements. For this reason, most of the DAS-II subtests have demonstration and teaching procedures built into the administration. Such teaching items enable an examiner to tell a child that he or she is correct (if this is the case), and, if the item has been failed, to give and explain the correct response or solution. The provision of feedback for designated teaching items even when an item is passed (an unusual provision in cognitive ability tests) ensures that a confused child who makes a lucky guess is not deprived of needed guidance.

3. Again, because many low-functioning children are likely to be assessed with the DAS-II, its subtests have been designed to have low floors. A *floor effect* in test norms is shown when a group of individuals in an age group all get raw scores of 0 or 1 point on the test. Such individuals find even the easiest items in the test to be too difficult; thus the test cannot discriminate among them, and an examiner cannot derive much useful information about such a child. This results in the normative scores' being *inflated* for those who obtain such low raw scores. For example, if, say, 10% of children in an age group obtain a raw score of 0 on a test, standard scores cannot reasonably go below 80. So a child who is actually at the 1st percentile in relation to his or her age group does not get a standard score that reflects this (i.e., a score of about 65), but instead gets a score of about 80. Later tables show that the DAS-II subtests and composites have low floors.

4. Because many children have had considerable experience of failing tasks set them by adults, the tests should minimize children's experience of failure to the greatest possible extent, and should maximize their enjoyment in success. The *item set* approach to test administration, which is used

throughout the DAS-II, meets this objective. The extent to which this approach is used in nearly every subtest in the battery is unique to the DAS-II and its predecessors.

5. At a practical level, the item set approach has two major additional advantages. First, it keeps the testing session moving briskly, with subtests ending and new ones starting more quickly than if traditional administration methods were employed. This has a positive impact on children's motivation and willingness to remain in the test situation. The second advantage is for examiners: The battery is relatively quick to administer. The Early Years battery has a median administration time for the core subtests of 31 minutes or less, while the core subtests of the School-Age battery have a median administration time of less than 40 minutes.

6. The normative overlap between the Early Years and School-Age batteries, described earlier, is 1 year wider than it was in the original DAS, and is designed to enable examiners to assess children whose developmental level is atypical for their age. Thus the Early Years battery may be given to children up to the age of 8:11, yielding composite scores with identical interpretation to those in the School-Age battery, if an examiner determines that the Early Years materials are developmentally more appropriate for a child. The choice of appropriate subtests for a child is left to the examiner's judgment, not decided by a rigid formula.

7. Out-of-level testing procedures and an extended GCA (taking the lowest GCA score down to 25) are provided for children with SLDs and developmental disabilities. Again, therefore, a school-age child may be assessed with the Early Years materials if these are considered by the examiner to be more developmentally appropriate. These procedures are described in detail elsewhere (Dumont et al., 2009).

8. Finally, because professionals assessing children with LDs and developmental disabilities need information at a finer level of detail than IQ scores, the DAS-II and its predecessors were designed to reflect modern knowledge on the nature and structure of cognitive abilities. A *pattern of strengths and weaknesses* (PSW) approach to assessing LDs has been broadly accepted by many professionals and by the U.S. government (Individuals with Disabilities Education Improvement Act of 2004 [IDEA 2004]; Daniel, Breaux, & Frey, 2010; Flanagan, Ortiz, & Alfonso, 2013; Hale & Fiorello, 2004). Because the DAS-II incorporates such an approach, examiners using it may obtain measures of seven broad abilities and a range of narrow abilities that reflect current theory on the structure of human cognitive abilities. This is discussed further below.

The major *technical* priority in the development of the DAS-II has been to produce a battery in which subtests and cluster scores are individually interpretable. For this, they need to have substantial reliability and need to be distinct measures of different cognitive functions. The high specificity of the DAS-II subtests and clusters (see later discussion in this chapter), which supports such interpretations of specific abilities, is a distinguishing feature of the battery.

What of the *theoretical* model? When the many theories of the structure of abilities were reviewed at the time of the DAS's initial development in the early 1980s, it was apparent that no single theory was entirely persuasive, and certainly no single theory had universal acceptance among theoreticians or practitioners. Because of this, the original DAS and BAS were not developed solely to reflect a single model of cognitive abilities, but reflected an eclectic number of theoretical perspectives. They were designed to address processes that often underlie children's difficulties in learning, as well as what we then knew about the neurological structures underlying these abilities.

During the years since the original DAS was published, a growing consensus has developed among factor theorists of human abilities. This centers on what became widely referred to as Gf-Gc theory, after the initial theory development by Cattell (1971) and Horn (Cattell & Horn, 1978; Horn & Blankson, 2012; Horn & Noll, 1997). The basic theory—that variance among multiple measures of cognitive ability can be accounted for by numerous first-order, narrow abilities and 8–10 broad, second-order factors—was also independently demonstrated by Carroll (1993, 2003, 2012), who showed that there are considerable similarities in the factor structures of cognitive test batteries. The contributions by Carroll and by Horn and Blankson make explicit the disagreement between Carroll and Horn about the reality of the general factor, *g*; Carroll strongly supported the construct, whereas Horn considered it to be a statistical artifact. Other than this disagreement, the similarities in the factors described by these two authors are considerable and impressive.

Because of the convergence between Carroll's and Horn's theoretical positions on the hierarchical structure of human abilities, Gf-Gc theory has more recently been referred to as Cattell–Horn-Carroll (CHC) theory (McGrew, 2005; see Flanagan et al., 2013; Schneider & McGrew, 2012 and Chapter 3, this volume). It also appears to be a unifying theory about which most workers in the area of the structure of human abilities broadly agree (Flanagan et al., 2013; Schneider & McGrew, 2012). As a result of the development of CHC theory, and before development of the DAS-II began, McGrew (1997, 2005), McGrew and Flanagan (1998), Flanagan, McGrew, and Ortiz (2000), Alfonso, Flanagan, and Radwan (2005), and Elliott (2005) were making links between CHC theory and findings on the factor structure of the DAS. And interestingly, at about the same time as the DAS-II was published, Sanders, McIntosh, Dunham, Rothlisberg, and Finch (2007) reported a joint factor analysis of the DAS and the Woodcock–Johnson III Tests of Cognitive Abilities (WJ III COG; Woodcock, McGrew, & Mather, 2001). Sanders and colleagues concluded that a three-stratum model provided the best fit to the data, with the DAS subtests measuring six of seven CHC broad ability factors.

Because of these theoretical developments, it was decided that the new DAS-II would be linked to CHC theory. Accordingly, all subtests are classified as measures of both narrow and broad CHC abilities. With one exception, all cluster scores have CHC broad ability classifications. The exception is the School Readiness cluster in the DAS-II Early Years battery, which is formed from a combination of three subtests measuring different CHC factors. It appears likely that in the early years at school, most teachers teach visual matching, early number concepts, and phonological awareness—skills that are defined by three of the DAS-II subtests. These three subtests "hang together" and form a factor that has a pragmatic rather than a theoretical basis, and that may prove useful for examiners who assess children in the early school years.

CHC theory continues to be a work in progress concerning (1) the number of factors representing independent abilities in the model; (2) the precise nature of each factor (see, e.g., the discussion by Schneider and McGrew (2012) on whether tests of rapid naming measure the broad ability of Gs or Glr); and (3) whether and to what extent subtests from different test batteries that purport to measure a given factor actually do so (see Keith & Reynolds, 2010).

ORGANIZATION AND FORMAT

Test Structure and Content

The subtests in the DAS-II Early Years (Upper Level) and School-Age cognitive batteries are listed in Tables 13.2 and 13.3, respectively. In each table, the subtests are grouped according to whether they are designated *core* subtests or *diagnostic* subtests. Each subtest has a brief description of the nature of its task, including its CHC broad ability classification. The core subtests are relatively strongly *g*-related and therefore measure complex processing and conceptual ability.

Subtests and Clusters in the DAS-II

All subtests that were in the original DAS are included in the DAS-II, as well as four new subtests. Recall of Sequential Order and Recall of Digits—Backward form a new diagnostic Working Memory cluster. A new Rapid Naming subtest combines with Speed of Information Processing to form a new diagnostic Processing Speed cluster. And Phonological Processing has been introduced to reflect the research done on this ability in relation to reading disability since the original DAS was published.

Moreover, the Matrices subtest has been extended downward to age 3:6 with a new set of colored pictorial items suitable for young children, thereby enabling the DAS-II Nonverbal Reasoning cluster (a measure of Gf) to extend down to age 3:6.

Block Building from the DAS has been merged into the Pattern Construction subtest, enabling that subtest to extend down to age 2:6. Technically, it was found during development that the goodness of fit to the Rasch model of the Block Building items was excellent when they and the Pattern Construction items were both included in the analysis, and they could therefore be considered to measure the same latent dimension.

The School-Age core subtests are identical to those in the original DAS. Five of the Early Years core subtests are identical, the exception being that Early Number Concepts is now designated a diagnostic subtest; its place as a core subtest has now been taken by the downward extension of Matrices. Some of the diagnostic subtests have a lower *g* saturation and measure such less cognitively complex functions as short-term memory and speed of information processing. However, the Working Memory subtests, the Phonological Processing subtest, and the Early Number Concepts subtests have substantial *g* loadings. Subtests have

TABLE 13.2. Subtests of the DAS-II Early Years (Upper Level) Battery (Ages 3:6–8:11), Showing Abilities Measured (and Relation of Measures to Broad CHC Ability Factors) and Their Contribution to Composites

Subtest	Description	CHC broad ability	Contribution to composite
Core subtests			
Verbal Comprehension	Using various materials, child gives a motor response to verbal commands	Gc	Verbal, GCA
Naming Vocabulary	Child sees pictures of objects and names them	Gc	Verbal, GCA
Picture Similarities	Child selects a picture or figure closest to a target picture or figure	Gf	Nonverbal Reasoning, GCA, SNC
Matrices	Child selects a picture or figure that completes a 2 × 2 or 3 × 3 matrix	Gf	Nonverbal Reasoning, GCA, SNC
Pattern Construction	Child replicates designs, using blocks or foam squares	Gv	Spatial, GCA, SNC
Copying	Child copies figure by drawing it on paper	Gv	Spatial, GCA, SNC
Diagnostic subtests			
Recall of Objects—Immediate	Examiner presents 20 objects on card; child recalls as many as possible; three trials	Glr	
Recall of Objects—Delayed	Child recalls as many objects as possible 10–30 minutes after third exposure	Glr	
Early Number Concepts	Child responds to questions requiring prenumerical and numerical concepts	Gc/Gf[a]	School Readiness
Matching Letter-Like Forms	Child matches a target figure to one of six alternatives	Gv	School Readiness
Recognition of Pictures	Child identifies previously seen pictures embedded in a larger display	Gv	
Phonological Processing	Child rhymes, blends, deletes, and identifies sounds in words	Ga	School Readiness
Recall of Digits—Forward	Child repeats spoken single-digit sequences	Gsm	
Recall of Digits—Backward	Child repeats spoken single-digit sequences in reverse order	Gsm	Working Memory
Recall of Sequential Order	Child reorganizes and repeats spoken lists of body parts and objects in correct order	Gsm	Working Memory
Speed of Information Processing	Child quickly selects the largest number of squares or the highest number in a row	Gs	Processing Speed
Rapid Naming	Child quickly names colors, objects, or colors and objects in a visual display	Gs	Processing Speed

Note. GCA, General Conceptual Ability; SNC, Special Nonverbal Composite; Gv, visual–spatial processing; Gc, crystallized intelligence or verbal ability; Gf, fluid reasoning; Gsm, auditory short-term memory; Glr, long-term storage and retrieval; Ga, auditory processing; Gs, processing speed.

[a] Note that in the DAS-II handbook (Elliott, 2007c, pp. 60–61), Early Number Concepts is characterized as measuring a mixture of Gc and Gf. However, Keith et al. (2010) have argued that Early Number Concepts is best conceived as a measure of fluid reasoning and not crystallized intelligence for ages 5 through 8. It appears that the influence of Gf on this subtest becomes stronger with increasing age.

normative scores in a *T*-score metric (mean = 50, standard deviation [*SD*] = 10).

Tables 13.2 and 13.3 also show the composites that can be derived from each of the core and the diagnostic subtests. Two types of composites are provided, all in a standard score metric (mean = 100, *SD* = 15). First are lower-order cluster scores. From age 3:6 onward, the core subtests yield three of these across the board in both Early Years and the School-Age batteries (Verbal, Nonverbal Reasoning, and Spatial). Three clusters are also derived from the diagnostic subtests (School Readiness, Working Memory, and Processing Speed). For the youngest children at the Lower Level of the Early Years battery (ages 2:6–3:5), there are just two cluster scores, Verbal and Nonverbal.

TABLE 13.3. Subtests of the DAS-II School-Age Battery (Ages 5:0–7:11), Showing Abilities Measured (and Relation of Measures to Broad CHC Ability Factors) and Their Contribution to Composites

Subtest	Description	CHC broad ability	Contribution to composite
Core subtests			
Word Definitions	Child tells the meaning of words given by the examiner	Gc	Verbal, GCA
Verbal Similarities	Child describes how three objects or concepts are similar	Gc	Verbal, GCA
Matrices	Child selects a picture or figure that completes a 2 × 2 or 3 × 3 matrix	Gf	Nonverbal Reasoning, GCA, SNC
Sequential and Quantitative Reasoning	Child completes a sequence of pictures, figures, or numbers	Gf	Nonverbal Reasoning, GCA, SNC
Pattern Construction	Child replicates designs, using blocks or foam squares	Gv	Spatial, GCA, SNC
Recall of Designs	Child draws figure after viewing it for 5 seconds	Gv	Spatial, GCA, SNC
Diagnostic subtests			
Recall of Objects—Immediate	Examiner presents 20 objects on card; child recalls as many as possible; three trials	Glr	
Recall of Objects—Delayed	Child recalls as many objects as possible 10–30 minutes after third exposure	Glr	
Recognition of Pictures	Child identifies previously seen pictures embedded in a larger display	Gv	
Phonological Processing	Child rhymes, blends, deletes, and identifies sounds in words	Ga	
Recall of Digits—Forward	Child repeats spoken single-digit sequences	Gsm	
Recall of Digits—Backward	Child repeats spoken single-digit sequences in reverse order	Gsm	Working Memory
Recall of Sequential Order	Child reorganizes and repeats spoken lists of body parts and objects in correct order	Gsm	Working Memory
Speed of Information Processing	Child quickly selects the largest number of squares or the highest number in a row	Gs	Processing Speed
Rapid Naming	Child quickly names colors, objects, or colors and objects in a visual display	Gs	Processing Speed

Note. GCA, General Conceptual Ability; SNC, Special Nonverbal Composite; Gv, visual–spatial processing; Gc, crystallized intelligence or verbal ability; Gf, fluid reasoning; Gsm, auditory short-term memory; Glr, long-term storage and retrieval; Ga, auditory processing; Gs, processing speed.

Both batteries provide two higher-order composites. For most children, the most general composite will be the GCA score. For children for whom it is judged that the verbal component of that score is inappropriate, the SNC score is provided. For the Early Years (Lower Level), this is identical to the lower-order Nonverbal cluster, formed from two subtests. For the Early Years (Upper Level) and School-Age batteries, this is formed from the four subtests in the Nonverbal Reasoning and Spatial clusters. Elliott (2007b) has left the choice between the GCA and the SNC as the better measure of an examinee's general ability up to the examiner, rather than imposing rigid rules or a formula.

One major change from the first DAS is that achievement tests are no longer part of the DAS-II battery. Instead, scores from the Wechsler Individual Achievement Test—Third Edition (WIAT-III; Pearson, 2009) have been linked to the DAS-II. In addition, correlational data have been provided between the DAS-II and the Kaufman Test of Educational Achievement, Third Edition (KTEA-3; Kaufman & Kaufman, 2014), and between the DAS-II and the WJ IV Tests of Cognitive Abilities, Achievement, and Oral Language (WJ IV COG, ACH, OL; McGrew, LaForte, & Schrank, 2014; Schrank, McGrew, & Mather, 2014). Discrepancies between ability (as measured by the DAS-II GCA or SNC) and WIAT-III or KTEA-3 achievement may be evaluated by taking either (1) the simple difference between the achievement score and the composite, a procedure we emphatically discourage; or (2) the difference between predicted and observed achievement, with predicted achievement being based on the GCA, Verbal, or Nonverbal score. The WIAT-III and KTEA-3 norms manuals (Breaux, 2010, pp. 462–473, 483–484; Kaufman & Kaufman with Breaux, 2014, pp. 535–539) provide information on the statistical significance of discrepancies (i.e., their reliability), and also on their frequency of occurrence (or unusualness) in the standardization sample.

Subtests as Specific Ability Measures

The chief aim in designing the content of the DAS-II was to produce subtests that are individually interpretable and can stand technically as separate, specific measures of various abilities. Once a specification was made of the desired tasks and dimensions to be measured, each subtest was designed to be unidimensional and homogeneous in content and distinct from other subtests, thus aiding the interpretation of children's performance. If a subtest score is to be interpreted as a measure of a specific, identifiable ability, the items within that subtest must be of similar content and must require the examinee to perform similar operations. For example, in each item of the Naming Vocabulary subtest, a child is asked to name an object in a picture. All items are therefore homogeneous. Naming Vocabulary is distinct from Verbal Comprehension, another verbal subtest because the former requires a verbal response and the latter does not.

Ideally, each subtest should be a clearly interpretable measure of a CHC narrow ability factor, and the clusters to which the subtests contribute should also be clearly interpretable measures of CHC broad ability factors. Subtests or clusters should not sit astride two factors, as it were, so that interpretation of performance becomes unclear (see "Factor Structure," below).

In addition to having homogeneous content that focuses on a distinct ability, each subtest should be reliable. Because the DAS-II emphasizes the identification of cognitive strengths and weaknesses, subtests must have a sufficient amount of reliable specificity to be separately interpretable (see "Accuracy and Reliability" and "Specificity," below).

Verbal Content

Although it was considered important to include measures of verbal ability in the DAS-II cognitive battery, too many verbal tasks would present problems for examiners wishing to assess children from multicultural or culturally disadvantaged backgrounds. Because of these considerations, measures of general knowledge, colloquialisms, or words with a specific meaning in the United States were eliminated as far as possible.

Because verbal abilities constitute a major component of cognition, it is certainly necessary to have some subtests that are purely verbally presented, particularly at the School-Age level. However, getting the balance right in a test battery is important, too. In development of the DAS-II content, only two core subtests were included with entirely verbal presentation and response (both at the School-Age level), plus the two verbally administered Recall of Digits subtests. Other than those subtests, the aim was to have subtests with varied tasks and materials. The "Test Materials" section below describes the range and variety of DAS-II stimulus materials.

Timed or Speeded Items

The DAS-II contains a diagnostic cluster called Processing Speed, contributed to by the Speed of Information Processing and Rapid Naming subtests, which are both timed. Apart from these two subtests, the DAS-II content minimizes the use of timed or speeded items. Of the other subtests, only one—Pattern Construction—gives extra points for correct completion of the designs within specified time limits. Of course, this feature of the subtest, which is appropriate for most individuals, is inappropriate for some children. Speed of response to the Pattern Construction items may not produce a valid measure for a child with a physical disability such as cerebral palsy, or one with an attentional problem, or one who takes an extremely deliberate approach to a task. For such children, an alternative procedure is provided, in which the score is based solely on accuracy within very liberal time limits. Confirmatory factor analyses (CFAs) reported in the DAS handbook (Elliott, 2007c) demonstrated the factorial equivalence of the standard and alternative versions of Pattern Construction, which are unchanged in the DAS-II. However, competing higher-order CFA models completed by Keith, Low, Reynolds, Patel, and Ridley (2010) found that the untimed version of Pattern Construction results in a cleaner measure of Gv. Elliott (2007b) has left the choice between using the standard or alternative score up to the examiner's professional judgment and knowledge of the examinee.

Test Materials

The DAS-II test kit includes three informational volumes: an administration and scoring manual (Elliott, 2007b), an introductory and technical handbook (Elliott, 2007c), and a manual of norms (Elliott, 2007d). Separate record forms are provided for the Early Years and School-Age batteries. The kit contains four stimulus books, as well as a variety of consumable booklets and manipulatives. Materials vary for each subtest. The materials were specifically designed to be colorful, varied, and engaging for children and students of all developmental levels, while also being easy to administer.

In the Early Years battery, only one subtest, Recall of Digits, is presented purely verbally, with no additional stimulus materials. In the School-Age battery, four subtests are presented purely verbally, with no additional stimulus materials. These are Word Definitions and Verbal Similarities, which constitute the Verbal cluster, and Recall of Digits—Forward and Recall of Digits—Backward, which measure aspects of verbal memory.

Translations

The DAS-II handbook (Elliott, 2007c, pp. 210–218) contains guidelines for the assessment of children with communication difficulties due to such causes as cultural differences, lack of proficiency in spoken English, and hearing impairments. To assist in assessing such children, the DAS-II has been published with two translations: Spanish and American Sign Language (ASL).

The manual contains an appendix in which are given the Spanish-language instructions needed to administer the subtests that do not require a verbal response from a child. The translated instructions are for the following Early Years core subtests: Copying, Matrices, Pattern Construction, and Picture Similarities. These subtests enable the Nonverbal Reasoning and Spatial cluster scores to be estimated, together with the SNC as a measure of *g*. For the School-Age battery, translated instructions are provided for Matrices, Pattern Construction, Recall of Designs, and Sequential and Quantitative Reasoning. Once again, these enable Nonverbal Reasoning, Spatial, and SNC scores to be obtained. Translations are also provided for the following diagnostic subtests: Matching Letter-Like Forms, Recognition of Pictures, and Speed of Information Processing. Of course, examiners should not attempt to use these Spanish instructions unless they are sufficiently fluent to understand and respond to a child's comments and questions. Examiners must also keep in mind that basing an assessment on tests of Gf, Gv, and Gs provides a seriously incomplete picture of a child's cognitive abilities.

The DAS-II kit includes a CD-ROM of signed administration directions in ASL for nine subtests. These include the same core subtests for the Early Years and the School-Age batteries as in the Spanish translation, thereby enabling Nonverbal Reasoning and Spatial cluster scores to be estimated, together with the SNC. In addition, three diagnostic subtests have been translated into ASL: Matching Letter-Like Forms, Recognition of Pictures, and Speed of Information Processing. The CD-ROM is intended to help an examiner or a certified interpreter to learn how to administer the subtests in ASL in a consistent, standardized format. The CD-ROM should never be used to administer the subtests.

TABLE 13.4. Subtest Floors for the DAS-II Early Years (Lower Level) Battery: *T* Scores, *z* Scores, and Percentiles Produced by a Raw Score of 1 on Each Subtest for Children Ages 2:6–2:9

Pattern Construction	27	–2.3	1

PSYCHOMETRIC PROPERTIES

The DAS-II standardization sample, the forming procedures, and data on the reliability and validity of the battery are by now well known, and are described elsewhere (Elliott, 2007c). The DAS-II followed essentially the same procedures in sampling, and in obtaining a substantial bias oversample, that were employed in the standardization of the DAS (Elliott, 1990b, 1997).

Subtest Floors

As explained earlier, because many low-functioning children are likely to be assessed with the DAS-II, its subtests have been designed to have low floors.

Table 13.4 shows the *T* scores, *z* scores (showing the number of standard deviations below the mean), and percentiles for a raw score of 1 on each of the four core subtests at ages 2:6–2:9, which is the lowest age group for the Early Years (Lower Level), If a child of this age happened to obtain raw scores of 1 on every subtest, this would yield standard scores of 56 and 64 on the Verbal and Nonverbal clusters, respectively, and a GCA score of 58. These three scores are at or below the 1st percentile. Clearly, because of the development of abilities in childhood, the floors of the subtests are lower than those in the table for children between the ages of 2:10 and 3:5, with lower values in the table, and with lower cluster and GCA scores.

Similarly, Table 13.5 shows the floors for children at ages 3:6–3:9—the lowest age group for the Early Years (Upper Level). These are for the six core subtests, which yield three cluster scores. Note that the two subtests that start at age 3:6 have the highest *T* scores for a raw score of 1. If a very low-functioning child were unable to understand these subtests, it is still possible to give the subtests from the Early Years (Lower Level) bat-

TABLE 13.5. Subtest Floors for the DAS-II Early Years (Upper Level) Battery: *T* Scores, *z* Scores, and Percentiles Produced by a Raw Score of 1 on Each Subtest for Children Ages 3:6–3:9

Clusters and subtests	*T* score	*z* score	Percentile
Verbal cluster			
Verbal Comprehension	14	–3.6	<0.1
Naming Vocabulary	15	–3.5	<0.1
Nonverbal Reasoning cluster

Pattern Construction	18	–3.2	<0.1

tery to obtain estimates of Verbal and Nonverbal ability, together with the GCA. If a child age 3:6 obtained raw scores of 1 on all six subtests, this would yield cluster standard scores of 39 (Verbal), 61 (Nonverbal Reasoning), and 60 (Spatial), with a GCA score of 47. All these scores would indicate that the child's ability in each area was below the 1st percentile.

Finally, Table 13.6 shows the floors of the DAS-II Early Years and School-Age batteries for children ages 7:0–7:5. At this age, the School-Age battery would normally be given. On this battery, three of the six core subtests and three diagnostic subtests have *T* scores above the lowest possible level of 10. The *z* scores and percentile columns show that a child who obtained a raw score of 1 on any of these six subtests would be estimated to be at or below the 1st percentile for his or her age. The subtest *T* scores in Table 13.6 yield cluster standard scores as follows: Verbal, 44; Nonverbal Reasoning, 46; Spatial, 38; School Readiness, 37; Working Memory, 59; Processing Speed, 42; and GCA, 40. However, as discussed earlier, the normative overlap between the Early Years and School-Age

batteries means that relatively low-functioning School-Age children ages 7:0–8:0 may be given the core subtests of the Early Years battery, which clearly has the lowest possible floors for children of that age—*T* scores of 10, four standard deviations below the mean for all subtests, which would yield a GCA score of 30.

The three age groups referred to in Tables 13.4, 13.5, and 13.6 are the lowest ages of children who would normally be given the Early Years (Lower Level), Early Years (Upper Level), and School-Age batteries. Low-functioning children in these young age groups would be most likely to have the greatest difficulty with the easiest items, and would show the greatest floor effects. Children in older age groups would show lesser effects the older they became. The tables show that floor effects are minimal, and that one of the goals of test development—to provide subtests with low floors—has been met.

Accuracy and Reliability

The DAS-II uses what is termed an *item set* approach to test administration, as noted earlier. This is a form of tailored testing that makes the assessment time-efficient while maintaining a high level of accuracy. This approach, and the procedures used in the DAS-II to achieve accuracy and reliability, are described in the DAS-II handbook (Elliott, 2007c).

Two diagnostic subtests (Recall of Objects—Immediate and Recognition of Pictures) have adequate mean internal-reliability coefficients of .79 at the Early Years level. All other Early Years subtests have internal reliabilities of .80 and above, nine of them being between .80 and .89, and five of them being .90 and over. At the School-Age level, Recognition of Pictures once again has an adequate but lower mean internal-reliability coefficient (.74) than other subtests. All other subtests have mean coefficients of .80 and above, nine of them being between .80 and .89, and six over .90.

The mean internal reliabilities of DAS-II cluster scores range from .89 to .95 for both the Early Years and School-Age levels. The mean internal reliabilities of the GCA and SNC are .95 (Early Years) and .96 (School-Age).

Without exception, the reliability coefficients improved for the DAS-II subtests retained from the original DAS; identical methods of estimation were used. Extensive further information on the reliability of the DAS-II is provided in the DAS-II handbook (Elliott, 2007c, pp. 121–140).

Specificity

The variance of test scores can be partitioned into a number of components. The *proportion of error variance* may be estimated and is defined as the value of 1 minus the reliability of a test. The *proportion of reliable variance* (i.e., the reliability of the test) may itself be partitioned into two components: *reliable common variance*, which is shared or overlapping with other tests in the battery, and *reliable specific variance*, which is not shared and does not overlap with other tests.

The proportion of common variance (often termed *communality*) may be estimated by the squared multiple correlation between a subtest and all others in the battery (Kaufman, 1979; Silverstein, 1976). The proportion of specific reliable variance is usually termed the *specificity* of a test and is estimated by subtracting the communality from the reliability coefficient of the test.

McGrew and Murphy (1995) consider test specificity to be high when it is (1) .25 or more (indicating that it accounts for 25% or more of the total variance of the test), and (2) greater than the proportion of error variance. Analyses of the specificity of the DAS-II (reported in detail in Elliott, 2007c, pp. 141–142) have shown every subtest to be of high specificity. For both the Early Years and the School-Age batteries, about 42% of subtest score variance is reliable specific variance. The range of subtest specificity is .31–.65 in the Early Years battery, and .31–.66 in the School-Age battery.

With one exception, the cluster scores in both batteries also show very high specificity, ranging from .37 to .57 (mean .47) for the Early Years battery and from .34 to .66 (mean .46) for the School-Age battery. The exception is the School Readiness cluster, which has a moderate specificity of .23 (falling just under the .25 criterion for high specificity). All subtest and cluster specificities substantially exceed the proportion of error variance.

Such values of specificity are very consistent with those previously found in the DAS and the BAS-II. These findings support the view that the original development goal of a battery with reliable, specific, individually interpretable subtests has been achieved. The results support the use of the DAS-II for the analysis of cognitive processing strengths and weaknesses, not just for measuring *g*, despite the recommendation of Canivez and McGill (2016) that "the DAS-II provides strong measurement of general intelligence but clinical interpretation should be primarily at that level"

(p. 1475). We believe that there is a sound foundation for interpreting patterns of strengths and weaknesses, following the guidelines and data for statistical significance and uncommonness in Elliott (2007c, 2007d).

Validity

The DAS-II handbook (Elliott, 2007c) contains extensive information on the instrument's validity. This can be broadly categorized into correlational studies, including CFAs of the structure of the battery, and studies on defined clinical samples of children with varying special needs. This section of the present chapter gives a brief description of studies on the factor structure of the DAS-II, and some data on the variety of significant strengths and weaknesses in cognitive abilities shown by children who are poor readers.

Factor Structure

The downward extension of Matrices in the DAS-II was expected to produce three core cluster scores in the Early Years battery that would be equivalent to those in the School-Age battery—namely, Verbal (Gc), Nonverbal Reasoning (Gf), and Spatial (Gv). The two new measures of working memory included in the DAS-II were also expected to form a cluster, and in addition it was thought that the new Rapid Naming subtest might cluster with Speed of Information Processing rather than with Phonological Processing when the final data were analyzed, as did similar subtests in the WJ III (McGrew & Woodcock, 2001). Thus it was anticipated that there would be two additional diagnostic clusters in the DAS-II—Working Memory and Processing Speed, measuring the CHC factors of Gsm and Gs, respectively.

Finally, the inclusion of the Phonological Processing subtest was expected to provide a measure of auditory processing—the CHC broad ability of Ga. This subtest would thereby fill a gap in the coverage of CHC broad ability factors that McGrew (1997, p. 160) noted in the original DAS. More importantly, it would also meet a clinical need for such a test that is relevant to reading acquisition and the assessment of reading disability.

Confirmatory Factor Analyses

Although the background of the DAS-II has remained eclectic, it was clear at the time of development that CHC theory had become the most dominant and widely accepted theory of the structure of human abilities. Accordingly, the DAS-II handbook (Elliott, 2007c) discusses the relation of the subtests and clusters to CHC theory in some detail. The major emphasis in conducting factor analyses was on using CFAs to test the correspondence of DAS-II subtests and clusters to the CHC model.

The DAS-II handbook contains details of the CFAs that were conducted to test the factor structure of the battery (Elliott, 2007c, pp. 153–162). The three clusters formed by the core subtests were confirmed as robust factors throughout the age range from 3:6 through 17:11, Elliott therefore continued to call these clusters Verbal, Nonverbal Reasoning, and Spatial—names given them in the first DAS. In CHC terms, they measure the broad abilities of Gc (crystallized intelligence/knowledge), Gf (fluid reasoning), and Gv (visual–spatial ability), respectively. Unfortunately, the name Nonverbal Reasoning for the Gf factor occasionally causes confusion with other nonverbal measures, such as visual–spatial ability or the SNC. Examiners should make clear in their reports that Nonverbal Reasoning is a measure of fluid reasoning (Gf).

Among the diagnostic subtests, a Working Memory factor was confirmed, formed by the subtests Recall of Digits—Forward, Recall of Digits—Backward, and Recall of Sequential Order. In CHC terms, this factor measures the broad ability of Gsm or Gwm (short-term working memory; the CHC terminology is continually evolving). This is clearly a verbal short-term memory factor because visual short-term memory tasks (CHC narrow ability MV) are always found under the Gv factor. Moreover, because working memory tasks requiring mental manipulation (Gwm WM) are cognitively more complex than simple digit recall or memory span (Gwm MS), Elliott found that the working memory subtests requiring mental manipulation (Recall of Digits—Backward, and Recall of Sequential Order) consistently had higher loadings on the factor than did Recall of Digits—Forward (Gwm MS). In order to avoid any ambiguity in interpretation (because Recall of Digits—Forward is not a measure of working memory capacity with mental manipulation or WM), only the two working memory subtests form the Working Memory cluster in the DAS-II.

The CFAs also confirmed the Processing Speed factor, formed by the Speed of Information Processing and Rapid Naming subtests.

As an example of the analyses that were conducted, Figure 13.1 shows the factor structure of the DAS-II School-Age battery for children ages 6:0–12:11. This is the operating age range of the Phonological Processing subtest, and is the age range in which all seven CHC broad factors are found and confirmed. Figure 13.1 represents the final model (the full CHC model), which fits the standardization data significantly better than any alternative model of one, two, three, or five factors (Elliott, 2007c, p. 156).

The robustness of the structure across age levels was confirmed in an independent study by Keith and colleagues (2010), using both DAS-II batteries (Early Years and School-Age) across the 4- to 17-year age range. Two of those authors commented that this detailed study demonstrated remarkable consistency of the DAS-II with CHC theory (Keith & Reynolds, 2010, p. 638). The chief difference between this study and those reported in the DAS-II handbook is that Keith and colleagues dropped the Phonological Processing subtest from the analysis because it is the only representative of the CHC G*a* factor in the battery.

As noted above, Canivez and McGill (2016) reported that results of their "exploratory factor analyses, multiple factor extraction criteria, and hierarchical exploratory factor analyses (Schmid & Leiman, 1957)" of the DAS-II standardization data

> indicated that most DAS–II subtests were properly associated with the theoretically proposed first-order factors. Hierarchical exploratory analyses with the Schmid and Leiman (1957) procedure, however, found that the hierarchical g factor accounted for large portions of total and common variance, while the two or three first-order factors accounted for small portions of total and common variance. It was concluded that the DAS–II provides strong measurement of general intelligence but clinical interpretation should be primarily at that level. (p. 1475)

We believe, however, that there is a sound foundation for interpreting patterns of strengths and weaknesses, following the guidelines and data for statistical significance and uncommonness provided by Elliott (2007c, 2007d).

Just as the Keith and colleagues (2010) study looked at the consistency and invariance of factor structure across a wide age range, so CFA was used to investigate construct bias in the instrument. A CFA study on the original DAS (Keith, Quirk, Schartzer, & Elliott, 1999) used the standardization sample and the bias oversample to test for construct bias. A hierarchical, multisample CFA was used to examine the constructs measured by the DAS in black, Hispanic, and white children. Results showed that the DAS measured the same constructs across all three ethnic groups across all age levels of the battery. The authors concluded that the DAS showed no construct bias, and that users of the battery could have confidence that the battery measures the same abilities for black, Hispanic, or white children and youth.

INTERPRETATION

Recommendations for Interpreting General, Broad, and Specific Cognitive Abilities

Chapters 4 and 5 in the DAS-II handbook (Elliott, 2007c) give detailed suggestions about cognitive processes underlying scores on the various DAS-II subtests and composites. The interpretive guidelines are largely (but not solely) based on the interpretation of subtests and clusters in terms of CHC broad and narrow abilities.

The DAS-II handbook also gives a systematic procedure for test interpretation. The procedure is partly based on the identification of scores that are significantly high or low at the .05 probability level. This is greatly facilitated by the user-friendly design of the summary page of the record form, which shows the size of differences that are significant at $p < .05$ between achievement tests, composites, and subtest scores.

Other comparisons are made possible by tables in the DAS-II handbook. In particular, the handbook provides tables enabling evaluation of discrepancies between observed and predicted achievement, as well as tables showing the frequency or unusualness of discrepancies. Because the development of individually interpretable subtests was a primary goal of the DAS-II, the handbook contains extensive interpretive guidelines for subtest scores.

Studies Conducted with Samples of Students with LDs

Research on DAS-II Score Profiles

DAS-II score profiles of 12 special populations have been reported in the handbook (Elliott, 2007c). Children were selected for each special-group sample according to specified inclusion and exclusion criteria. These studies provided the means and standard deviations of standard scores of each group on each cluster and subtest.

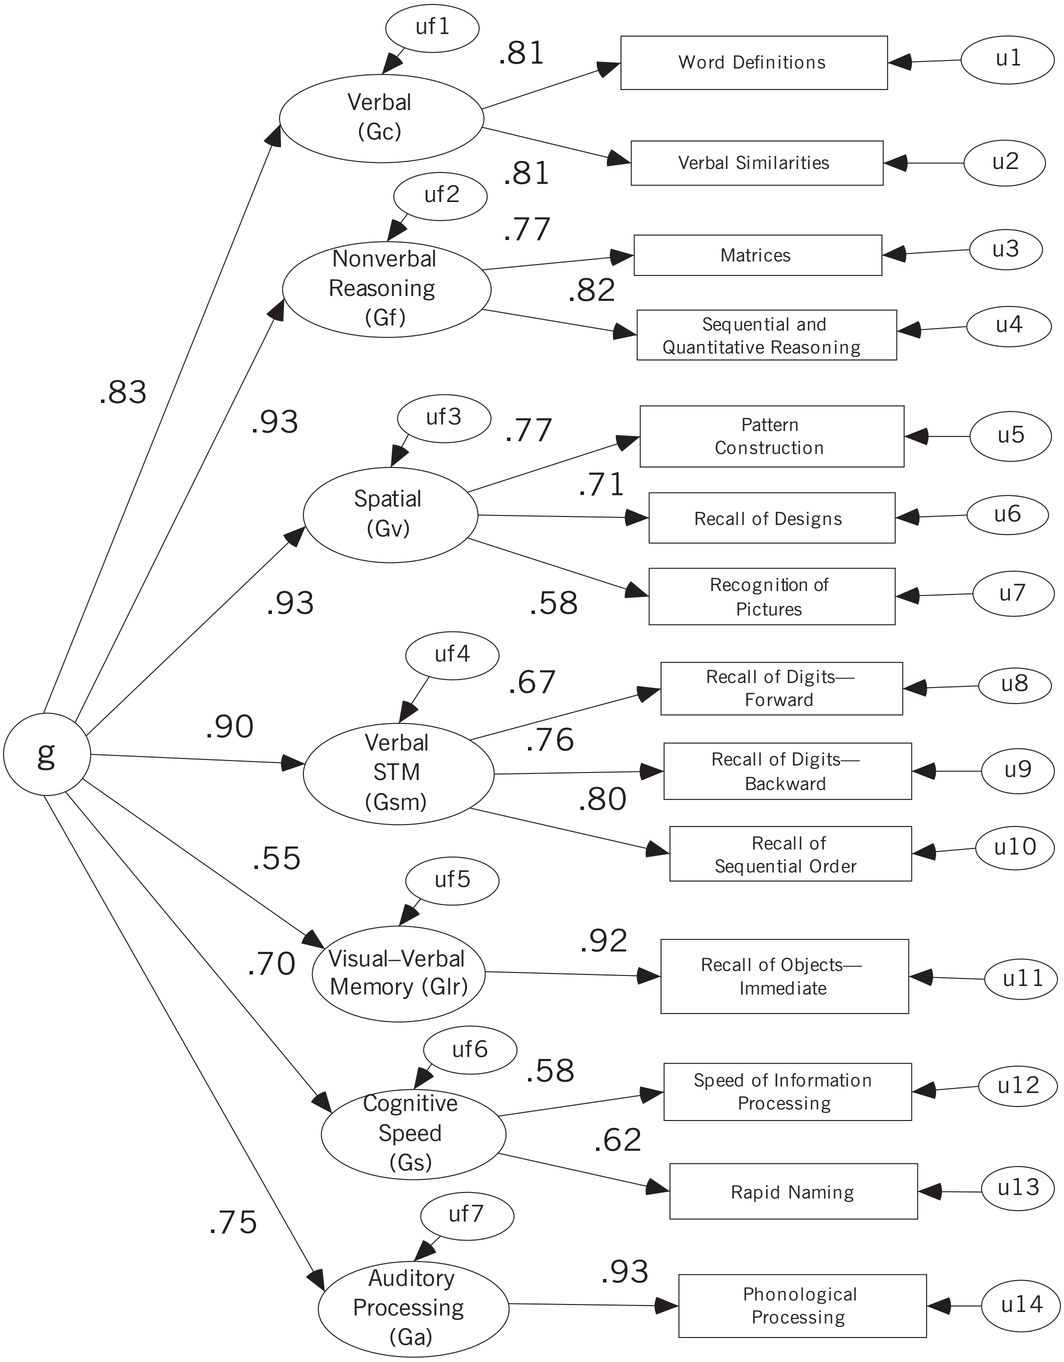

FIGURE 13.1. Factor structure of DAS-II School-Age battery for children ages 6:0–12:11, showing seven CHC broad ability factors.

Although such studies are of some interest—particularly when relatively homogeneous groups are being studied, such as children who are gifted and talented, or those with mild to moderate intellectual disabilities—such studies can be misleading when applied to heterogeneous groups such as those with LDs, where there are likely to be a wide range of causal influences for the disorders, resulting in a wide range of score profiles.

This is illustrated in Table 13.7, which shows that students who were poor readers and those with an LD in math had a wide range of cognitive profiles on the DAS-II. First, a sample of 293 poor readers was drawn from the DAS-II standardization sample, together with extra individuals who were tested at the time of standardization. Some of these children were surplus to the sampling requirements of the project; others belonged to the special groups referred to above and also had an LD in literacy. All 293 poor readers showed a significant discrepancy between their obtained Word Reading scores on the WIAT-II (Psychological Corporation, 2001) and their predicted Word Reading scores based on their GCA scores. The second sample of 43 children consisted of the special group of children who had been identified as having an LD in math.

Score profiles on the five DAS-II cluster scores were defined as follows:

- *Low Spatial, High Verbal:* The Verbal cluster score was significantly higher ($p < .05$) than the Spatial cluster. Also, the Nonverbal Reasoning score was intermediate, being lower than Verbal, and at or above the level of the Spatial score. This pattern might possibly suggest a nonverbal LD.
- *Low Verbal, High Spatial:* The Verbal cluster score was significantly lower than the Spatial cluster. Again, the Nonverbal Reasoning score was intermediate, being lower than Spatial, and at or above the level of the Verbal score. This has been a typically reported pattern for poor readers (e.g., British Psychological Society, 1999; Snow, Burns, & Griffin, 1998).
- *High Nonverbal Reasoning:* The Nonverbal Reasoning cluster score was higher than both the Verbal and Spatial scores, and significantly higher than at least one of them. This pattern might signify good ability to process complex auditory–visual information.
- *Low Nonverbal Reasoning:* The Nonverbal Reasoning cluster score was lower than both the Verbal and Spatial scores, and significantly lower than at least one of them. This core cluster profile might suggest difficulty in processing complex auditory–visual information. Elliott (2005) analyzed the scores obtained from various samples of children who had been identified

TABLE 13.7. Percentage of Students with Significantly High or Low Scores on DAS-II Clusters: Comparison of Poor Readers (*n* = 293), Those with LDs in Math (*n* = 43), and the Standardization Sample for Ages 6:0–17:11 (*N* = 2,600)

Type of profile	Poor readers (with significant discrepancy)	LDs in math	DAS-II standardization sample
No significant differences between clusters	14.3	14.0	11.5
Low Spatial, high Verbal	10.2	16.3	13.3
Low Verbal, high Spatial	17.1	7.0	13.3
High Nonverbal Reasoning	17.1	16.3	18.5
Low Nonverbal Reasoning	19.8	27.9	18.8
High Processing Speed	28.0	20.9	25.3
Low Processing Speed	22.2	34.9	25.0
High Working Memory	16.7	16.3	22.1
Low Working Memory	25.9	27.9	24.2

Note. The term *poor readers* refers to children with standard scores below 85 on WIAT-II Word Reading. The term *discrepancy* refers to the presence or absence of a statistically significant difference ($p < .05$) between obtained and predicted WIAT-II Word Reading scores (the prediction was based on the GCA score).

as having an LD in reading, and reported that approximately one-third of them had this low Nonverbal Reasoning profile.

- *High Processing Speed:* The Processing Speed cluster score was significantly higher than the GCA score.
- *Low Processing Speed:* The Processing Speed cluster was significantly lower than the GCA score.
- *High Working Memory:* The Working Memory cluster score was significantly higher than the GCA score.
- *Low Working Memory:* The Working Memory cluster score was significantly lower than the GCA score.

Table 13.7 shows the percentage of children in each sample who showed each profile. The table also shows the frequency of each profile in the total DAS-II standardization sample for ages 6:0 through 17:11. What we can conclude from an initial inspection of these profile frequencies is that there was no common profile for poor readers or for children with an LD in math. Some children in each sample clearly had profiles that were the exact opposites of those shown by other children in the same sample.

Table 13.7 indicates that over 85% of children in the population would be expected to have one or more significantly high or significantly low cluster scores. There are also interesting differences in profile frequencies between the two samples of poor achievers.

It should be noted that the poor readers were in general not children who had been formally identified as having an LD in reading. About 20% had the low Nonverbal Reasoning profile previously reported to have been found in about one-third of previous samples who had an LD in reading. However, over a quarter of the sample with an LD in math had such a profile. Also, about one-third of the children in this sample also had significantly low Processing Speed scores, while very few (7%) had high Spatial ability. Both samples had a higher percentage of children with significantly low Working Memory than those with high Working Memory.

It appears that there are a number of contrasting subgroups within each group of children with reading or math difficulties. If one subgroup has significantly low mean scores on a DAS-II cluster, and the other subgroup has significantly high ones on the same cluster, the resulting mean for the total group would be attenuated, tending toward some midvalue. Correlations between this cluster and other variables would also be attenuated. Despite such likely problems, correlational studies have been conducted on samples of children with achievement problems in reading and math.

Correlational Studies

The interpretation of intelligence tests has been and remains one of the most controversial and divisive issues in cognitive assessment. Some authors (e.g., Canivez & McGill, 2016; Glutting, McDermott, Konold, Snelbaker, & Watkins, 1998; Glutting, Watkins, Konold, & McDermott, 2006; Kahana, Youngstrom, & Glutting, 2002; Kotz, Watkins, & McDermott, 2008; Watkins & Smith, 2013) dispute the validity, stability, and utility of patterns of performance, and affirm that there is little value in interpreting cognitive scores beyond a global ability estimate such as IQ or GCA.

Forty years of work on the development of the DAS-II and its predecessors run counter to this suggestion. Statistically significant intraindividual differences between subtest and cluster scores are, by definition, reliable; they indicate the presence of strengths and weaknesses in processing information that are not artifacts of measurement error. The DAS and the DAS-II standardization data indicate that a large proportion of children show such differences (see Table 13.7). The *raison d'être* of the DAS-Il is that significant intraindividual differences between cluster and subtest scores should lead us to consider whether and how they illuminate processing strengths and weaknesses that may be related to the problem for which the child has been referred for assessment.

The evidence in favor of this approach is strong. CFAs conducted on the DAS-II standardization data, reviewed above, show that a model with multiple factors fits the data highly significantly better than a single-factor *g* model. The analyses demonstrate that the general factor g is not sufficient to explain the relationships between the subtests and clusters. Similarly, Vanderwood, McGrew, Flanagan, and Keith (2001) showed that specific cognitive abilities provide a better-fitting model for predicting reading achievement than does general cognitive ability.

Additional evidence on these issues has been provided by two studies, summarized below, which used the DAS-II (Elliott, Hale, Fiorello, Dorvil, & Moldovan, 2010; Hale et al., 2008). Interested readers can also see references in these articles to methodological criticisms of the Glutting, Watkins, and McDermott group's use of multicollinear datasets.

Prediction of WIAT-II Math Scores

Hale and colleagues (2008) used regression commonality analysis to examine the unique and shared variance components among DAS-II CHC factors in the prediction of WIAT-II Numerical Operations and Math Reasoning skills for the DAS-II normative sample and for a sample of children with a math LD. Because of the likely attenuation of correlations, it is possible (even probable) that this would reduce the number of variables found to have significant interrelationships. However, it was considered to be important to demonstrate, even from correlational data derived from heterogeneous samples, that the broad and narrow abilities represented in the DAS-II clusters and subtests would explain significantly more variance in math achievement than the GCA alone.

Results showed that the DAS-II predictors accounted for more achievement variance in typical children than in children with a math LD. The reason for this is very likely to be a restriction of range in the Math scores of the latter group. For typical children, DAS-II predictors accounted for 46% of variance in Numerical Operations and 58% of variance in Math Reasoning. On the other hand, the DAS-II predictors accounted for 33% of variance in Numerical Operations and 50% of variance in Math Reasoning for the children with a math LD. There was substantial loss of predictive validity when the GCA was used instead of cluster or subtest scores: 13% loss for the typical group on both math tests, and 56% loss on Numerical Operations and 20% loss on Math Reasoning for the group with a math LD.

Prediction of WIAT-II Reading Scores

Elliott and colleagues (2010) used both commonality analysis and structural equation modeling (SEM) to investigate the effect of broad CHC abilities measured by the DAS-II, together with the effect of the general factor (*g*) on reading achievement measured by the WIAT-II.

The SEM analyses indicated that for typical children drawn from the standardization sample, four CHC-related measures were significant direct predictors of Reading Decoding (a combination of WIAT-II Word Reading and Pseudoword Decoding). These predictors were the Verbal (Gc), Nonverbal Reasoning (Gf), and Working Memory (Gsm) clusters, together with the Phonological Processing (Ga) subtest.

A similar analysis was conducted for a sample of 230 poor readers drawn from the standardization sample; children who were tested for standardization but who were surplus to requirements; and children with reading disorder, reading and written expression disorder, mathematics disorder, attention-deficit/hyperactivity disorder (ADHD), or ADHD with LD—samples gathered for studies of special populations at the time of standardization, and referred to above. For this sample, Phonological Processing was again found to be a significant predictor, together with the Spatial Ability (Gv) and Processing Speed (Gs) clusters, and the Recall of Objects—Immediate subtest (Glr).

Although Phonological Processing had a significant large effect on Reading Decoding for both samples, no other effects were significant for both samples. Each sample had three significant but different CHC factors that produced significant effects on Reading Decoding. When both analyses were considered together, the results showed that every CHC broad ability factor was a significant predictor in one or the other analysis. In both analyses, the effect of the general factor (*g*) was indirect. In other words, its effect was mediated through the three first-order factors measuring it (Verbal, Nonverbal Reasoning, and Spatial). The results demonstrated that children with reading problems have different cognitive predictor–reading achievement relationships than adequate readers.

The commonality analyses examined DAS-II predictors of WIAT-II Word Reading and Reading Comprehension scores. Once again, as might be expected, different commonalities were found for the typical sample and a sample of children with an LD in reading. Across all analyses, Verbal Ability (Gc), Nonverbal Reasoning Ability (Gf), Spatial Ability (Gv), Working Memory (Gsm), and Phonological Processing (Ga) showed important and significant effects, and explained significant amounts of variance over and above that explained by estimates of *g*. The data from the studies on both math and reading suggested that practitioners should not emphasize global GCA, but should instead interpret cluster and subtest scores and their interrelationships in developing hypotheses about an individual's processing strengths and weaknesses.

Appendix 13.1 presents a case study that demonstrates how the WIAT-III and DAS-II can be integrated into a comprehensive evaluation. All personally identifiable information has been altered in the case study report to preserve the confidentiality of the examinee.

CONCLUSIONS

This chapter has outlined various ways in which the DAS-II has been designed to be appealing and accessible to children of all abilities across a very wide age range, from 2:6 to 17:11. Its good floors, and its procedures to help the least able examinees understand what is required in each task, make the battery highly appropriate for use with clinically referred populations. It has also been designed for speed and efficiency in administration. Its cluster and subtest scores have essential qualities of reliability and interpretability. Its consistency and clarity in measuring the constructs of CHC theory make it an ideal instrument for cross-battery assessment (Flanagan et al., 2013). When the DAS was first published in 1990, it was at first virtually unknown and seemed so different in its procedures that professionals probably feared it was difficult to learn. Now in its second edition, it is widely used, and is accepted as an instrument that enjoyably engages children and helps to identify their processing strengths and weaknesses with efficiency and precision.

APPENDIX 13.1

Brief Case Study

Michelle (age 8:11), a white female in grade 3, was referred for assessment when her child study team reported their concern that she had not responded to the reading interventions provided as part of her regular instructional program. She struggled to name high-frequency words, and her team felt she needed additional targeted instructional recommendations.

Michelle's achievement scores on the Wechsler Individual Achievement Test—Third Edition (WIAT-III) and her cognitive ability scores on the Differential Ability Scales—Second Edition (DAS-II) are shown in Table 13.A.1. Examination of her WIAT-III scores shows that she has a specific difficulty with Word Reading. Her higher score on Pseudoword Decoding suggests that she finds decoding phonetically regular made-up words (such as *flarp*) easier than decoding irregular real

TABLE 13.A.1. WIAT-III and DAS-II Subtest and Cluster Scores for Michelle (Age 8:11)

Subtest or cluster	Score[a]
WIAT-III	
Total Reading	69
Word Reading	58
Pseudoword Decoding	86
Reading Comprehension	72
Oral Reading Fluency	66
Written Expression	77
Sentence Composition	84
Essay Composition	79
Spelling	79
Mathematics	99
Math Problem Solving	97
Numerical Operations	101
DAS-II core clusters (School-Age battery)[b]	
Verbal	102
Nonverbal Reasoning[c]	89
Spatial	102
{GCA	97}
DAS-II diagnostic clusters and subtests	
Working Memory	93
Recall of Sequential Order	*T* = 40
Recall of Digits—Backward	*T* = 52
Processing Speed	89
Speed of Information Processing	*T* = 51
Rapid Naming	*T* = 38
Additional DAS-II diagnostic subtests	
Recall of Objects—Immediate	*T* = 40
Recall of Objects—Delayed	*T* = 41
Recall of Digits—Forward	*T* = 53
Recognition of Pictures	*T* = 54
Phonological Processing	*T* = 51

[a] Standard scores except where indicated.

[b] There are no significant differences between subtests within each cluster

[c] The Nonverbal Reasoning cluster score is significantly lower than *both* the Verbal and Spatial cluster scores.

words. Such irregular words make demands on visual memory; they are often called *sight words,* because they have to be remembered as a whole rather than being solvable phonetically. Michelle's oral reading fluency for passages was only slightly stronger than her reading of real words, and much weaker than her decoding of made-up words. The initial hypothesis is that Michelle may have visual information-processing difficulties.

On the DAS-II, the core clusters show a significant difference between Nonverbal Reasoning and both of the other clusters. Any hypothesis concerning poor processing of purely visual information is disconfirmed by Michelle's Spatial cluster score, which is average and at the same level as her Verbal cluster score. The subtests within each cluster have consistent scores, so the cluster scores may be interpreted without further qualification. Because of Michelle's significantly low Nonverbal Reasoning score, it makes little sense to report her General Conceptual Ability (GCA) score, which has little or nothing to offer in terms of describing Michelle's cognitive processing.

The DAS-II Nonverbal Reasoning Gf tasks are called *nonverbal* because they are presented visually. However, to solve the problems effectively, the individual needs to use internal language to encode the components of the visual stimulus, and to generate hypotheses, to test them, and to identify the correct solution. These tasks are therefore characterized in the DAS-II handbook (Elliott, 2007c) as requiring integrated analysis and complex transformation of both visual and verbal information. Problems in this type of processing may be at the root of Michelle's problems in learning to read.

The diagnostic clusters of Working Memory and Processing Speed offer further information. Michelle's Working Memory score is not significantly lower than her GCA score. However, this conclusion is qualified by a significant difference between the two component subtest scores. Recall of Digits—Backward is a purely verbal subtest, and Michelle's score on this is average for her age. On the other hand, her score on Recall of Sequential Order is 12 *T*-score points below her Recall of Digits—Backward score. This difference is highly significant ($p < .01$). Recall of Sequential Order is verbally presented, but requires the examinee to visualize the position of various parts of the body.

Based on the results from the Nonverbal Reasoning cluster, and supported by the results from the Working Memory subtests, it appears that Michelle's processing difficulties do not appear to be shown when she is working with purely auditory–verbal or purely visual–spatial information. Our revised hypothesis is that she seems to have particular difficulties in processing auditory–visual information.

Such a view is confirmed by Michelle's scores on the Processing Speed cluster. Once again, her overall cluster score of 89 is not significantly lower than her GCA score. However, her score on the Rapid Naming subtest is 13 *T*-score points lower than her score on Speed of Information Processing, a statistically significant difference ($p < .05$). Rapid Naming presents colors and pictures that have to be named quickly, and this is another example of a subtest that requires auditory–visual processing.

The diagnostic subtest Recall of Objects is another visual–verbal task, which that yields separate scores for Immediate and Delayed recall. The subtest presents a visual array of pictures, which are named by the examiner and then removed from view. The student is asked to recall them verbally and then recall them two more times after seeing them again, but not hearing them named. Michelle's scores on Recall of Objects are below average, and significantly below the average level of her scores on the core subtests ($p < .05$). The other diagnostic subtests, on which Michelle has achieved average scores for her age, require either purely verbal or purely visual processing.

As a result of these analyses, there is now strong support for the hypothesis that Michelle's cognitive processing difficulties center on problems with auditory–visual materials. Her reading scores support this hypothesis. Reading requires a high level of visual–verbal integration in order to convert visual printed codes into sounds and words. For fluent reading, and for recognition of common words or letter strings, an individual needs information in the auditory–verbal and visual processing systems to be effectively integrated. Similarly, to perform well on the DAS-II Nonverbal Reasoning tasks (or, indeed, any good measures of fluid reasoning), and on the Recall of Sequential Order, Rapid Naming, and Recall of Objects subtests, one needs good integration of the visual and verbal processing systems. These tasks, like the task of reading, present visual information—but to solve the problems effectively, the use of internal language to label and to mediate the solution of the problems is generally essential. In the case of an individual who has excellent verbal and spatial abilities, if the two brain processing systems specialized for those abilities do not "talk" to each other effectively, this may have an adverse effect on performance both in reasoning and in reading acquisition.

The question now arises about appropriate intervention methods for students who have a consistent pattern of difficulties with tasks requiring auditory–visual integration. For many years, teachers of children with dyslexia have actively advocated multisensory teaching methods, despite research evidence that appeared to discredit auditory–visual integration as a cause of poor reading acquisition (e.g., Bryant, 1968). Teachers appear to have long held the view that children with dyslexia have difficulty integrating visual and verbal information. Thus it has been recommended that multisensory teaching methods should be used as much as possible in teaching Michelle basic literacy skills. Useful references to multisensory teaching approaches are given by Thomson and Watkins (1998), Augur and Briggs (1992), Walker and Brooks (1993), Birsh (1999), and Walker (2000).

CHAPTER 14

The Woodcock–Johnson IV

Tests of Cognitive Abilities, Tests of Oral Language, Tests of Achievement

Fredrick A. Schrank
Barbara J. Wendling

The Woodcock–Johnson IV (WJ IV; Schrank, McGrew, & Mather, 2014a) is a comprehensive, co-normed psychoeducational assessment system that includes three test batteries: the Woodcock–Johnson IV Tests of Cognitive Abilities (WJ IV COG; Schrank, McGrew, & Mather, 2014b), the Woodcock–Johnson IV Tests of Oral Language (WJ IV OL; Schrank, Mather, & McGrew, 2014b), and the Woodcock–Johnson IV Tests of Achievement (WJ IV ACH; Schrank, Mather, & McGrew, 2014a). Although some of the WJ IV tests can be used with children as young as 24 months (particularly the WJ IV OL), the WJ IV COG and ACH are best suited for use with individuals from 5 to 95 years of age. Scores from all three batteries can be compared and contrasted with various intra-ability variations and ability–achievement comparison procedures, which can help examiners determine the presence and severity of any intraindividual strengths and weaknesses or performance discrepancies. Normative information was obtained on a large, nationally representative sample of 7,416 individuals ranging in age from 2 to 90+ years of age. A co-normed but separate battery of early development tests called the Woodcock–Johnson IV Tests of Early Cognitive and Academic Development (ECAD; Schrank, McGrew, & Mather, 2015b) is designed primarily for use with children from 30 months through 7 years of age, and is also appropriate for use with children ages 8 through 9 who have cognitive-developmental delays. We have discussed the ECAD in Chapter 10 of this volume.

The WJ IV COG, WJ IV OL, and WJ IV ACH can be used independently or in any combination. Additional interpretive options are available when the batteries are used together. Following a broad overview of general administration procedures and an update to the theoretical model that applies to all three batteries, this chapter is organized into three major sections that address each battery individually. Each section includes information on the organization of the tests and clusters that constitute the battery, any unique administration and scoring rules for some tests, a summary of psychometric properties, and interpretive information that includes an emphasis on what we refer to as *consequential validity*—how the WJ IV can be used to relate any measured limitations in test performance to evidence-based interventions, strategies, accommodations, or instructional planning.

GENERAL ADMINISTRATION AND SCORING PRINCIPLES

Administration and scoring of the WJ IV tests requires knowledge of the exact administration and scoring procedures, as well as an understanding of the importance of adhering to standardized procedures. Each examiner's manual provides guidelines for this purpose. Additionally, the test books contain an abbreviated set of instructions for administering and scoring items on each test; these are found on the introductory page of each test (the first printed page after the tabbed page). Additional instructions may appear on the test pages, such as in boxes with special instructions.

Typically, it is not necessary to administer all tests in a battery. The WJ IV COG, WJ IV OL, and WJ IV ACH each include a small set of core tests that provide some of the most useful information and form the foundation of the intra-ability analytic procedures for each battery. The core tests are placed in a head-initial position in each battery, so that examiners can begin testing with the first test in the test book and discontinue administering tests at preferred junctures. After the core tests are administered, additional tests can be administered as desired, and can also be included in an analysis of relative strengths and weaknesses. Alternatively, examiners can use the Selective Testing Table for each battery to determine which tests to administer; the tests may be administered in any order deemed appropriate, and testing can be discontinued after completion of any test.

Administration of some tests requires the examiner to use a response booklet and an audio recording. Directions for using the response booklet are provided in the test book. The audio recording is used to ensure standardized presentation of certain auditory processing, short-term working memory, oral language, and some language-related tasks. The audio equipment used must have a good speaker, be in good working order, and produce a faithful, clear reproduction of the test items. Using headphones is recommended, as they were used in the standardization. Examiners can wear a monaural earphone or wear only one headphone over one ear to monitor the audio recording, while the examinee is also listening through his or her headphones.

To help examiners document general testing observations, each test record includes a brief, seven-category behavior rating scale on the first page. The categories include levels of conversational proficiency, cooperation, level of activity, attention and concentration, self-confidence, care in responding, and response to difficult tasks. Each category has a range of possible responses, in order to help an examiner identify whether the behavior is typical or atypical for the age or grade of the individual being assessed. This checklist should be completed at the end of the testing session.

Examiners will need to learn how to establish a basal and a ceiling level for several tests. Basal and ceiling criteria are included in the test book for each test requiring them. If an examinee fails to meet the basal criterion for any test, the examiner is directed to test backward until the examinee has met the basal criterion or until item 1 has been administered. When stimuli are visible to the examinee, the examiner is required to test by complete pages. The complete-page rule may affect the process of establishing a basal or a ceiling. For example, if the basal is not established on the first page administered, the examiner tests backward full page by full page until the basal is established or item 1 is administered. Conversely, if the ceiling appears to be reached on a page, the examiner must complete that page. If in the process of completing the page, the examinee responds correctly to an item, testing must continue until the ceiling rule is met and the page is completed. Note that the basal rule is based on the lowest-numbered correct responses specified, and the ceiling is based on the highest-numbered incorrect responses specified. For some tests, examinees begin with item 1 and test until they reach their ceiling level; these tests do not require a basal. Other tests are arranged with item sets or groups; for these tests, specific criteria are outlined in the corresponding manual, test book, and test record.

Individual test items are scored during test administration. Many tests use a 1 (correct) or 0 (incorrect) scoring rule for determining raw scores. Examiners will need to learn how to score items and calculate the raw score for each test. Generally, raw scores are determined by adding the number of correctly completed items to the number of test items below the basal. Scores for sample or practice items should not be included when calculating raw scores. The correct and incorrect keys in the test books are intended to be guides to demonstrate how certain responses are scored, and not all possible or acceptable responses are included in the keys. Completion of the scoring procedure requires using the Woodcock–Johnson Online Scoring and Reporting System (Schrank & Dailey, 2014). Additionally, examiners may purchase and use the WJ IV Interpretation and Instructional Interventions Program (WIIIP; Schrank & Wendling, 2015a), an online option for generating narrative interpretive text and related interventions. The WIIIP simplifies the process of linking assessment to instruction by using WJ IV test results to generate evidence-based interventions.

Although both age and grade norms are provided for the WJ IV, age norms are often preferred for cognitive assessments. The associated scoring and interpretive programs provide a number of different interpretive report options, profiles, and a full array of interpretive scores, including age- and grade-equivalent scores, relative proficiency indexes (RPIs), and peer comparison scores (e.g., standard scores and percentile ranks). Different types of scores provide different perspectives on test performance and are not interchangeable. Schrank, Decker, and Garruto (2016) provide some perspective on recommended scores for inclusion in a report:

- Age-equivalent (AE) scores express the individual's performance in terms of the age equivalent in the standardization sample that is associated with the raw score. As such, these scores provide information about an individual's developmental age.
- Proficiency-level terms (e.g., *very advanced, advanced, average, limited, very limited, extremely limited*) describe the individual's ability with the measured tasks in relation to individuals of the same age. These terms have objective meaning because they are tied directly to task proficiency on the WJ IV and are not related to standard score classifications. The associated RPI scores express proficiency as a ratio that compares the individual's task proficiency to the relative proficiency of a typical, or median, individual of the same age (e.g., 82/90).
- Standard scores and percentile ranks provide information about the individual's relative position among peers. Standard scores are often required and can be useful for many comparative purposes. However, because standard scores lack objective meaning, the associated percentile ranks are recommended: They provide information on how common or rare the individual's ability level is within the general population, in a metric that is more commonly understood by both professional and nonprofessional consumers of report information.

EVOLUTION OF THE WJ IV INTERPRETIVE MODEL

The WJ IV is associated with the contemporary version of the Cattell–Horn–Carroll (CHC) theory of cognitive abilities, sometimes referred to as *CHC version 2* (McGrew, LaForte, & Schrank, 2014; Schneider & McGrew, 2012 and Chapter 3, this volume). Analysis of the Woodcock–Johnson—Revised (WJ-R; Woodcock & Johnson, 1989), Woodcock–Johnson III (WJ III; Woodcock, McGrew, & Mather, 2001), and WJ IV standardization samples (none of which were analyzed by Carroll, 1993) provided three large, multiple-ability datasets to either confirm or revise prior CHC construct specifications. Additional impetus for changes to some of the interpretive constructs or terminology was gleaned from other sources of neuroscience research, such as that reported in McGrew and colleagues (2014) and Schrank and colleagues (2016). The concept of *cognitive complexity* (Lohman & Lakin, 2011) was employed in test construction to increase ecological validity and diagnostic relevance. Perhaps the most significant changes to the previous CHC constructs are derived from external neurocognitive and psychometric research in the domains of working memory and attentional control, memory consolidation and retrieval, and auditory intelligence.

Working Memory and Attentional Control

Within the past 35-plus years, the term *working memory* became increasingly cited in neuroscience research (Unsworth, 2016), often with operational definitions that either replaced or included the construct of *short-term memory*. In its broadest sense, *working memory* refers to a dynamic, temporary storage system that allows information—either sensory inputs or prior knowledge—to be held in *primary memory* (James, 1890) (sometimes referred to as *immediate awareness*) and manipulated (Atkinson & Shiffrin, 1968; 1971; Baddeley & Hitch, 1974; Goldman-Rakic, 1992; Miller, Galanter, & Pribram, 1960). In contrast, the term *short-term memory* has come to refer more narrowly to "tasks that involve significant storage but only minimal processing" (Gathercole & Alloway, 2008, p. 21).

In contemporary professional nomenclature, working memory refers to a broader, more complex construct than short-term memory span. In contrast to the WJ IV narrow Memory Span (MS) cluster, which consists solely of tasks that measure passive holding onto verbal information, the WJ IV Short-Term Working Memory (Gwm) clusters comprise tasks that involve both temporary storage *and* active review or manipulation of words and numbers, and, as a consequence of task complexity, rely more heavily on increased control of attention for successful completion of any retrieval, recoding, or reorganization subprocesses. The term *working* suggests that working memory is the active "hub" of human cognition (Camos, 2015) and can invoke other cognitive functions or abilities to effect goal attainment, such as visualization, phonology, reasoning, and retrieval or secondary memory. In addition, in both neuroscience and contemporary CHC theory, the construct of working memory includes the attentional control processes that bring representations into heightened activation and maintain the representations free from distraction (Unsworth, 2016).

Klingberg (2009) suggested that working memory is important for at least two reasons. First, it is the mechanism by which we focus our attention. Second, its *capacity* places one of the most important limitations on the brain's ability to process information and is "fundamental and vital to numerous mental tasks, from attention control to solving logical problems" (p. 33). All stimulus-driven attention requires working memory; consequently, limitations in working memory capacity have important educational and functional implications. As noted by Klingberg, "Working memory is used to control attention, to remember instructions, to keep in mind a plan of things to do, and to solve complex problems" (p. 45).

Working memory capacity appears to be domain-general, and its influence cuts across a wide variety of complex learning tasks (Kyllonen & Stephens, 1990; Unsworth, 2016). Limited working memory capacity can act as a bottleneck for learning and may be related to learning disabilities (Gathercole, 2004; Gathercole, Lamont, & Alloway, 2006). Many children with identified reading, writing, and mathematics disabilities show related impairments in working memory capacity (Bull & Scerif, 2001; de Jong, 1998; Mayringer & Wimmer, 2000; Siegel & Ryan, 1989; Swanson, 1994; Swanson, Ashbaker, & Lee, 1996). Limited working memory capacity may also be related to learning disabilities that are not domain-specific. Gathercole and Alloway (2008) stated, "Learning difficulties that extend across both reading and mathematics, or language, therefore appear to be characteristic of children with poor working memory function" (p. 25).

Research beyond the initial specifications of CHC theory suggested that working memory, working memory capacity, and attentional control appear to be valid interpretive constructs. In contemporary CHC theory, the term *working* was added to the name of the former short-term memory factor to become *short-term working memory* (Gwm). The WJ IV Gwm clusters are designed to contain different measures of working memory capacity (WM), a quantifiable aspect of the more broadly encompassing working memory construct used in contemporary neuroscience. In addition, attentional control (AC) has attained greater specification in CHC theory as a facet, or perhaps a correlate, of working memory capacity (Unsworth, 2016).

Updates to the constructs of working memory and attentional control in contemporary CHC theory are reflected in the WJ IV. The WJ IV COG includes three different types of complex working memory capacity tasks and one verbal memory span test. COG Test 3: Verbal Attention measures an individual's temporary storage of verbal information and assesses the ability to retrieve and reactivate information that might not be actively maintained in primary memory (Unsworth, 2016) via a cue-dependent search process (Unsworth & Engle, 2007a). COG Test 10: Numbers Reversed taps the recoding function of working memory. COG Test 16: Object–Number Sequencing evaluates the reorganization and assembly functions of working memory. In contrast, COG Test 18: Memory for Words measures verbal short-term memory span for unrelated words. Finally, because working memory capacity is related to vocabulary learning (Daneman & Green, 1986), reading, and language comprehension (Daneman & Carpenter, 1980), the WJ IV OL includes two ecologically relevant tests for evaluating working memory for language processing. OL Test 5: Sentence Repetition is an expressive language measure of verbal, auditory memory span. OL Test 6: Understanding Directions assesses the ability to follow directions from orally imparted instructions, and is thus a receptive language measure requiring working memory.

All of the WJ IV short-term working memory tests require varying parameters of attentional control. Complex working memory tasks (those involving a storage function in the context of processing) require higher allocation of attentional resources than pure memory span tasks (those involving passive storage only) do, and individuals with higher working memory capacities are better able to sustain attention on complex tasks than are individuals with limited working memory capacities (Unsworth, 2016). For example, individuals with lower levels of attentional control may be subject to the influences of external distraction or may let their minds wander when performing complex tasks. The different WJ IV working memory tests provide opportunities for highly knowledgeable professionals to draw inferences or make clinical hypotheses about the relationships between examinees' levels of working memory capacities and attentional control under different conditions.

Memory Consolidation and Retrieval

In contemporary CHC theory and in the WJ IV, an important distinction is made between tests and clusters that measure storage *and* retrieval functions on the one hand, and tests and clusters that solely measure retrieval functions on the other. This distinction was initially posited by Carroll (1993), whose three-stratum theory articulated separate and distinct stratum II factors for (1) general memory and learning and (2) broad retrieval ability. However, in the initial conceptualization of CHC theory (McGrew, 1997), the Glr factor included both types of functions.

In retrospect, the initial CHC misspecification of both storage and retrieval and retrieval-only cognitive functions into one common broad factor might have been a classic "wrong turn at Albuquerque."[1] In addition to the misspecification error, many professionals routinely dropped the word *storage* from the name of the Glr construct and simply referred to the factor or cluster as *long-term retrieval.* This tendency may have caused some confusion with the neurocognitive construct of long-term memory. Consequently, because of an initial "wrong turn" and the simultaneous verbal (*long-term retrieval*) shortcut, changes to contemporary CHC theory nomenclature as represented in the WJ IV provide cleaner distinctions between retrieval measures that do, and those that do not, involve the storage function.

The WJ IV COG Long-Term Storage and Retrieval (Glr) cluster measures the integrity of consolidation (encoding) of semantic (meaning-based) representations into long-term memory. The tests that constitute the Glr cluster measure two different processes by which semantic memories (Tulving, 1972, 1985) are created, using standardized formats for evaluating the integrity of semantic memory consolidation functions in working memory. COG Test 6: Story Recall measures the development, consolidation, and reconstruction of mental representations from orally imparted discourse. In CHC theory, this is referred to as the narrow ability of *meaningful memory* (MM), an aspect of semantic storage and retrieval. Measures of MM may have practical, incremental validity for predicting success in learning situations, beyond what an individual's general intellectual ability might suggest (Cucina, Su, Busciglio, & Peyton, 2015). COG Test 13: Visual–Auditory Learning measures the ability to associate words with rebus representations. In CHC theory, this narrow ability is called *associative memory* (MA).

In the WJ IV ACH, Test 12: Reading Recall is also a measure of Glr and MM. This task requires reading a short story and then retelling the principal components. The Reading Recall test measures the development and consolidation of mental representations from textual material. Although successful performance on this task is dependent on background knowledge and foundational basic reading skills, the central cognitive operation utilized is called *mapping,* wherein key elements of the story are added to a mental representation being built in working memory during the process of reading (Ashcraft, 2002; Zhou & Black, 2000). The recall or retelling phase of each story merely provides a test of whether encoding (e.g., storage of story elements) has occurred during the reading phase.

The WJ IV COG Glr cluster and associated tests represent critically important links between the constructs of working memory and long-term memory. The storage aspect of the Glr tests and clusters refers to the consolidation of semantic memories, a cognitive function that is critically important to learning. Thus Glr, in contemporary CHC theory and in the WJ IV, may be described as the gateway between *information to be learned* and *learned information.*

In contrast, the WJ IV OL Speed of Lexical Access (LA) cluster measures the *retrieval-only* function that Carroll (1993) would probably have associated with his broad retrieval ability factor. Schneider and McGrew (Chapter 3, this volume) have suggested the initialism Gr to represent this function as a broad factor of retrieval ability; this helps distinguish it from the WJ IV COG Glr cluster, which includes the memory consolidation function. WJ IV OL Test 4: Rapid Picture Naming and OL Test 8: Retrieval Fluency, as well as Part B Word Fluency of WJ IV COG Test 5: Phonological Processing, all measure retrieval of names and words from previously stored knowledge. A type of verbal efficiency (Perfetti, 1985) or automaticity for lexical access (LaBerge & Samuels, 1974; Neely, 1977) may be a common overt characteristic of these tasks, contrasting its nature with the memory consolidation function that is the primary distinguishing characteristic of the WJ IV Glr tests.

Cognitive Complexity and Auditory Intelligence

In the design of several new tests and in revision of some other tests, cognitive complexity was infused by increasing or expanding the breadth of information-processing demands. Cognitively complex information processing typically requires greater allocation of key cognitive resources (such as working memory and attention control) and involves more executive functions (Arend et al., 2003; Jensen, 2011; Lohman & Lakin, 2011; Marshalek, Lohman, & Snow, 1983: McGrew, 2012). As a consequence of the conjoint integration or hierarchical application of other critical cognitive processes and capacities, storage and retrieval functions, or basic fluency mechanisms, cognitively complex tasks often correlate with other tests that tap similar abilities, and will thus load on more than one cognitive factor. Although cognitive complexity is not the same as factorial complexity (e.g., a mixed measure of Gf and Gv), task requirements of cognitively complex tests often require the interplay of more than one CHC ability, just as typical classroom or occupational task demands do.

Cognitively complex tests tend to correlate highly with psychometric *g*, making them well suited for evaluation of general intellectual ability and prediction of academic achievement. Consequently, the concept of cognitive complexity was an important criterion in selection of the new tests that compose the WJ IV COG General Intellectual Ability (GIA) score and the Scholastic Aptitude clusters, including in particular COG Test 2: Number Series, COG Test 3: Verbal Attention, and COG Test 5: Phonological Processing. These tests correlate highly with measures of *g*—not necessarily because the tasks require high-level abstract reasoning or problem solving, but because each task requires the efficient interaction of simple cognitive operations (e.g., searching a person's mental lexicon network based on sounds) or conjointly taxes the parameters of cognitive efficiency (e.g., working memory capacity and attentional control).

The tests that compose the WJ IV COG Auditory Processing (Ga) cluster are cognitively complex, in terms of both information-processing demands and factor composition. For example, COG Test 5: Phonological Processing measures three aspects of speech sound processing that lead to the construction of sound-based lexical representations; the three aspects invoke parameters of language development, word fluency, and phonological sensitivity. In terms of contemporary CHC theory, COG Test 5: Phonological Processing involves comprehension–knowledge as a broad cognitive ability and invokes applications of phonetic coding (PC), language development (LD), word fluency (FW), and speed of lexical access (LA). COG Test 12: Nonword Repetition is a complex task that is best explained by a combination of two factors—auditory short-term working memory and "a further ability that is specific to the repetition of novel multisyllabic phonological forms" (Archibald & Gathercole, 2007, p. 923). Although primarily phonological in nature, nonword repetition ability is constrained by phonological storage capacity (Baddeley, Gathercole, & Papagno, 1998; Gathercole, 2006). COG Test 12: Nonword Repetition measures both span in short-term working memory and phonological sensitivity in auditory processing (McGrew et al., 2014).

As a factor of intelligence, auditory processing (Ga) has historically received far less attention (and was less likely to be measured in intelligence tests) than its parallel cognitive construct, visual processing (Gv). Although broad auditory perception was firmly established as a factor of general intelligence by Carroll (1993), seminal works by Stankov and Horn (1980) and Horn and Stankov (1982) were foundational to a recognition of the importance of auditory abilities to academic performance, particularly orthographic skill development. A relative latecomer to the table of intellectual abilities, the construct of auditory processing is still being refined in terms of scope and defining nomenclature (McGrew et al., 2014).

Another body of research, not previously integrated into CHC theory, posited the existence of a phonological storage ability or short-term memory function for speech sounds (Gathercole & Baddeley, 1989; Gathercole, Willis, Emslie, & Baddeley, 1992, 1994). Although Carroll (1993) identified a narrow auditory processing ability apparently involving memory as a critical component, his datasets were small and consisted primarily of tests utilizing patterns of nonspeech sounds. However, it is of interest to note that Carroll was able to distinguish an aspect of auditory processing involving memory, and he was intrigued with the possibility of distinguishing an auditory factor analogous to the narrow visual memory (MV) factor (Carroll, 1993, p. 391). Consequently, a growing body of research that relates auditory abilities to the development of language and cognition, including the studies of Gathercole and colleagues, has suggested a need to expand the initial description of the CHC narrow ability called *memory for sound patterns* (UM) to include memory for speech sounds; it also supports the inclusion of the auditory short-term working memory tasks as part of the construct of auditory processing.

Related research led to the suggestion that auditory abilities can be involved in reasoning as well as memory functions. Conzelmann and Süß (2015) credited the research of Seidel (2007) in a proposed definition of auditory intelligence as "the ability to discriminate, remember, reason, and work creatively on auditory stimuli, which may consist of tones, environmental sounds, and speech units" (p. 28). The expansion of the construct of auditory processing to include aspects of reasoning with auditory stimuli is supported by the phonological mediation hypothesis (Van Orden, 1987; Van Orden & Goldinger, 1996), which suggests that phonological codes (or cues) can convey or transmit information that facilitates word identification. Consequently, in contemporary CHC theory (see Schneider & McGrew, Chapter 3, this volume), auditory processing includes the activation and restructuring of information in primary (working) memory and retrieval of information from secondary (long-term) memory based on phonological codes.

Phonological codes play an important role in the cognitive processes involved in identifying word meaning and in word production (Vitevitch & Goldstein, 2014). The ability to reason with speech sounds and retrieve words based on phonological cues is particularly applicable to reading, including identifying words and understanding passages (Leinenger, 2014). For example, when a person is reading silently, orthographic information is often recoded into phonological information. The process of phonological coding produces the sensation of an inner voice that can activate—by making a connection to—candidate words in the individual's lexicon. In fact, some researchers have argued that phonological codes are the primary means by which readers achieve lexical access and understand what they read (Lukatela & Turvey, 1994a, 1994b; Van Orden, 1987). As Van Orden and Goldinger (1996) suggested, "We read in order to 'hear,' in order to understand" (p. 206).

Although auditory processing abilities are measured in several different ways in several WJ IV tests, the WJ IV COG Auditory Processing (Ga) cluster was designed to best represent the broader construct of auditory intelligence that includes the phonological memory and reasoning functions alluded to by Conzelmann and Süß (2015). As a component of general intelligence and predictor of achievement, COG Test 5: Phonological Processing measures three aspects of speech sound processing that lead to the construction of lexical representations from phonological codes. Also referred to as tasks of *phonological awareness* or *phonological sensitivity,* these types of tasks are closely associated with learning new words (de Jong, Seveke, & van Veen, 2000), learning to read (Liberman, Shankweiler, & Liberman, 1989; Wagner, Torgesen, Laughon, Simmons, & Rashotte, 1993; Wagner, Torgesen, & Rashotte, 1994), and the ability remains critical even for mature readers when approaching difficult, infrequent, or unfamiliar words in text (Jared, Levy, & Rayner, 1999; McCusker, Hillinger, & Bias, 1981).

Although changes to CHC constructs in the domains of working memory and attentional control, memory consolidation and retrieval, and auditory intelligence are not the only modifications to CHC theory since its debut in the WJ III (Woodcock et al., 2001), these examples demonstrate how the evolving interpretation of the WJ IV has been based on an accumulation of knowledge about the structure of, and interplay among, cognitive abilities. In each subsequent section of this chapter, information is provided about what each WJ IV test or cluster measures according to contemporary CHC theory, as well as relationships of the WJ IV tests to other measures that assess the same or similar interpretive constructs. Very important, we think, is the concept of *consequential validity*—the idea that valid measures of cognitive, linguistic, and academic abilities should be relevant for purposes of an evaluation, and that scores from the WJ IV should have meaning for planning and decision making. For the WJ IV tests and clusters, the links to practical suggestions and educational interventions or accommodations provide evidence of consequential validity.

WJ IV TESTS OF COGNITIVE ABILITIES

The WJ IV COG includes 18 tests for measuring intellectual ability, broad and narrow cognitive abilities, and related aspects of cognitive functioning. The WJ IV COG is best suited for use with school-age children, adolescents, and adults.

Organization of the WJ IV COG

Figure 14.1 presents the Selective Testing Table for the WJ IV COG. Tests 1–10 comprise the Standard Battery; Tests 11–18 comprise the Extended Battery. Combinations of tests comprise clusters for interpretive purposes. Three cognitive composites are available: General Intellectual Ability (GIA), Brief Intellectual Ability (BIA), and the Gf-Gc Composite. The WJ IV COG has the following clusters that measure seven broad CHC factors: Comprehension–Knowledge (Gc), Fluid Reasoning (Gf), Short-Term Working Memory (Gwm), Cognitive Processing Speed (Gs), Auditory Processing (Ga), Long-Term Storage and Retrieval (Glr), and Visual Processing (Gv). Measures of several narrow CHC abilities or otherwise clinically useful clusters are also available, including Quantitative Reasoning (RQ), Number Facility (N), Perceptual Speed (P), and Cognitive Efficiency. When selected tests from the WJ IV OL are administered with designated tests from the WJ IV COG, clusters that measure additional narrow abilities are available: Auditory Memory Span (MS) and Vocabulary (VL/LD). This section of the chapter contains definitions of what is measured by each of the WJ IV COG tests and clusters, and, based on the cognitive processing demands

			Cognitive Composites			CHC Factors							Narrow Ability and Other Clinical Clusters					
			General Intellectual Ability (GIA)	Brief Intellectual Ability	Gf-Gc Composite	Comprehension-Knowledge (Gc)	Fluid Reasoning (Gf)	Short-Term Working Memory (Gwm)	Cognitive Processing Speed (Gs)	Auditory Processing (Ga)	Long-Term Retrieval (Glr)	Visual Processing (Gv)	Quantitative Reasoning (RQ)	Auditory Memory Span (MS)	Number Facility (N)	Perceptual Speed (P)	Vocabulary (VL/LD)	Cognitive Efficiency
Standard Battery	COG 1	Oral Vocabulary	■	■	■	■											■	
	COG 2	Number Series	■	■	■		■						■					
	COG 3	Verbal Attention	■	■				■										□

required for performance on the tests, provides links to interventions or accommodations that may be helpful in many situations for developing a targeted educational plan that is based in part on an individual's cognitive profile. Figure 14.1 can be used to help examiners determine which tests to administer for the desired level of interpretive information in an evaluation.

How to Administer the WJ IV COG Tests

The WJ IV COG tests are placed in an order that facilitates both administration and interpretation. For example, examiners can begin testing with Test 1, administer additional tests in sequential order, and discontinue testing at a point that provides the level of information desired or required. Administration of the core tests (Tests 1–7) allows examiners to obtain an evaluation of any intra-individual differences among component scores. Administering the core tests often yields the most essential information in the least amount of testing time because each of the first seven tests is the best single indicator of a broad ability. Any information or clinical observations obtained during or from administration of the core tests can prompt an examiner to administer additional tests (e.g., to obtain a cluster score). An important point to remember is that administering the core tests meets the minimal requirement for calculation of intra-individual variations, and that additional tests and clusters can also be included in the same analysis.

Many examiners routinely administer Tests 1–10 because of the depth of interpretive information obtained, including clusters scores for Gc, Gf, Gwm, Cognitive Efficiency, the Gf-Gc Composite, and an automated comparison of the Gwm and Cognitive Efficiency scores to the Gf-Gc Composite. This is called a *standard administration protocol* for the WJ IV COG (Schrank et al., 2016). Any additional WJ IV clusters that are not primarily Gc or Gf can also be compared to the Gf-Gc Composite to determine whether other intraindividual strengths and weaknesses exist relative to the Gf-Gc Composite. The Gf-Gc Composite may have particular relevance as a measure of intellectual development or intellectual level for some individuals who have a limitation in one or more areas of cognitive processing or efficiency. This can be true for individuals whose Gf-Gc Composite scores are markedly higher than their scores from other cognitive, oral language, or achievement clusters, which may help define the nature of a disability (Schrank, McGrew, & Mather, 2015a; Schrank et al., 2016). In fact, the WJ IV authors recommend use of the Gf-Gc Composite as the most appropriate index of intellectual level for comparison to measures of other cognitive processes, cognitive–linguistic abilities, and areas of academic performance for identification of a specific learning disability (Schrank et al., 2015a).

Selected tests from the WJ IV COG can be used in conjunction with the WJ IV ACH to determine if an individual is achieving as well as would be predicted from scores on a small set of closely related cognitive tests. In the WJ IV, these are called *scholastic aptitude–achievement comparisons*. However, the Scholastic Aptitude clusters are not meant to determine the presence of a specific learning disability, and using them in this way is counter to the meaning of determining an ability–achievement discrepancy as described in federal guidance and state eligibility guidelines.

Administration Time

As a general rule, experienced examiners require about 35–40 minutes to administer the seven core tests, or 50–60 minutes to administer all of the tests in the Standard Battery. As a general guideline, an examiner should allow approximately 5 minutes per additional cognitive or oral language test administered.

Testing Materials

Testing materials required for administration of the WJ IV COG include the test book, a test record, the audio CD, appropriate audio equipment, pencils, and a stopwatch.

Summary of Key Administration and Scoring Points

Most tests use suggested starting points and basal and ceiling rules, and responses are scored 1 or 0. Table 14.1 summarizes the key administration and scoring points for each test.

Special Administration and Scoring Considerations

Although the WJ IV COG examiner's manual (Mather & Wendling, 2014b) and test book provide detailed rules for test administration, this section presents important reminders about tests that have special administration or scoring rules.

TABLE 14.1. Summary of WJ IV COG Test Administration and Scoring Rules

Test name	Item scoring rule	Sample items?	Basal/ceiling rules?[a]	Administration notes	Extra materials required for administration
			Standard Battery tests		
Test 1: Oral Vocabulary				Both subtests must be administered.	
1A: Synonyms	1, 0	Yes	Yes; 6/6	Suggested starting points are available after sample items.	
1B: Antonyms	1, 0	Yes	Yes; 6/6	Suggested starting points are available after sample items.	
Test 2: Number Series	1, 0	Yes	Yes; 5/5	Suggested starting points are available after sample item.	Response booklet; stopwatch to monitor response time
Test 3: Verbal Attention	1, 0	Yes	Yes; 6/6	Suggested starting points available.	Audio
Test 4: Letter–Pattern Matching	1 for each correct pair in 3 minutes	Yes	No; 3-minute time limit	All begin after sample items and practice exercise; use scoring guide.	Stopwatch (timed test); response booklet
Test 5: Phonological Processing				All three subtests must be administered.	
5A: Word Access	1, 0	Yes	Yes; 6/6	Begin with sample item based on estimated ability.	Audio
5B: Word Fluency	1 for each correct word in 1 minute	No	No; 1-minute time limit per item	All examinees are administered both items.	Stopwatch (timed test)
5C: Substitution	1, 0	Yes	Yes; 6/6	Locate suggested starting point based on estimated ability; then begin with sample items.	Audio
Test 6: Story Recall	1 for each correct element	No	No; ceiling determined by continuation instructions	Suggested starting points are available; scoring is based on administration of specific groups of stories.	Audio
Test 7: Visualization				Both subtests must be administered.	
7A: Spatial Relations	1, 0	Yes	Item 1 is basal; ceiling is 5	All begin with the introduction.	
7B: Block Rotation	1, 0	Yes	Item 1 is basal; ceiling is 5	Suggested starting points are available; all begin with an introduction.	Stopwatch to monitor response time

Test 8: General Information				Both subtests must be administered.	
8A: Where	1, 0	No	Yes; 4/4	Suggested starting points are available.	
8B: What	1, 0	No	Yes; 4/4	Suggested starting points are available.	
Test 9: Concept Formation	1, 0	Yes	No; ceiling determined by cutoffs	Suggested starting points are available; proceed to introduction and sample items.	Stopwatch to monitor response time
Test 10: Numbers Reversed	1, 0	Yes	Yes; 5/5	Suggested starting points are available; then begin with sample item.	Audio
			Extended Battery tests		
Test 11: Number–Pattern Matching	1 for each correct pair in 3 minutes	Yes	No; 3-minute time limit	All begin after sample items and practice exercise; use scoring guide.	Stopwatch (timed test); response booklet
Test 12: Nonword Repetition	1, 0	Yes	Yes, 6/6	All begin with sample items; then use suggested starting points.	Audio
Test 13: Visual–Auditory Learning	Count of errors	No	All begin with Introduction 1; ceiling determined by cutoffs	Record number of errors for each story on test record; scoring is based on stories administered.	Stopwatch to monitor response time
Test 14: Picture Recognition	1, 0	Yes	Yes; 6/6	Suggested starting points are available; then begin with sample item.	Stopwatch to monitor time to view stimulus
Test 15: Analysis–Synthesis	1, 0	Yes	All begin with item 1; ceiling determined by cutoffs	All begin with color pretest, then Introduction 1 and sample item; scoring is based on items administered.	Stopwatch to monitor response time
Test 16: Object–Number Sequencing	1, 0	Yes	Yes; 5/5	All begin with sample item; then use suggested starting points.	Audio
Test 17: Pair Cancellation	1 for each correct pair in 3 minutes	Yes	No; 3-minute time limit	All begin with sample items and practice exercise; use scoring guide.	Stopwatch (timed test); response booklet
Test 18: Memory for Words	1, 0	Yes	Yes; 4/4	All begin with sample items; then use suggested starting points.	Audio

---

[a] May be modified by complete-page rule.

Timed Tests

The WJ IV COG contains four timed tests. Test 4: Letter–Pattern Matching, Test 11: Number–Pattern Matching, and Test 17: Pair Cancellation each have a 3-minute time limit. Part B Word Fluency of Test 5: Phonological Processing is also timed; this subtest has two items that each have a 1-minute time limit. The time limits are noted on the appropriate test book pages as well as on the test record. Administering these tests requires using a stopwatch or a watch with a second hand.

For Part B Word Fluency of Test 5: Phonological Processing, duplicate responses are not accepted, but variations of a word do receive credit (e.g., *do, doing, does*). Words presented as examples do not count toward credit (e.g., *milk* and *dog*). An examiner should record a tally mark for each correct response, grouping by fives. For each item, the examiner counts the correct responses and records the total in the Number Correct box. The maximum number that can be entered for each item is 99.

Audio Tests

The standardized audio recording should be used to present Test 3: Verbal Attention, Part A Word Access of Test 5: Phonological Processing, Test 6: Story Recall, Test 10: Numbers Reversed, Test 12: Nonword Repetition, Test 16: Object–Number Sequencing, and Test 18: Memory for Words. An examiner should not repeat or replay any item unless the directions permit it (e.g., on sample items).

Test 6: Story Recall

The score on Test 6: Story Recall is based on the number of correct responses the examinee has on the set of stories administered. Each story element is based on a keyword set in boldface type in the test record, which must be recalled exactly to receive a score of 1. Synonyms that preserve the meaning of the boldface word are also scored 1 (e.g., *speak* for *talk*). Derivations of or possessive case added to proper names are also scored 1 (e.g., *Rick* for *Rick's*). Responses that vary in verb tense or number (e.g., singular–plural) are scored 1 (e.g., *star* for *stars*). Nonboldface words do not need to be recalled exactly, but can be recalled as a general concept. In the score entry section of the test record, an examiner should enter the number of points for each set of stories administered and enter an X if a set was not administered. To obtain estimated age and grade equivalents, the examiner locates the number of points in the appropriate column corresponding to the group of stories administered.

Test 13: Visual–Auditory Learning

In Test 13: Visual–Auditory Learning, the score is based on the number of errors the examinee makes. In the Test Record, the examiner circles each word the examinee misses or is told after a 5-second pause. Omitted words, inserted words, synonyms are scored as errors. For words with two symbols (e.g., *ride . . . ing*), each symbol is considered separately in scoring. If one part of a two-symbol word is incorrect, only the incorrect part is scored as an error. The total number of errors at each cutoff point is entered in the box provided in the test record. The examiner enters the number of errors and the letter corresponding to the set of test stories administered in the score entry box in the test record, and in the corresponding field in the Online Scoring and Reporting System.

Reliability and Validity

Examiners can also selectively administer any tests and clusters to meet an assessment purpose. Each test and cluster should be interpreted from the perspective of available validity evidence, including coefficients of stability. Median reliability coefficients for the WJ IV COG tests are reported in Table 14.2. With the exception of the timed tests, coefficients of stability are reported as median internal-consistency (r_{11}) and median standard error of measurement *(SEM)* values. The internal-consistency reliabilities were calculated with the split-half procedure (odd and even items) and corrected for length with the Spearman–Brown formula. *SEM* values provide information about the precision of each test's scores. For the three timed tests, test–retest values (r_{12}) were used as the most appropriate coefficient of stability. Mosier's (1943) formula was used to calculate reliabilities for tests with subtests, such as COG Test 5: Phonological Processing. Mosier's formula uses individual subtest reliabilities that were obtained from either, or a combination of, the split-half procedure or the test–retest procedures.

Table 14.3 contains the median cluster reliability coefficients (r_{cc}) and median standard errors of measurement for obtained cluster standard scores, or *SEM* (SS), as calculated via Mosier's formula. All of the WJ IV COG CHC-based broad and nar-

Note. r_{11}, internal-consistency reliability; r_{12}, test–retest reliability for speeded tests.

row ability clusters, with the exception of Visual Processing (Gv), exceed the commonly referenced professional standard of .90 for decision-making purposes. The reliability coefficients for the GIA and Gf-Gc Composite are very high. Most of the WJ IV COG tests exceed the .80 value, with some test reliabilities exceeding .90. The reported test reliabilities support use and interpretation of the test-level scores as single indicators of a broad cognitive ability for inferential and qualitative analysis, but the higher cluster reliabilities support the recommendation that the WJ IV COG clusters are the preferred indexes for most decision-making purposes, such as determining a deficit or impairment in cognitive processing. Note also that reliabilities for most of the WJ IV COG Scholastic Aptitude clusters do not exceed .90 (although they approach that value), and that these clusters should not be used to supplant use of the WJ IV COG GIA or Gf-Gc Composite for purposes of determining an ability–achievement discrepancy or determining whether a pattern of strengths and weaknesses exists. The Scholastic Aptitude clusters are intended for descriptive analysis only.

Table 14.4 contains the correlations for the WJ IV COG GIA, BIA, and Gf-Gc Composite with other composite measures of intellectual ability, including the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV; Wechsler, 2003), the Wechsler Adult Intelligence Scale—Fourth Edition (WAIS-IV; Wechsler, 2008), the Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004a), and the Stanford–Binet Intelligence Scales, Fifth Edition (SB5; Roid, 2003). As noted by Reynolds and Niileksela (2015), “Correlations between corresponding scores from the WJ IV COG and the Wechsler scales were especially strong” (p. 389). The consistently strong correlations of the WJ IV GIA, BIA, and Gf-Gc Composite scores with Full Scale IQ scores from the WISC-IV, WAIS-IV, and SB5 supports the validity of the WJ IV indexes as valid measures of psychometric intelligence. Of particular interest is the notably lower correlation of the WJ IV COG Gf-Gc Composite with the KABC-II Mental Processing Index; this supports the interpretation of the WJ IV COG Gf-Gc Composite as a measure of intellectual level for use in an evaluation of learning disabilities because it is less influenced by mental processing abilities or disabilities than the WJ IV COG GIA or BIA scores (Schrank et al., 2015a).

Interpretation

The WJ IV COG can be interpreted at the cluster and test levels, depending on the purposes of an evaluation. The broad and narrow abilities described in contemporary CHC theory provide the basic interpretive architecture for the validity of the clusters and tests. Interpretation is based on extensive psychometric data and analyses provided by McGrew and colleagues (2014), as well as a trove of related research outside the WJ IV literature (see Schrank et al., 2016) that provides support for our interpretation of the underlying cognitive processes required for performance on each test. Table 14.5 identifies the broad and narrow cognitive abilities measured by each test in the WJ IV COG; it also includes brief test descriptions. The WJ IV COG tests are organized into clusters for interpretive purposes; these clusters are outlined in Table 14.6. The WJ IV COG clusters and tests are described in this section. The WJ IV COG options for measuring intellectual level or ability are also described. Finally, we describe several variation and discrepancy procedures that are available to assist examiners in comparing scores, determining profiles of abilities, and making diagnostic decisions.

TABLE 14.4. Correlations for Select WJ IV COG Measures and Other Measures of Cognitive Abilities

Other measure	General Intellectual Ability (GIA)	Brief Intellectual Ability (*g*)	Gf-Gc Composite
Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV)[a]	.86	.83	.83
Wechsler Adult Intelligence Scale—Fourth Edition (WAIS-IV)[a]	.84	.74	.78
Kaufman Assessment Battery for Children—Second Edition (KABC-II)[b]	.72	.67	.57
Stanford–Binet Intelligence Scales, Fifth Edition (SB5)[a]	.80	.79	.82

[a] The measure reported is the Full Scale IQ (*g*) score.

[b] The measure reported is the Mental Processing Index score.

TABLE 14.5. WJ IV COG Tests, CHC Broad and Narrow Abilities Measured, and Brief Test Descriptions

Test name	Primary broad CHC ability *Narrow ability*	Brief test description
Test 1: Oral Vocabulary	Comprehension–knowledge (Gc) *Lexical knowledge* (VL) *Language development* (LD)	Measures knowledge of words and word meanings.
Test 2: Number Series	Fluid reasoning (Gf) *Quantitative reasoning* (RQ) *Inductive reasoning* (I)	Assesses quantitative reasoning.
Test 3: Verbal Attention	Short-term working memory (Gwm) *Working memory capacity* (WM) *Attentional control* (AC)	Measures temporary storage of verbal information and the cue-dependent search function of primary memory.
Test 4: Letter–Pattern Matching	Cognitive processing speed (Gs) *Perceptual speed* (P)	Evaluates orthographic visual-perceptual discrimination ability under timed conditions.
Test 5: Phonological Processing	Auditory processing (Ga) *Phonetic coding* (PC) *Speed of lexical access* (LA) *Word fluency* (FW)	Measures word activation, fluency of word access, and word restructuring via phonological codes.
Test 6: Story Recall	Long-term storage and retrieval (Glr) *Meaningful memory* (MM) *Listening ability* (LS)	Assesses listening ability with attention to orally imparted details; formation of mental representations in the stimulus phase; story reconstruction in the response phase.
Test 7: Visualization	Visual processing (Gv) *Visualization* (Vz)	Evaluates size and shape perception, part-to-whole analysis, and mentally transforming two- and three-dimensional images.
Test 8: General Information	Comprehension–knowledge (Gc) *General (verbal) information* (K0)	Measures general object knowledge.
Test 9: Concept Formation	Fluid reasoning (Gf) *Inductive reasoning* (I)	Evaluates verbal (language-based) inductive reasoning.
Test 10: Numbers Reversed	Short-term working memory (Gwm) *Working memory capacity* (WM)	Measures temporary storage and recoding of numerical information in primary memory
Test 11: Number–Pattern Matching	Cognitive processing speed (Gs) *Perceptual speed* (P)	Assesses numerical visual-perceptual discrimination ability under timed conditions.
Test 12: Nonword Repetition	Auditory processing (Ga) *Phonetic coding* (PC) *Memory for sound patterns* (UM) *Auditory memory span* (MS)	Assesses phonological short-term working memory, sensitivity, and capacity.
Test 13: Visual–Auditory Learning	Long-term storage and retrieval (Glr) *Associative memory* (MA)	Measures visual–auditory paired-associate encoding in the learning phase; identification and word retrieval in the response phase.
Test 14: Picture Recognition	Visual processing (Gv) *Visual memory* (MV)	Evaluates formation (passive storage) of images in the visual cache and recognition of previously presented visual stimuli.
Test 15: Analysis–Synthesis	Fluid reasoning (Gf) *General sequential (deductive) reasoning* (RG)	Measures algorithmic, deductive reasoning.

(continued)

TABLE 14.5. *(continued)*

Test name	Primary broad CHC ability *Narrow ability*	Brief test description
Test 16: Object–Number Sequencing	Short-term working memory (Gwm) *Working memory capacity* (WM)	Assesses assembly of new cognitive structures out of information maintained in working memory.
Test 17: Pair Cancellation	Cognitive processing speed (Gs) *Perceptual speed* (P) *Spatial scanning* (SS) *Attentional control* (AC)	Evaluates symbolic visual-perceptual discrimination ability requiring cognitive control under timed conditions.
Test 18: Memory for Words	Short-term working memory (Gwm) *Auditory memory span* (MS)	Measures storage capacity for unrelated words in primary memory.

TABLE 14.6. WJ IV COG Clusters and Brief Cluster Descriptions

Cluster	Brief cluster description
General Intellectual Ability (GIA)	Measures psychometric *g* as distilled from a broad spectrum of important cognitive abilities and functions: knowledge of words and their meanings; quantitative reasoning; temporary storage of verbal information, including the cue-dependent search function of primary memory; orthographic visual-perceptual discrimination ability under timed conditions; word activation, fluency of word access, and word restructuring via phonological codes; listening and attention to orally imparted details that facilitate formation and reconstruction of mental representations; and size and shape perception, part-to-whole analysis, and mentally transforming two- and three-dimensional images.
Gf-Gc Composite	Assesses intellectual level or development based solely on fluid reasoning (Gf) and comprehension–knowledge (Gc) tests.
Brief Intellectual Ability (BIA)	Provides a short but highly reliable measure of intellectual ability based on a sampling of verbal comprehension–knowledge (Gc) and quantitative fluid reasoning (Gf) abilities, and the executive information-lookup and storage capacity functions in short-term working memory (Gwm).
Comprehension-Knowledge	Assesses comprehension of words and general object knowledge.
Comprehension-Knowledge—Ext.	Assesses comprehension of words and general object knowledge, including knowledge of object names.
Fluid Reasoning	Measures quantitative and verbal reasoning.
Fluid Reasoning—Ext.	Measures quantitative, algorithmic, and verbal reasoning.
Short-Term Working Memory	Assesses cue-dependent search and recoding functions from temporary stores of verbal and numerical information in primary memory.
Short-Term Working Memory—Ext.	Assesses cue-dependent search, recoding, and assembly functions from temporary stores of verbal and numerical information in primary memory.
Cognitive Processing Speed	Evaluates orthographic and symbolic visual-perceptual discrimination ability and attentional control under timed conditions.
Auditory Processing	Measures word activation, access, restructuring via phonological codes, and phonological sensitivity capacity in working memory.

(continued)

TABLE 14.6. *(continued)*

Cluster	Brief cluster description
Long-Term Storage and Retrieval	Assesses consolidation (encoding) of semantic (meaning-based) representations into secondary memory.
Visual Processing	Measures visual–spatial analysis, formation of internal visual images, mental transformation of images in working memory, passive storage, and recognition of images.
Cognitive Efficiency	Evaluates efficiencies of orthographic visual-perceptual discrimination ability under timed conditions. and temporary storage and recoding of numeric information in primary memory.
Cognitive Efficiency—Ext.	Measures a combination of orthographic visual-perceptual discrimination ability under timed conditions, and cue-dependent search and recoding functions from temporary stores of verbal and numeric information.
Perceptual Speed	Evaluates orthographic visual-perceptual discrimination ability under timed conditions.
Quantitative Reasoning	Measures quantitative and non-numerical algorithmic reasoning.
Number Facility	Evaluates efficiencies of visual-perceptual discrimination, temporary storage, and processing of numerical information in working memory.
Vocabulary[a]	Measures knowledge of object names and words and their meanings.
Auditory Memory Span[b]	Assesses storage capacity for unrelated words and connected discourse in primary memory.

[a] Requires WJ IV OL Test 1: Picture Vocabulary.

[b] Requires WJ IV OL Test 5: Sentence Repetition.

Comprehension–Knowledge (Gc)

Comprehension–knowledge (Gc) is a CHC broad ability that is also sometimes referred to as either *verbal ability* or *crystallized intelligence* (Keith & Reynolds, 2010). Although Cattell (1941, 1943, 1963) suggested that the constructs of verbal ability and crystallized intelligence are not synonymous, Carroll (1993) argued that it is purely a matter of individual preference whether Gc is interpreted as verbal ability or crystallized intelligence. To help bridge this chasm, the WJ IV COG Gc cluster is broadly based, measuring both comprehension of words (an aspect of verbal ability) and general knowledge (an aspect of crystallized intelligence). The two tests that compose the Gc cluster are Test 1: Oral Vocabulary and Test 8: General Information.

Test 1: Oral Vocabulary

Oral Vocabulary measures knowledge of words and word meanings (Schrank et al., 2016). The CHC narrow abilities are described as lexical knowledge (i.e., vocabulary knowledge) and language development (i.e., general development of spoken language skills that do not require reading ability). Oral Vocabulary includes two subtests, Synonyms and Antonyms. An analysis of the task demands from an information-processing perspective suggests that a stimulus word is connected to a concept via semantic access, which then activates or primes its meaning in the lexicon and consequently activates closely associated words (Caplan, 1992; Gazzaniga, Irvy, & Mangun, 1998). Synonym and antonym associations from known stimulus words are matched more or less directly and automatically in the neural semantic memory networks of individuals with large vocabularies (Martin, 1998). When a stimulus word is unknown or unfamiliar, a response can be attempted by parsing or segmenting the stimulus word into any recognizable phonological, orthographic, or morphological units (Van Orden & Goldinger, 1994, 1996) for clues that can be used to support an information search within working memory.

Knowledge of words is critically important to school success (Anderson & Nagy, 1992; Baker, Simmons, & Kame'enui, 1998), and no area of cognition is more responsive to intervention than vocabulary knowledge. Many interventions for vocabulary development exist (Schrank & Wendling, 2015b; Wendling & Mather, 2009). To be maximally effective, vocabulary development instruction must be multifaceted and appropriate to the individual's age and ability level (National Reading Panel, 2000). Table 14.7 includes a summary of suggested interventions related to the WJ IV COG tests.

Test 8: General Information

The General Information test measures general object knowledge (Schrank et al., 2016). In this task, an individual is asked to identify where an object is typically found or what people typically do with an object. As suggested by Cattell's (1987) thesis, performance on general information tests is a reflection of background knowledge---the level of general knowledge that an individual brings to the learning situation (Schrank et al., 2016). Background knowledge is extremely important for new learning and complex problem solving because the integration of prior knowledge with new information is the basis for constructing the higher-order cognitive representations required for greater levels of knowledge (Hannon & Daneman, 2014; Oberauer, Süß, Wilhelm, & Wittman, 2008).

Limitations observed in the General Information test may suggest the need for building background knowledge. This involves developing a connection between the topic of instruction and what the learner already knows (sometimes referred to as activating prior knowledge). Activating what a student already knows from personal experience, prior schooling, or family history will aid in understanding of current instructional tasks. When students are encouraged to relate their background knowledge to the material being studied, they become more engaged in the learning process. Learners of any age will benefit from connecting new learning to prior knowledge and/or building background knowledge if necessary (Moje et al., 2004). See Table 14.7.

Fluid Reasoning (Gf)

Fluid reasoning (Gf) is a complex aspect of intelligence that can rely on many cognitive processes, depending on the nature and requirements of the task (Gray, Chabris, & Braver, 2003; Kosslyn & Smith, 2000). Reasoning ability is considered to be a scaffold for the development of many other cognitive abilities, particularly those in the acquired knowledge domain (Blair, 2006; Cattell, 1987; McArdle, 2001). Consequently, measured deficits in Gf may provide insights into observed learning difficulties and may suggest that reasoning skills might need to be specifically modeled, taught, and practiced in an academic context.

Test 2: Number Series, a measure of deductive and inductive quantitative reasoning, and Test 9: Concept Formation, a measure of verbal, language-based inductive reasoning, are two tests that compose the Gf cluster. An additional Gf test, Test 15: Analysis–Synthesis, can be described as a measure of algorithmic reasoning. All three tests combine to create the Fluid Reasoning—Extended cluster.

Test 2: Number Series

Number Series measures the ability to identify and apply an analogue or rule to complete a numerical sequence. The task is cognitively complex (Holzman, Pellegrino, & Glaser, 1983) and requires the application of several narrow abilities, cognitive processes, and executive functions. To be able to deduce a pattern in an item sequence, an examinee must be able to count and (depending on the difficulty level of the item) carry out foundational arithmetic operations, including addition, subtraction, multiplication, and division—so the task also requires application of mathematics knowledge (KM). To perform successfully, an individual must have a solid foundation in math facts (Geary, 1990; Geary & Brown, 1991). The test is a measure of reasoning with numbers, or quantitative reasoning (RQ); general sequential reasoning (deduction) (RG) is required to determine the analogue or rule that solves the task; and induction (I) is required to determine the value that completes the numeric analogy. The level and integrities of other broad and narrow CHC abilities can play supporting or inhibiting roles in performance on Number Series, including retrieval of counting sequences and/or math facts from semantic memory (Temple, 1991), cognitive processing speed (Gs), working memory capacity (WM), and attentional control (AC). Finally, the executive function of place keeping (Hambrick & Altmann, 2015) supports the systematic exploration of hypotheses to generate a problem solution.

TABLE 14.7. Examples of Interventions, Strategies, and Accommodations Related to Limitations in Performance on WJ IV COG Tests

Test	Brief intervention, strategy, or accommodation
Test 1: Oral Vocabulary	Creating a vocabulary-rich environment; reading aloud to a young child and discussing new words; text talks; directed vocabulary thinking activities; explicit teaching of specific words; direct instruction in morphology; semantic feature analysis; semantic maps; association of key words to prior knowledge; reexposure to words; reading for a variety of purposes; independent word-learning strategies; use of computer technology to develop word knowledge.
Test 2: Number Series	Teaching number patterns and core math concepts; counting by increments; use of manipulatives; developing a sense of numerical quantity; math talk.
Test 3: Verbal Attention	Active learning environments; complex computer games; rehearsal; reducing distractions; reducing amount of material to be remembered at any one time; simplifying linguistic structures of verbal material; restructuring complex tasks into separate and independent steps; repeating important information.
Test 4: Letter–Pattern Matching	Focus on learning and recognition of specific English-language orthographic patterns; emphasizing speediness; building perceptual speed via repetition; extended time; reducing quantity of work; eliminating or limiting copying activities.
Test 5: Phonological Processing	Activities that focus on the sounds in words; games to increase production of words with the same sound; rhyming and alliteration games; pictures to stimulate fluent production of object names; oral practice with onset–rime patterns of spoken words; explicit modeling of word pronunciations; intensive practice on word pronunciation in the learning phase; explicit, systematic, synthetic phonics instruction; targeted small-group instruction in syllable dividing and rehearsal; use of semantics in word instruction.
Test 6: Story Recall	Opportunities to hear and practice language; active learning; elaborative rehearsal; direct instruction in semantics; use of visual representations; use of mnemonics.
Test 7: Visualization	Activities designed to develop ability to discriminate visual features, mentally manipulate visual images, and match visual information; increased exposure to graphs, charts, maps; video games; three-dimensional sketching exercises.
Test 8: General Information	Text talks; reading for different purposes; use of relevant, real-word examples for learning; cooperative learning environments.
Test 9: Concept Formation	Categorizing real objects; developing skills in drawing conclusions; performing hands-on problem-solving tasks; making meaningful associations; providing concrete examples of grouping objects; commercially available reasoning games; think-aloud procedures; cooperative learning groups; reciprocal teaching; slowing down in response to difficult reasoning tasks.
Test 10: Numbers Reversed	Chunking strategies; rehearsal; providing visual cues; complex computer games; reducing distractions; reducing working memory loads (reducing amount of material to be remembered at any one time, simplifying linguistic structures of verbal material, restructuring complex tasks into separate and independent steps); repeating important information.

(continued)

TABLE 14.7. *(continued)*

Test	Brief intervention, strategy, or accommodation
Test 11: Number–Pattern Matching	Focus on learning and expression of place value in mathematics; speed drills; building speed via repetition; computer matching games; extended time; reducing quantity of work; eliminating or limiting copying activities.
Test 12: Nonword Repetition	Increased exposure to new words; repeating (uttering) new words when they are learned; activities that require repetition and construction of nonwords; vocalization strategy for new words; increased time spent reading.
Test 13: Visual–Auditory Learning	Active, successful learning experiences; rehearsal; overlearning; mnemonics; illustrating or visualizing content.
Test 14: Picture Recognition	Activities designed to discriminate/match visual features and recall visual information.
Test 15: Analysis–Synthesis	Deductive reasoning activities using concrete objects; hands-on problem-solving tasks; metacognitive strategies; think-aloud procedures.
Test 16: Object–Number Sequencing	Focusing attention on one thing at a time; avoiding multitasking.
Test 17: Pair Cancellation	Emphasizing speediness; slowing down if errors are caused by working too quickly; increasing perceptual speed with computer games.
Test 18: Memory for Words	Listening and repeating games; chunking strategies; mnemonics.

Difficulties with the lowest-numbered Number Series items may suggest a need for the development of foundational knowledge in mathematics, perhaps with manipulatives or board games that require counting and help develop a sense of numerical quantity, patterns, core mathematical concepts, and the relationships among numbers (Gersten et al., 2008; National Council of Teachers of Mathematics, 2000; Ramani & Siegler, 2005). See Table 14.7. For young children, a key ability is the concept of *counting on* (Gersten et al., 2009; National Council of Teachers of Mathematics, 2000). For older children and adolescents, interventions include the development of seriation, pattern recognition, and geometric sequencing skills (National Council of Teachers of Mathematics, 2000)—particularly when used in conjunction with *math talk,* which requires the teacher to listen and provide corrective feedback as the student explains his or her reasoning, step by step, to obtain solutions to problems (High/Scope Educational Research Foundation, 2003; Kroesbergen & Van Luit, 2003).

Test 9: Concept Formation

In contrast to the Number Series test, Concept Formation measures verbal, language-based fluid reasoning, or the ability to use language concepts to categorize and compare—a basis for abstracting universal or rational concepts (Andrewes, 2001; Wang, 1987). The first five items measure categorical perception (Goldstone & Hendrickson, 2010), which requires understanding of the word *different* and the more abstract concept of *most different.* These items measure the ability to recognize and identify the essential, rather than any secondary, characteristic of target objects. This is the first stage in the development of an object concept. Item 6 and beyond require familiarity with and understanding of a number of terms, including *red, yellow, big, little, round, square, one,* and *two.* Concept Formation also requires rule application and frequent switching from one rule to another.

Interventions that are designed to develop skills in categorization and drawing conclusions, that involve connecting new concepts to prior knowledge, that use teacher demonstrations and guided practice, and that provide feedback on performance may positively influence the development of reasoning abilities (Klauer, Willmes, & Phye, 2002). In addition, there are many different board and computer games designed to help develop patterning skills (Willis, 2008), such as finding similarities and differences, sorting, matching, and categorizing (Mackey, Hill, Stone, & Bunge, 2010). See Table 14.7.

Test 15: Analysis–Synthesis

Analysis–Synthesis measures algorithmic, deductive reasoning through the process of analyzing puzzles (using symbolic formulations) to determine missing components. This test requires drawing correct conclusions from stated conditions or premises, often from a series of sequential steps. Because of its use of specific solution keys that, if followed correctly, furnish the correct answer to each test item, Analysis–Synthesis can be described as a measure of algorithmic reasoning. Algorithmic reasoning can be specifically taught (see Table 14.7). When Analysis–Synthesis is administered in conjunction with Number Series, the narrow Quantitative Reasoning (RQ) cluster is obtained.

Short-Term Working Memory (Gwm)

The WJ IV COG Gwm cluster is operationally defined as measuring cue-dependent search and recoding functions from temporary stores of verbal and numeric information in primary memory (Schrank et al, 2016). This cluster consists of Test 3: Verbal Attention and Test 10: Numbers Reversed. Because a combination of qualitatively different working memory tasks creates a cluster that is more broadly predictive of outcomes on a wide variety of cognitive tasks (Oberauer, Süß, Schulze, Wilhelm, & Wittman, 2000; Unsworth & Engle, 2006), a three-test Short-Term Working Memory—Extended cluster that includes Test 16: Object–Number Sequencing is also available; this cluster is operationally defined as measuring a combination of cue-dependent search, recoding, and assembly functions from temporary stores of verbal and numeric information in primary memory (Schrank et al., 2016). Because working memory is a very broad construct, the WJ IV COG includes four working memory tests, each measuring a different function of working memory or aspect of working memory capacity.

Test 3: Verbal Attention

The Verbal Attention test measures the size of a person's attentional focus in primary memory (Cowan, Nugent, Elliott, Ponomarev, & Saults, 1999; Unsworth & Engle, 2007b). This test includes the executive search and updating processes that are characterized by the adjective *working* as a modifier for *memory*. In this task, the individual is required to answer a series of questions, each based on a verbally presented string of unrelated object names and numbers. Verbal Attention represents the Unsworth and Engle (2007b) dual-component model of working memory capacity, in which information is maintained in primary memory through the controlled allocation of attention where a focus of attention is retrieved through a cue-dependent search process.

Performance on this test can be described as maintaining a focus of attention and/or the ability to retrieve information that has been momentarily displaced from attention (Shipstead, Lindsey, Marshall, & Engle, 2014). The cued-recall questions tap the real-time updating function of an individual's working memory (Bunting, Cowan, & Saults, 2006; Dahlin, Stigsdotter Neely, Larsson, Bäckman, & Nyberg, 2008; Miyake et al., 2000). Kosslyn, Alpert, and Thompson (1995) suggested that this "information-lookup" process plays a critical role in working memory. Limitations in the ability to actively maintain and/or retrieve information from working memory may require additional evaluation and compensatory strategies. See Table 14.7.

Test 10: Numbers Reversed

In the Numbers Reversed task, the individual is asked to repeat a series of digits backward. This requires the ability to temporarily store and recode orally presented numerical information in primary memory—a complex span task (Daneman & Carpenter, 1980). Typically, performing complex span tasks reflects the executive, controlled-attention aspect of working memory (Engle, 2002; Kane, Brown, et al., 2007; Kane, Conway, Hambrick, & Engle, 2007); requires intense allocation of attention (Kane, Brown, et al., 2007; Kane, Conway, et al., 2007; Unsworth & Engle, 2006); and is strongly predictive of an individual's attentional control in the service of complex cognitive processing (Hutchison, 2007; Unsworth & Spillers, 2010). Strategies (Schrank & Wendling, 2015b; see Table 14.7) can be employed to extend capacity limits by recoding information into fewer chunks (Hardiman, 2003).

Test 16: Object–Number Sequencing

The Object–Number Sequencing test measures the ability to assemble new cognitive structures out of information maintained in working memory (Schrank et al., 2016). This cognitively complex task is best described by the model of working memory developed by Cowan (1995), Oberauer (2002, 2009), and Oberauer and Hein (2012). Oberauer and Hein distinguish between a *region of direct access* and a *focus of attention*. The region of direct access provides a broad focus (sometimes called a *blackboard*) and has a limited capacity, about four chunks of information (Cowan, 2001; Oberauer & Kliegel, 2006). The primary function of the broad focus is to bind or chunk multiple representations or units together for information processing, such as assembling new structures out of the selected representations. In Object–Number Sequencing, the objects and numbers presented for each item must be retained as chunks in the broad (blackboard) focus of working memory. Then a list of objects must be assembled in sequential order, requiring a single focus of attention. After the sequentially ordered object list is created, the individual must return to the broad focus blackboard and create a new focus of attention by creating a sequential list of numbers from the broad focus blackboard. Individuals who have extreme difficulties with this type of task may benefit by learning to avoid multitasking and focus attention on one thing at a time (Alloway, 2011; Gathercole & Alloway, 2007). See Table 14.7.

Test 18: Memory for Words

Memory for Words measures an individual's storage capacity for unrelated words (Schrank et al., 2016). It is a simple running memory span task that is valuable as a measure of absolute working memory capacity when complex processing is not required (Broadway & Engle, 2010; Bunting et al., 2006). Many individuals who perform well on this type of task employ a strategy to encode and/or recall the words (Mueller, 2002). For example, some individuals use rehearsal as a strategy to maintain or refresh the string of words in immediate awareness, and other individuals employ a chunking strategy to encode the unrelated words into distinct blocks of words or create compound nonwords (Hardiman, 2003; Logie, Della Sala, Laiacona, & Chalmers, 1996). Chunking strategies enable a person to group related items into units, making the information more manageable for understanding, storage, and recall. See Table 14.7.

Perceptual Speed (P) and Cognitive Processing Speed (Gs)

In contemporary CHC theory, perceptual speed (P) is a narrow ability included under the broad domain of cognitive processing speed (Gs). The WJ IV COG Perceptual Speed cluster measures orthographic visual-perceptual discrimination ability under timed conditions (Schrank et al., 2016); this cluster is designed to measure rapid processing with two educationally relevant types of stimuli, representing critical visual inspection efficiencies that are closely related to reading, writing, and mathematics fluency. In contrast, the WJ IV COG Cognitive Processing Speed (Gs) cluster includes more breadth; it measures orthographic and symbolic visual discrimination ability and attentional control under timed conditions (Schrank et al., 2016) and may be more representative of overall cognitive speediness.

For many years, cognitive speediness, or mental quickness, has been considered an important aspect of intelligence (Nettelbeck, 1994; Vernon, 1983). "In the face of limited processing resources, the speed of processing is critical because it determines in part how rapidly limited resources can be reallocated to other cognitive tasks" (Kail, 1991, p. 152). In the WJ IV COG, Test 4: Letter–Pattern Matching and Test 11: Number–Pattern Matching compose the Perceptual Speed (P) cluster. Test 4: Letter–Pattern Matching and Test 17: Pair Cancellation compose the Cognitive Processing Speed (Gs) cluster. Limitations in cognitive speediness, particularly perceptual speed, may have implications for the provision of educational accommodations (Geary & Brown, 1991; Hayes, Hynd, & Wisenbaker, 1986; Kail, 1990, 1991, 2003; Kail, Hall, & Caskey, 1999; Ofiesh, 2000; Shaywitz, 2003; Wolff, Michel, Ovrut, & Drake, 1990).

Test 4: Letter–Pattern Matching

The WJ IV COG Letter–Pattern Matching test measures orthographic visual perceptual discrimination ability under timed conditions (Schrank et al., 2016). Performance on this test is facilitated by well-developed sublexical orthographic recognition and chunking efficiencies. Sublexical orthographic recognition efficiency allows the individual to recognize a pattern as a single chunk for purposes of comparison to other letter strings, rather than attempting to hold a string of letters in primary memory while searching for a match. Learning to quickly recognize and subvocally process orthographic chunks of information is thought to play a critical role in the development of automatic word recognition skill, which supports the development of reading fluency (Apel, 2009) and reading speed (O'Brien, Wolf, Miller, Lovett, & Morris, 2011). Limitations in letter pattern recognition may also be related to spelling problems (Gerber, 1984) such as an overreliance on phonology rather than orthographic knowledge when spelling (Cornelissen, Bradley, Fowler, & Stein, 1994). If so, targeted interventions that focus on learning and recognition of specific English-language spelling patterns may be beneficial (Blevins, 2001; Moats, 2004, 2009). See Table 14.7. An accommodation, such as extended time, may be required if a well-substantiated orthographic visual-perceptual discrimination limitation impairs the individual's ability to demonstrate knowledge under time constraints. For example, some individuals with dyslexia have been observed to show deficits on tasks that require rapid detection of letter position (Cornelissen & Hansen, 1998; Cornelissen, Hansen, Hutton, Evangelinou, & Stein, 1998; Katz, 1977; Pammer, Lavis, Hansen, & Cornelissen, 2004) and may require more time to overcome any adverse impact inherent in timed tasks that require rapid orthographic visual-perceptual discrimination.

Test 11: Number–Pattern Matching

Number–Pattern Matching measures numerical visual perceptual discrimination ability under timed conditions (Schrank et al., 2016); this test is the numerical counterpart to Test 4: Letter–Pattern Matching. Just as Letter–Pattern Matching ability is facilitated by well-developed recognition and chunking strategies for English-language regular letter patterns, Test 11: Number–Pattern Matching ability is influenced by well-developed number-chunking mechanisms. As stated by Schrank and colleagues (2016), "Individuals who are able to mentally represent a string of numbers as a 1-item chunk will possess a processing advantage over individuals who perceive each string of numbers as an unassociated series of numerals" (p. 172). Chunking is an aspect of cognitive processing efficiency (Oberauer & Hein, 2012), and number chunking allows an individual to perceive and process multidigit numbers rapidly and efficiently. Selection of interventions is dependent on whether any limitations are due to poorly developed number-chunking abilities or a more generalized limitation in cognitive speediness. Development of number chunking efficiency is one possible intervention for low performance on Number–Pattern Matching, and perceptual speediness can sometimes be improved with repetitive practice, speed drills, and use of computer games that require quick perceptual decisions (Klingberg, 2009; Mahncke, Bronstone, & Merzenich, 2006; Tallal et al., 1996). See Table 14.7.

Test 17: Pair Cancellation

Pair Cancellation measures speeded visual-perceptual attention (Schrank et al., 2016), an aspect of cognitive control that is responsible for preferential concentration on stimuli of relative importance (Andrewes, 2001). The ability to sustain one's attention is sometimes called *vigilance* (Bunge, Mackey, & Whitaker, 2009; Posner & DiGirolamo, 2000). Good cognitive control—or vigilance—is required for tasks where prior knowledge alone is insufficient to meet task demands, such as learning something new. This is because well-developed cognitive control supports working memory, selective attention, long-term retrieval, response inhibition, and response selection (Cohen, Dunbar, & McClelland, 1990; Desimone & Duncan, 1995; Miller & Cohen, 2001; Race, Kuhl, Badre, & Wagner, 2009). Selection of interventions requires careful analysis of related abilities and test session observations. For example, if analysis of the response worksheet reveals several errors of commission (e.g., circling an incorrect set or pair of pictures), the individual may benefit from interventions designed to increase cognitive control, such as slowing down to increase response accuracy. See Table 14.7.

Auditory Processing (Ga)

The WJ IV COG Auditory Processing (Ga) cluster measures word activation, word access, word restructuring via phonological codes, and phonological sensitivity capacity in working memory (Schrank et al., 2016). In the WJ IV COG, the operational definition of auditory processing has been redefined and distinguished from measures of phonological awareness by an increased emphasis on tasks that involve memory and reasoning processes with auditory stimuli (Conzelmann & Süß, 2015). More so than in prior editions of the COG, the WJ IV Ga cluster accurately reflects the concept of auditory intelligence (Conzelmann & Süß, 2015; Seidel, 2007). The WJ IV COG Ga tests are cognitively complex, requiring a mix of cognitive functions and parameters of cognitive efficiency. Performance on each test requires a combination of narrow abilities that span one or more broad ability. The two component Ga tests are Test 5: Phonological Processing and Test 12: Nonword Repetition.

Test 5: Phonological Processing

Phonological Processing measures word activation, fluency of word access, and word reconstruction via phonological codes (Schrank et al., 2016). This test is based on a growing body of evidence that phonological codes are routes to word access (Leinenger, 2014) and are the initial and primary ways that a word accesses a semantic representation in memory (Lukatela & Turvey, 1994b). Test 5: Phonological Processing is highly correlated with psychometric *g* (McGrew et al., 2014), perhaps because phonological codes can activate, integrate, restructure, and/or sustain information in working memory (Baddeley, 1979; Baddeley, Eldridge, & Lewis, 1981; Klatt, 1979; Levy, 1978; McCusker et al., 1981; Slowiaczek & Clifton, 1980).

Test 5: Phonological Processing involves the reasoning and memory functions required to tap long-term phonological knowledge—an important link between primary (working) memory and long-term memory (Jones, Gobet, & Pine, 2007). Although Phonological Processing is primarily a measure of auditory processing and the narrow ability of phonetic coding (PC), its factor structure is complex: It includes aspects of comprehension–knowledge such as semantic memory and other narrow ability variance, specifically language development (LD), speed of lexical access (LA), and word fluency (FW). In addition, this test measures multiple cognitive operations and parameters of cognitive efficiency. Part A Word Access measures the depth of word access from phonemic cues; Part B Word Fluency measures the breadth and fluency of word activation from phonemic cues; Part C Substitution measures lexical substitution from phonemic cues in working memory.

Interventions for limitations in phonological processing depend on the impact of any delay or disability on learning. See Table 14.7. For example, well-developed phonological awareness is foundational in learning to read because phonology is mapped onto orthography when words are sounded out (Liberman et al., 1989; Wagner et al., 1993, 1994).

Test 12: Nonword Repetition

Nonword Repetition is a cognitively complex test that measures phonemic sensitivity and phonological short-term working memory capacity (Schrank et al., 2016). Although the test's primary psychometric factor loading is on short-term working memory, the constituent ability is interpreted as memory for sound patterns (UM), a narrow ability of auditory processing in contemporary CHC theory (McGrew et al., 2014).

Nonword repetition tests have gained wide acceptance because the task demands closely match the phonological processes involved in learning new words (Coady & Evans, 2008; Gathercole, 2006; Gathercole, Hitch, Service, & Martin, 1997), and because many individuals who perform poorly on nonword repetition tasks often have difficulties learning the phonological form of language (Archibald & Gathercole, 2007) and learning new words (Edwards, Beckman, & Munson, 2004; Gathercole, 2006; Michas & Henry, 1994). In addition, nonword repetition tests may be time-efficient and reliable tools to identify individuals with or at risk for language impairments (Bishop, North, & Donlan, 1996; Coady & Evans, 2008; Conti-Ramsden, 2003; Conti-Ramsden, Botting, & Farragher, 2001; Conti-Ramsden & Hesketh, 2003; Dollaghan & Campbell, 1998; Ellis Weismer et al., 2000; Gray, 2003; Horohov & Oetting, 2004; Taylor, Lean, & Schwartz, 1989). Interventions for limited proficiency in nonword repetition focus on phonologically based language development activities. See Table 14.7.

Long-Term Storage and Retrieval (Glr)

The CHC ability of long-term storage and retrieval (Glr) involves the cognitive processes of storing and retrieving information. *Storage* refers to the process by which semantic memories (Tulving, 1972, 1985) are created. Whether it is through the development and consolidation of mental representations from orally imparted discourse in Test 6: Story Recall, or through the association of words with rebus representations in Test 13: Visual–Auditory Learning, each test in the WJ IV COG Glr cluster is a standardized experiment for assessment of memory consolidation. Retrieval is a function of whether consolidation (encoding) of meaning-based representations has occurred. Consequently, the WJ IV COG Glr cluster measures consolidation (encoding) of semantic (meaning-based) representations into secondary memory (Schrank et al., 2016).

Test 6: Story Recall

Test 6: Story Recall is a cognitively complex task that requires listening ability, as well as background knowledge for the words, objects, or situations that are described in the stimulus phase; it is also influenced by working memory capacity.

Attention to orally imparted details supports the *formation of mental representations* (storage) during the stimulus phase; the response phase requires *reconstruction of the story details* (retrieval) through meaningful memory. Because the Story Recall task is so complex, interventions may be related to the development of listening ability (LS), background knowledge (K0), and/or meaningful memory (MM). Also, examiners should consider whether the ability to retain the story elements might be influenced by the individual's working memory capacity (WM), which places limits on the volume of information that can be reconstructed into a coherent and connected representation of the objects, events, or situations in the story-retelling phase (van den Broek, 1989). See Table 14.7.

Test 13: Visual–Auditory Learning

Test 13 measures visual–auditory paired-associate encoding in the learning phase; identification and word retrieval in the response phase (Schrank et al., 2016). The initial task requires associating a visual rebus symbol with a verbal label. The controlled-learning format of this test employs *directed-spotlight attention* (Gazzaniga et al., 1998)—the mental, attention-focusing process that prepares the examinee to encode the stimulus (Brefczynski & DeYoe, 1999; Klingberg, 2009; Sengpiel & Hubener, 1999). The retrieval phase requires the examinee to match a rebus presentation with its stored representation; this process is called *identification*. The directed-spotlight attention mechanism provides a cue to an intervention known as *active learning* (Marzano, Pickering, & Pollock, 2001). Active learning is required for the creation of meaning-based codes that are subsequently used to relate new information or task requirements to previously acquired knowledge. See Table 14.7.

Visual Processing (Gv)

The WJ IV COG Visual Processing (Gv) cluster measures visual–spatial analysis, formation of internal visual images, mental transformation of images in working memory, and passive storage for subsequent recognition of images (Schrank et al., 2016). Visual–spatial abilities are important in academic areas where reasoning with figures, patterns, and shapes is essential (Lubinski, 2010). Test 7: Visualization and Test 14: Picture Recognition are the two tests that create the Gv cluster.

Test 7: Visualization

Visualization measures size and shape perception, part-to-whole analysis, and mentally transforming two- and three-dimensional images (Schrank et al., 2016). Visualization ability may be related to the ability to construct mental representations, which is of fundamental importance across many cognitive domains and for the development of academic skills, including number sense (Gunderson, Ramirez, Beilock, & Levine, 2012) and reading comprehension (De Koning & van der Schoot, 2013). Although there are many specific interventions for the development of visualization skills, integrating spatially challenging activities into the curriculum is an easy-to-implement suggestion for improving visualization skills (Federation of American Scientists, 2006; Foreman et al., 2004; Gee, 2003; McAuliffe, 2003; Newcombe, Uttal, & Sauter, 2013). See Table 14.7.

Test 14: Picture Recognition

Picture Recognition is a visual memory task that measures the recognition of previously presented visual stimuli from images or icons held in passive storage (Schrank et al., 2016). The passive storage of visual images is called the *visual cache* (Baddeley & Hitch, 1994), part of the working memory system. The visual cache is of limited capacity, typically three to four items (Luck & Vogel, 1997). Images can be retained in the visual cache for several seconds (Vogel, Woodman, & Luck, 2001). Individuals with limited performance on Picture Recognition may benefit from interventions designed to develop skills in attending to and discriminating visual features, matching, and recalling visual information. See Table 14.7.

Other Narrow Ability or Clinical Clusters

In addition to the Perceptual Speed (P) cluster previously discussed, some WJ IV COG tests can be combined (sometimes with tests from the WJ IV OL) to provide measures of CHC narrow cognitive abilities. These clusters include Quantitative Reasoning (RQ), Number Facility (N), Auditory Memory Span (MS), and Vocabulary (VL/LD). An additional cluster, Cognitive Efficiency, is a cognitively complex score that has interpretive value for some evaluation purposes.

Quantitative Reasoning

Composed of Test 2: Number Series and Test 15: Analysis–Synthesis, the Quantitative Reasoning cluster measures both quantitative and non-numerical algorithmic reasoning (Schrank et al., 2016).

Number Facility

Composed of Test 10: Numbers Reversed and Test 11: Number–Pattern Matching, the Number Facility cluster measures the efficiencies of visual-perceptual discrimination, temporary storage, and processing of numerical information in working memory (Schrank et al., 2016).

Auditory Memory Span

Composed of Test 18: Memory for Words and WJ IV OL Test 5: Sentence Repetition, the Auditory Memory Span cluster measures storage capacity for both unrelated words and connected discourse in primary memory (Schrank et al., 2016).

Vocabulary

Composed of Test 1: Oral Vocabulary and WJ IV OL Test 1: Picture Vocabulary, the Vocabulary cluster measures knowledge of object names, as well as knowledge of words and their meanings (Schrank et al., 2016).

Cognitive Efficiency

Composed of Test 4: Letter–Pattern Matching and Test 10: Numbers Reversed, the Cognitive Efficiency cluster measures efficiencies of orthographic visual-perceptual discrimination ability under timed conditions, as well as temporary storage and recoding of numeric information in primary memory (Schrank et al., 2016). The Cognitive Efficiency—Extended cluster includes the same two tests, and also Test 3: Verbal Attention and Test 11: Number–Pattern Matching; this cluster measures a combination of orthographic visual-perceptual discrimination ability under timed conditions, and cue-dependent search and recoding functions from temporary stores of verbal and numerical information (Schrank et al., 2016). The Cognitive Efficiency clusters are often used for descriptive comparison to clusters measuring other abilities or combinations of other abilities, such as the Gf-Gc Composite.

Intellectual Level and Scholastic Aptitude Clusters

As noted earlier, the WJ IV COG includes three score options to determine intellectual level: the BIA score, the GIA score, and the Gf-Gc Composite. In addition, differential Scholastic Aptitude clusters can be created from combinations of selected tests.

Brief Intellectual Ability

The BIA score is a short but highly reliable measure of intellectual ability. The BIA is an equally weighted score derived from Test 1: Oral Vocabulary, Test 2: Number Series, and Test 3: Verbal Attention. The BIA includes markers for three important CHC abilities for estimating general intellectual ability, or *g*—comprehension–knowledge (G*c*), fluid reasoning (G*f*), and short-term working memory (G*wm*).

General Intellectual Ability

The GIA score is a measure of psychometric *g* that is broadly derived from the first seven tests in the WJ IV COG Standard Battery. Each of the seven tests was selected for inclusion in the GIA score because it is a highly representative, single measure of one of the seven primary broad CHC intellectual abilities; has high loadings on general intelligence (*g*); is relatively high in cognitive complexity; and is a strong predictor of achievement in the WJ IV ACH (McGrew et al., 2014). The GIA score provides assessment professionals with the best predictor score in the WJ IV COG—*across individuals*—of overall school achievement and other life outcomes that have some relationship to general intelligence. However, the GIA score may not be the best predictor score for any given individual, particularly if it is characterized by remarkable profile scatter and is attenuated by discrepantly low performance on one or more of the component tests (Schrank et al., 2015a).

Gf-Gc Composite

The Gf-Gc Composite is a measure of intellectual level that is derived from two tests of fluid reasoning and two tests of comprehension–knowledge—the two highest-order (*g*-loaded or *g*-saturated) factors included in the CHC theory of cognitive abilities (McGrew, 2005, 2009; McGrew et al., 2014; Schneider & McGrew, 2012 and Chapter 3, this volume). The composite can be operationally defined as a combined measure of verbal, inductive reasoning; quantitative, deductive reasoning; knowledge of words; and general object knowledge. The G*f*-Gc Composite is a measure of intellectual level or development that provides an alternative to the WJ IV GIA or any full-scale intelligence score when an individual has a significant limitation in one or more of the basic cognitive processes, memory storage and retrieval functions, or mechanisms of cognitive efficiency that are included in calculation of the GIA or a full-scale intelligence score. The Gf-Gc Composite represents the level of intelligence the individual has developed, regardless of any limitations in Gwm, Ga, Gv, Glr, Gs, or any of their associated narrow abilities, such as perceptual speed, working memory capacity, or phonological processing (Schrank et al., 2015a).

Scholastic Aptitude Clusters

The WJ IV COG includes a number of Scholastic Aptitude clusters. Each Scholastic Aptitude cluster is a small set of WJ IV cognitive tests that is statistically associated with performance on different WJ IV achievement clusters. Figure 14.2 contains the Selective Testing Table for the Scholastic Aptitude clusters and the associated target tasks for scholastic aptitude–achievement comparisons. These clusters are primarily intended to be used for short, academic-domain-focused assessments (McGrew, 2012; McGrew & Wendling, 2010), to determine if an individual is performing academically as well as would be expected based on a small set of closely associated cognitive abilities; these clusters are not intended for use in determining the presence of a specific learning disability. Students with a specific learning disability may not exhibit a scholastic aptitude–achievement discrepancy because a low achievement score may be reflected in low cognitive test scores that are closely related to the achievement area.

			Target Tasks for Scholastic Aptitude/ Achievement Comparisons													
			Reading						**Mathematics**				**Writing**			
			Reading	Broad Reading	Basic Reading Skills	Reading Comprehension	Reading Fluency	Reading Rate	Mathematics	Broad Mathematics	Math Calculation Skills	Math Problem Solving	Written Language	Broad Written Language	Basic Writing Skills	Written Expression
Standard Battery	COG 1	Oral Vocabulary	■	■	■	■	■	■	■	■	■	■	■	■	■	■
	COG 2	Number Series							■	■	■					
	COG 3	Verbal Attention			■										■

Score Comparison Procedures

The WJ IV Online Scoring and Reporting System (Schrank & Dailey, 2014) includes a number of procedures that are useful for making comparisons between and among scores within the WJ IV COG, as well as comparisons that include scores from the WJ IV OL and WJ IV ACH.

Intracognitive Variation Procedure

The first procedure compares performance among tests and clusters to determine the presence and severity of any within-individual profile variations. Based on a selected standard error of the estimate (*SEE*) cutoff score, a profile-discrepant test or cluster can be defined as a relative (within individual) strength or weakness. Tests 1–7 must be administered, at a minimum, to evoke this procedure.

Gf-Gc Composite–Other Ability Comparison Procedure

The second procedure compares the Gf-Gc Composite score to other WJ IV COG, OL, or ACH cluster scores that primarily measure other (non-Gf and non-Gc) abilities. Although calculated via the traditional ability–achievement discrepancy model (with attendant cutoff score criteria), a target cluster score that is significantly lower than the Gf-Gc Composite is also interpreted as an intraindividual weakness, and a target cluster score that is significantly higher than the Gf-Gc Composite is interpreted as an intraindividual strength. The Gf-Gc Composite–Other Ability comparison procedure is appropriate for analyzing a pattern of strengths and weaknesses, as well as an ability–achievement discrepancy. This procedure is particularly useful when an individual's Gf and Gc abilities are relatively intact, compared to other cognitive abilities that may be a source of a learning disability (Schrank et al., 2016). Documentation of a relative weakness in an area of cognitive processing—relative to the Gf-Gc Composite of intellectual level—can be an important component of a specific learning disability determination (Schrank et al., 2015a).

GIA–Achievement Discrepancy Procedure

The third procedure compares the GIA score to selected WJ IV OL and WJ IV ACH cluster scores, to determine the presence and significance of any discrepancies between current levels of general intellectual ability and achievement or oral language ability. This procedure is based on the traditional intellectual ability–achievement discrepancy model, but uses actual discrepancy norms (McGrew et al., 2014), which reduce the error inherent in comparisons made between tests derived from different normative samples.

Scholastic Aptitude–Achievement Discrepancy Procedure

The fourth procedure compares a predicted score that is based on a small set of cognitive tests to selected WJ IV ACH cluster scores, to determine the presence and significance of any discrepancies between current levels of achievement and a set of cognitive tests that is highly predictive of the academic area of interest. This procedure is sometimes useful for short, selective, focused assessment purposes, where the comparison to achievement is used descriptively (not diagnostically). Alternatively, as part of a comprehensive evaluation, a scholastic aptitude–achievement comparison can provide a highly knowledgeable professional with additional descriptive information that may be useful in evaluating a clinical hypothesis of any concordance or discordance between clusters of highly predictive cognitive tests and expected academic performance in a particular domain. However, it is important to note that the term *aptitude* may suggest that these clusters measure something they do not. Although these clusters can be useful for comparing an individual's current academic performance levels to his or her levels of domain-associated cognitive abilities for inferential analysis, the Scholastic Aptitude clusters are not intended to predict an individual's potential for scholastic success (Schrank et al., 2016).

WJ IV TESTS OF ORAL LANGUAGE

The WJ IV OL (Schrank, Mather, & McGrew, 2014b) is a set of tests that may be administered independently or in conjunction with the WJ IV COG or the WJ IV ACH.

Organization of the WJ IV OL

The WJ IV OL has 12 tests measuring varied aspects of receptive and expressive oral language. There are nine English tests (Tests 1–9) and three Spanish tests (Tests 10–12). The three Spanish tests are adaptations of Test 1: Picture Vocabulary, Test 2: Oral Comprehension, and Test 6: Understanding Directions. All 12 tests are contained within one easel test book. Figure 14.3 presents the Selective Testing Table of the WJ IV OL. Table 14.8 provides an overview of the primary broad and narrow CHC abilities measured, as well as task demands for each of the oral language tests.

How to Administer the WJ IV OL Tests

The WJ IV OL tests may be administered in any order. However, it is generally recommended that the core tests, Tests 1–4, be administered first. Not all tests need to be administered, as test choice is guided by referral concerns and selective testing principles (see Figure 14.3).

Administration Time

As a general rule, experienced examiners require about 40 minutes to administer the first eight tests. This varies depending on the age and ability level of the examinee. Test 9: Sound Awareness is a screening measure for younger students or those who have poor phonological awareness so it is not administered in every case. About 15–20 minutes should be allowed for administration of the Spanish tests.

Testing Materials

The testing materials required for administration of the WJ IV OL include the test book, a test record, the audio CD, appropriate audio equipment, pencils, and a stopwatch.

			Oral Language Clusters									OL + COG	
			Oral Language	Broad Oral Language	Oral Expression	Listening Comprehension	Phonetic Coding	Speed of Lexical Access	Lenguaje oral	Amplio lenguaje oral	Comprensión auditiva	Vocabulary (VL/LD)	Auditory Memory Span (MS)
Oral Language Battery	OL 1	Picture Vocabulary	■	■	■							■	
	OL 2	Oral Comprehension	■	■		■							
	OL 3	Segmentation					■						
	OL 4	Rapid Picture Naming						■					
	OL 5	Sentence Repetition			■								■
	OL 6	Understanding Directions		■		■							
	OL 7	Sound Blending					■						
	OL 8	Retrieval Fluency						■					
	OL 9	Sound Awareness[1]

TABLE 14.8. Broad and Narrow CHC Abilities Measured and Task Demands of WJ IV OL Tests

Test name	Primary broad CHC ability *Narrow ability*	Task demands
Test 1: Picture Vocabulary; Test 10: Vocabulario sobre dibujos	Comprehension–knowledge (Gc) *Lexical knowledge* (VL) *Language development* (LD)	Requires naming familiar to less familiar pictured objects in English (or Spanish).
Test 2: Oral Comprehension; Test 11: Comprensión oral	Comprehension–knowledge (Gc) *Listening ability* (LS)	Requires listening to a short passage in English (or Spanish) and supplying a key missing word.
Test 3: Segmentation	Auditory processing (Ga) *Phonetic coding* (PC)	Requires listening to a word and breaking it into its parts (compound words, syllables, phonemes).
Test 4: Rapid Picture Naming	Long-term storage and retrieval (Glr) *Naming facility* (NA) *Speed of lexical access* (LA)	Requires naming simple pictures quickly.
Test 5: Sentence Repetition	Short-term working memory (Gwm) *Memory span* (MS) Comprehension–knowledge (Gc) *Listening ability* (LS)	Requires listening to a word, phrase, or sentence and repeating it verbatim.
Test 6: Understanding Directions; Test 12: Comprensión de indicaciones	Short-term working memory (Gwm) *Working memory capacity* (WM) Comprehension–knowledge (Gc) *Listening ability* (LS)	Requires listening to a sequence of directions in English (or Spanish), and then following those directions by pointing to objects in a picture.
Test 7: Sound Blending	Auditory processing (Ga) *Phonetic coding* (PC)	Requires listening to a series of syllables or phonemes and then blending the sounds into a word.
Test 8: Retrieval Fluency	Long-term storage and retrieval (Glr) *Speed of lexical access* (LA) *Ideational fluency* (FI)	Requires naming as many items as possible in a given category within a 1-minute time limit.
Test 9: Sound Awareness	Auditory processing (Ga) *Phonetic coding* (PC)	Requires providing a rhyming word in 9A and deleting a word part or sound to form a new word in 9B.

Summary of Key Administration and Scoring Points

Most tests use suggested starting points and basal and ceiling rules, and responses are scored 1 or 0. Table 14.9 summarizes key administration and scoring points for each test.

Special Administration and Scoring Considerations

Although the WJ IV OL examiner's manual (Mather & Wendling, 2014c) and test book provide detailed rules for test-by-test administration, this section presents important reminders about tests that have special administration or scoring rules.

Spanish Tests

If the Spanish-language tests are administered, the examiner must be bilingual in Spanish and English, or a primary–ancillary examiner procedure must be employed. This procedure is described in the WJ IV OL examiner's manual. When evaluating an English-language learner or when using the Spanish tests in the WJ IV OL, an examiner may wish to complete the Language Exposure and Use Questionnaire on the last page of the test record, which includes a number of questions about the history of the examinee's language use.

Timed Tests

The WJ IV OL contains two timed tests: Rapid Picture Naming and Retrieval Fluency. The time

TABLE 14.9. Summary of WJ IV OL Test Administration and Scoring Rules

Test name	Item scoring rule	Sample items?	Basal/ceiling rules?[a]	Administration notes	Extra materials required for administration
Test 1: Picture Vocabulary	1, 0	Yes (PreK)	Yes; 6/6	Suggested starting points are available.	
Test 2: Oral Comprehension	1, 0	Yes	Yes; 6/6	Suggested starting points are available after sample items.	Audio
Test 3: Segmentation	1, 0	Yes	Yes; 5/5	All begin with either Introduction 1 or 2.	
Test 4: Rapid Picture Naming	1, 0	Yes	No; 2-minute time limit	All begin with sample items, then proceed to item 1.	Stopwatch (timed test)
Test 5: Sentence Repetition	1, 0	Yes	Yes; 4/4	Suggested starting points are available; then begin with sample item for pre-grade 3 starting point.	Audio
Test 6: Understanding Directions	1, 0	No	No; ceiling determined by continuation instructions	Suggested starting points are available; scoring is based on administration of specific group of pictures.	Audio
Test 7: Sound Blending	1, 0	Yes	Yes; 6/6	Suggested starting points are available after sample items.	Audio
Test 8: Retrieval Fluency	1 for each correct response	No	No; 1-minute time limit per item	All examinees are administered all three items.	Stopwatch (timed test)
Test 9: Sound Awareness				Both subtests must be administered.	
9A: Rhyming	1, 0	Yes	Yes; 6/6	Suggested starting points are available; all begin with either Introduction 1 or 2.	
9B: Deletion	1, 0	Yes	Item 1 is basal; ceiling is 6	All begin with sample items, then proceed to item 1.	Audio
Test 10: Vocabulario sobre dibujos	1, 0	Yes (Pre)	Yes; 6/6	Suggested starting points are available; examiner must be fluent in Spanish; parallel to Test 1: Picture Vocabulary.	
Test 11: Comprensión oral	1, 0	Yes	Yes; 6/6	Suggested starting points are available after sample items; examiner must be fluent in Spanish; parallel to Test 2: Oral Comprehension.	Audio
Test 12: Comprensión de indicaciones	1, 0	No	No; ceiling determined by continuation instructions	Suggested starting points are available; scoring is based on administration of specific group of pictures; examiner must be fluent in Spanish; parallel to Test 6: Understanding Directions.	Audio

[a] May be modified by complete-page rule.

limits are noted on the test page, as well as on the test record. Administration of these tests requires a stopwatch or a watch with a second hand. When administering Rapid Picture Naming, the examiner must be prepared to turn each page as soon as the examinee names the last picture on the page.

For Retrieval Fluency, duplicate responses should not be accepted, although variations are acceptable (e.g., *Bob, Bobby*). The raw score for Retrieval Fluency is based on the total number of tally marks recorded for each of the three items. The examiner records a tally mark for each correct response, grouping them by fives. For each item, the correct responses are counted, and the total is recorded in the Number Correct box. The maximum number that can be entered for each item is 99. To obtain estimated age and grade equivalents, the examiner adds the three item totals together and locates that sum in the scoring table.

Audio Tests

The standardized audio recording should be used to present Oral Comprehension, Sentence Repetition, Understanding Directions, Sound Blending, Sound Awareness (Deletion), Comprensión oral, and Comprensión de indicaciones. The examiner should not repeat or replay any items unless directions permit it (e.g., on sample items).

Test 3: Segmentation

Examiners must say the sound a letter makes when it is presented between slash marks (e.g., /s/). On items 11–20, a response is correct if the correct number of segments is provided even if pronunciation is not perfect. On items 21–37, all sounds must be given in order to score the response as correct. This test can be difficult to score correctly for some examiners who have trouble hearing sounds in words. In these cases, the examiner may wish to have a speech–language professional or reading specialist administer the test.

Test 6: Understanding Directions and Test 12: Comprensión de indicaciones

Examiners should familiarize themselves with each picture in order to follow examinees' pointing responses. Examinees must be given 10 seconds to study each picture before any item is administered. The score on Understanding Directions is based on the number of correct responses the examinee has on the set of pictures administered. Each correct response is scored 1, and each incorrect response is scored 0. On the test record, an examiner writes the number of points earned for each picture in the space provided. When indicated on the test record, the examiner records the cumulative total for the two pictures specified. In the score entry section on the test record, the examiner enters the number of points for each picture or set of pictures administered, or an X if the set was not administered. To obtain estimated age and grade equivalents, the examiner locates the number of points in the appropriate column corresponding to the group of pictures administered. If more than one group of pictures has been administered, the last group administered following the continuation instructions is used to estimate age and grade equivalents.

Reliability and Validity

Following is a summary of reliability and validity information for the WJ IV OL. More complete information is available in the WJ IV technical manual (McGrew et al., 2014) and the discussion of CHC theory in the introductory section of this chapter.

Median reliability coefficients for the WJ IV OL tests are reported in Table 14.10. With the exception of the timed tests, coefficients of stability are reported as median internal-consistency (r_{11}) and median *SEM* values. For the two timed tests, test–retest values (r_{12}) are used as the most appropriate coefficient of stability. Mosier's (1943) formula was used to calculate reliabilities for tests with subtests, such as Test 9: Sound Awareness. Table 14.11 contains the median cluster reliability coefficients (r_{cc}) and median *SEM* (SS), as calculated via Mosier's formula. All of the WJ IV OL clusters, with the exception of Oral Expression (.89) and Speed of Lexical Access (.89), exceed the commonly referenced professional standard of .90 for decision-making purposes. Although the test reliabilities support use and interpretation of the test-level scores as single indicators of an ability, the WJ IV OL clusters are preferred for most decision-making purposes, due to their higher reliabilities.

Table 14.12 contains a summary of correlations for the primary WJ IV OL clusters with other measures of oral language abilities, including the Clinical Evaluation of Language Fundamentals—Fourth Edition (CELF-4; Semel, Wiig, & Secord, 2003), the Peabody Picture Vocabulary Test, Fourth Edition (PPVT-4; Dunn & Dunn, 2007), the Comprehensive Assessment of Spoken Language (CASL; Carrow-Woolfolk, 1999), and the

TABLE 14.10. WJ IV OL Median Test Reliability Statistics

Test	Median r_{11}	Median *SEM* (SS)	Median r_{12}
Test 1: Picture Vocabulary	.88	5.47	—
Test 2: Oral Comprehension	.82	7.06	—
Test 3: Segmentation	.94	4.14	—
Test 4: Rapid Picture Naming	—	—	.90
Test 5: Sentence Repetition	.83	6.48	—
Test 6: Understanding Directions	.87	6.42	—
Test 7: Sound Blending	.89	5.99	—
Test 8: Retrieval Fluency	.80	6.00	—
Test 9: Sound Awareness	.82	9.49	—

Note. r_{11}, internal-consistency reliability; r_{12}, test–retest reliability for speeded tests.

Oral and Written Language Scales: Listening/Comprehension/Oral Expression (OWLS; Carrow-Woolfolk, 1995). The significant correlations of the WJ IV Oral Language, Oral Expression, and Listening Comprehension clusters with the CELF-4 composites, the total PPVT-4 score, the CASL Core Composite, and the OWLS composites support the validity of the WJ IV OL clusters as valid measures of general oral language abilities. The lower correlations for the WJ IV OL Speed of Lexical Access cluster indicate that it is measuring unique abilities not measured in the CELF-4, PPVT-4, CASL, or OWLS.

Interpretation

Critically important for success in life and academics, oral language is the foundation for and the primary means of communicating and learning. Even thinking and metacognition rely on language. Key aspects of oral language are measured in the WJ IV OL, which aids in early identification of weaknesses in these building blocks of learning and helps explore the role of oral language in an individual's achievement performance.

TABLE 14.11. WJ IV OL Median Cluster Reliability Statistics

Cluster	r_{cc}	Median *SEM* (SS)
Oral Language	.90	4.74
Broad Oral Language	.92	4.50
Oral Expression	.89	5.20
Listening Comprehension	.90	5.61
Phonetic Coding	.95	3.97
Speed of Lexical Access	.89	4.97
Vocabulary[a]	.93	4.97

[a] Requires WJ IV COG Test 1: Oral Vocabulary.

An individual's performance on various linguistic and cognitive abilities can be evaluated by using the WJ IV OL tests and clusters, including two of the Individuals with Disabilities Education Improvement Act (IDEA, 2004) eligibility areas for specific learning disabilities: oral expression and listening comprehension. Several different linguistic abilities, including phonological awareness, speed of lexical access, memory, vocabulary, and listening comprehension, are evaluated. In terms of CHC theory, the WJ IV OL tests measure aspects of comprehension–knowledge, short-term working memory, long-term storage and retrieval, cognitive processing speed, and auditory processing. Additionally, if the parallel English and Spanish clusters are administered, examiners can explore language dominance and proficiency (using the Comparative Language Index or CLI).

Interpretation requires knowledge of all derived scores and profiles, as well as the intra-ability variation and ability–achievement comparison procedures. While cluster-level information is preferred for decision making, the individual tests provide important insights into functioning and aid in program planning. Examples of evidence-based interventions are included for each test, and selected interventions are summarized in Table 14.13.

There are nine English oral language clusters available (Oral Language, Broad Oral Language, Phonetic Coding, Speed of Lexical Access, Listening Comprehension, and Oral Expression) and

TABLE 14.12. Correlations for Select WJ IV OL Measures and Other Measures of Oral Language Abilities

Other measures	Oral Language	Oral Expression	Listening Comprehension	Speed of Lexical Access
Clinical Evaluation of Language Fundamentals—Fourth Edition (CELF-4)[a]				
Core Language	.63	.74	.64	.31

[a] Ages 5–8.

[b] Ages 7–17.

three Spanish clusters (Lenguaje oral, Amplio lenguaje oral, and Comprensión auditiva). Two additional clusters are available when tests from the WJ IV COG are also used (Vocabulary and Auditory Memory Span).

Oral Language

Two clusters, Oral Language and Broad Oral Language, provide estimates of the individual's verbal ability. The first cluster is composed of two tests, Test 1: Picture Vocabulary and Test 2: Oral Comprehension. The Broad cluster is composed of three tests—the two in Oral Language plus Test 6: Understanding Directions. The two parallel Spanish clusters are Lenguaje oral and Amplio lenguaje oral. Broad Oral Language or Amplio lenguaje oral can be used as the predictor in the oral language–achievement comparison procedure.

Test 1: Picture Vocabulary (Test 10: Vocabulario sobre dibujos)

Picture Vocabulary measures vocabulary, verbal ability, and cultural knowledge, all aspects of comprehension–knowledge. It is primarily a single-word expressive language task.

An individual may have difficulty with this test due to limited knowledge of word meanings, word retrieval difficulties, English as a second language, limited experiences and opportunities, or cultural differences. Observing performance and analyzing errors will help determine whether poor performance is a result of limited vocabulary or retrieval problems. When an error is related to the correct response (e.g., describes an attribute or function), it may indicate a retrieval or word-finding problem. An error that is not directly associated with the correct response may indicate a weakness in vocabulary knowledge. Although an error that is associated with the word meaning is scored as incorrect, it does suggest some knowledge or understanding is present. Sometimes an individual may know the function of an object, but may not be able to come up with the exact name.

One intervention for building vocabulary in younger children is reading aloud to them (Adams, 1990). Effectiveness is increased when an interactive read-aloud method such as *dialogic reading,* which requires the reader to actively engage the child with the text, is used. For older children and adolescents, possible interventions for building vocabulary include reading for different purposes (National Reading Panel, 2000) and intentional explicit word instruction (teaching synonyms, antonyms, multiple-meaning words) (Graves, Juel, & Graves, 2004; McKeown & Beck, 2004; National Reading Panel, 2000). See Table 14.13 for additional intervention suggestions.

Test 2: Oral Comprehension (Test 11: Comprensión oral)

Oral Comprehension measures listening ability and language development, both aspects of comprehension–knowledge. The individual must use previously acquired knowledge, syntax, and context clues to identify the missing word. Oral Comprehension is primarily a receptive language task.

Low performance may result from limited semantic or syntactic knowledge, limited exposure to English, or poor attention. Similar in format to the WJ IV ACH Passage Comprehension test, this oral test requires the examinee to listen to a passage instead of read a passage. The results of these two tests may be compared to help determine whether limited oral language or limited decoding skill are impairing reading comprehension performance. Several of the same abilities, such as vocabulary, reasoning, and background knowledge, are involved with both reading and listening comprehension. Individuals who have oral language impairments or intellectual disabilities may obtain similar scores on both measures of listening and reading comprehension. Individuals with reading disabilities will frequently score higher on measures of listening comprehension than on measures of reading comprehension. However, when an individual scores higher on Passage Comprehension than on Oral Comprehension, it suggests that comprehension improves when reading. The permanence of the text facilitates comprehension because it reduces the effects of memory and gives the individual greater control over the rate of input. Consideration of

TABLE 14.13. Examples of Interventions, Strategies, and Accommodations Related to Limitations in Performance on WJ IV OL Tests

Test	Brief intervention, strategy, or accommodation
Test 1: Picture Vocabulary; Test 10: Vocabulario sobre dibujos	Creating a vocabulary-rich environment; text talks; intentional, explicit word instruction; preteaching vocabulary; use of semantic maps.
Test 2: Oral Comprehension; Test 11: Comprensión oral	Rehearsal and oral elaboration; use of echo activities; reducing amount of material to be remembered at any one time; simplifying linguistic structures of verbal material.
Test 3: Segmentation	Explicit, systematic instruction in phonics; teaching the six syllable types; practice in segmenting words for spelling; use of letter tiles to teach segmentation skills.
Test 4: Rapid Picture Naming	Increasing fluency through speed drills and monitoring progress.
Test 5: Sentence Repetition	Playing listening and repeating games; teaching chunking strategies; use of mnemonics; asking student to paraphrase directions to ensure understanding; providing visual cues such as outlines of key points.
Test 6: Understanding Directions; Test 12: Comprensión de indicaciones	Playing barrier games (taking turns giving and following directions); presenting tasks in separate and independent steps; repeating important information.
Test 7: Sound Blending	Providing early exposure to language sounds; prompting phonological awareness; direct instruction in sound blending; use of manipulatives to teach blending skills.
Test 8: Retrieval Fluency	Oral elaboration; use of cues; allowing more time for thinking and responding.
Test 9: Sound Awareness	Use of manipulatives to teach adding, deleting, substituting, and rearranging sounds; practicing rhyming skills (e.g., discriminating words that rhyme or don't rhyme; producing a rhyming word).

the discrepancies between listening and reading comprehension can help determine the presence of a specific reading disability or a more generalized language problem.

Use of directed vocabulary thinking activities (Graves, 2000) helps develop listening comprehension skills. School-age children who have difficulties following a teacher's oral discourse in the classroom may benefit from an outline of key points (Wallach & Butler, 1994) on the board or overhead projector prior to the beginning of each instructional unit. See Table 14.13.

Test 6: Understanding Directions (Test 12: Comprensión de indicaciones)

Understanding Directions measures listening ability and language development, both aspects of comprehension–knowledge. Understanding Directions also measures memory span and working memory, two aspects of short-term working memory. Some of the items are simple memory span tasks (e.g., "Point to the cat"); others engage working memory because they involve rearranging or reordering the sequence (e.g., "Before you point to the cat, point to the tree and then the flower"). An individual may have low scores on this test for several reasons: poor attention, limited receptive vocabulary knowledge, or weaknesses in listening comprehension, attention, or memory.

Interventions related to limited proficiency on Understanding Directions include opportunities to practice listening and following directions (Galda & Cullinan, 1991; Leung & Pikulski, 1990), and echo activities (Clay, 1991). Accommodations include modifying the listening environment (Hardiman, 2003).

Phonetic Coding

The Phonetic Coding cluster has two tests, Test 3: Segmentation and Test 7: Sound Blending. Both measure aspects of *phonetic coding,* a narrow ability of auditory processing. Phonetic coding is the ability to hear phonemes, to blend sounds into words, and to segment words into parts or phonemes. Test 3: Segmentation involves the ability to break apart the sounds in words which is a fundamental skill underlying spelling. Test 7: Sound Blending involves pushing together sounds to form words which underlies the application of phonics.

Phonological awareness provides the foundation for learning to apply phonics knowledge to reading and spelling. The two most important phonological awareness skills are blending and segmenting, both of which are measured in this cluster.

Test 3: Segmentation

Segmentation is a critical phonological ability that underlies aspects of spelling—that is, the ability to break apart the sounds within a word. Poor performance on the Segmentation test suggests that the individual may have difficulty recognizing the individual phonemes and then putting the sounds in the correct order when spelling words. An individual could have low scores on this test for several reasons: poor phonological awareness, English as a second language, articulation difficulties, weak memory, or inadequate instruction. Providing explicit code instruction (e.g., mapping phonemes to graphemes) facilitates development of the segmenting skills required for spelling (Berninger & Amtmann, 2003).

Test 7: Sound Blending

Sound blending is a key ability of phonemic processing, a narrow auditory processing ability. An individual could have low scores on the Sound Blending test for several reasons: poor phonological awareness, English as a second language, articulation difficulties, weak memory, or inadequate instruction. When an individual has a low score on Sound Blending, it is also likely that he or she may have a low score on the WJ IV ACH Word Attack test. In order to read phonically regular nonsense words, the individual has to push together the sounds, or blend the sounds, to form the word. Conversely, an individual with a high score on Sound Blending is likely to have good phonics skills, unless this type of instruction has been limited. With appropriate instruction, blending skills can be developed.

For school-age children and some adolescents with limited phonemic awareness, interventions include explicit, systematic instruction in phonics (National Reading Panel, 2000) and use of decodable texts for daily practice (Meyer & Felton, 1999). See Table 14.13.

Speed of Lexical Access

Speed of lexical access is an individual's ability to retrieve words rapidly from his or her lexicon by using orthographic, phonological, or semantic characteristics of words. Initially thought of as a narrow aspect of long-term storage and retrieval, Schneider and McGrew (Chapter 3, this volume) now suggest that the Speed of Lexical Access cluster is distinct from measures that involve the storage of information because it measures the retrieval function only.

This cluster consists of Test 4: Rapid Picture Naming and Test 8: Retrieval Fluency, both timed measures of word retrieval. A difference in performance on these two tests may occur because of the task demands and the underlying narrow abilities. Rapid Picture Naming is a confrontational naming task that requires the person to label specific pictures, a sequential naming facility task. Retrieval Fluency is a measure of ideational fluency and requires the person to produce as many words as possible belonging to a specific category.

A considerable body of research suggests that speed of lexical access, or how quickly individuals can name highly familiar visual stimuli, is a strong predictor of reading performance and a cognitive marker of developmental dyslexia (Georgiou & Parrila, 2013). This type of task appears most related to reading fluency. In remediating reading fluency, it is important to make sure that the reader is accurate on the text before focusing on building speed. Deficits in rapid automatized naming have also been found in individuals with speech and language disorders (Georgiou & Parrila, 2013; Windsor & Kohnert, 2008). If the problem is severe enough, an individual may be classified as having an expressive language impairment.

Test 4: Rapid Picture Naming

Rapid Picture Naming measures the narrow abilities of naming facility and speed of lexical access (i.e., the speed of producing names for objects). An individual could have low scores on this test for several reasons: poor attention, slow articulation speed, word-finding difficulties, or slow word retrieval speed. Observing the pace and accuracy of an individual's performance (e.g., slow and accurate, fast and accurate, slow and inaccurate, or fast and inaccurate), can help identify appropriate instruction and accommodations. See Table 14.13.

Test 8: Retrieval Fluency

The Retrieval Fluency test does not include the encoding and storage processes, but rather measures the rate or automaticity of word retrieval. In CHC theory, the cognitive abilities measured by Retrieval Fluency are ideational fluency and speed of lexical access. Martin (2009) described this type of retrieval task as *associative or encyclopedic knowledge,* which has three principal characteristics: Retrieval is explicit (e.g., specific names); there is no intrinsic limit on the amount of information that can be retrieved; and this type of knowledge is idiosyncratic (some people will produce many responses; others will not). An individual may have a low score on this test for several reasons: poor attention, limited vocabulary, weaknesses in word retrieval, or limited use of categorical strategies. Oral elaboration (Wolf, Bowers, & Biddle, 2000; Wolfe, 2001) may be an effective intervention to improve fluency of retrieval.

Oral Expression

The Oral Expression cluster is composed of two tests, Test 1: Picture Vocabulary and Test 5: Sentence Repetition. It measures expressive vocabulary and primary memory span in connected oral discourse. A significant difference between the two tests of this cluster may indicate a specific strength or weakness in vocabulary or memory span. (See the information given above in the section on the Oral Language cluster for Test 1: Picture Vocabulary.)

Test 5: Sentence Repetition

Sentence Repetition measures auditory memory span, a narrow ability of short-term working memory. It is the ability to encode and maintain verbal information in memory and then accurately reproduce it in sequence. Performance on this task can be aided by meaning and use of the sentence context. However, in some cases, the context and syntax of language may interfere with performance. As a result, performance may be better on a task that has less language context, such as repeating a list of unrelated words (see Auditory Memory Span). An individual could obtain low scores on this test for several reasons, such as limited attention, poor memory, or limited oral language.

An appropriate intervention linked to limited proficiency on Sentence Repetition is rehearsal of the information to be remembered (Medina, 2008; Squire & Schacter, 2003). Accommodations may be needed to compensate for limitations in short-term memory or working memory capacity, such as keeping oral directions short and simple, asking the student to paraphrase directions to ensure understanding, and providing visual cues for directions or steps to be followed (Gathercole & Alloway, 2008).

Listening Comprehension

The Listening Comprehension cluster is composed of two tests, Test 2: Oral Comprehension and Test 6: Understanding Directions. The cluster measures listening ability and verbal comprehension. Both of these tasks involve receptive language, as well as memory span and working memory. The parallel Spanish cluster is Comprensión auditiva. (See information for both Test 2 and Test 6 in the discussion of the Oral Language cluster, above.)

In the field of reading disabilities, listening comprehension is an important construct in an evaluationof dyslexia, based on the assumption thatan individual's reading comprehension should be comparable to his or her listening comprehension. When performance is better on listening comprehension than on reading comprehension, it suggests the presence of underdeveloped reading competence or a specific reading disability. When performance is low on listening comprehension, it suggests a more generalized language problem and accommodations may be needed such as providing shortened directions, writing directions on the board, or asking the individual to repeat or paraphrase directions.

Vocabulary

The Vocabulary cluster includes two expressive vocabulary measures, Test 1: Picture Vocabulary and (from the WJ IV COG) Test 1: Oral Vocabulary. In some cases, performance may vary between Picture Vocabulary and Oral Vocabulary, due to differences in task demands. Picture Vocabulary measures knowledge of object names using pictured objects, and Oral Vocabulary measures knowledge of synonyms and antonyms for vocabulary words. Vocabulary knowledge is highly related to reading comprehension and to school success in general (Anderson & Nagy, 1992). The importance of word knowledge increases as reading skill develops, progressing from learning to read to reading to learn.

Auditory Memory Span

Auditory memory span can be considered a narrow ability within the broader construct of working memory because the tasks require controlled, focal attention to retain a string of orally presented information, often the first requirement of a working memory task. Additionally, memory span capacity, which reflects the amount of information that can be actively maintained in immediate awareness, is required for the two tests in this cluster, Test 5: Sentence Repetition and (from the WJ IV COG) Test 18: Memory for Words. A difference may exist in a person's performance on these two tests. Sentence Repetition has more linguistic context than Memory for Words, which requires repeating a string of unrelated words. Comparing the results of these two tests can help identify whether the context of language helps or interferes with performance.

Screening Test

Test 9: Sound Awareness does not contribute to any cluster. Its primary use is as a screening measure for children in kindergarten through third grade. However, it can be useful in evaluating both beginning readers and older individuals who are experiencing reading difficulty because it does not require reading and measures two specific aspects of phonological awareness: rhyming and deletion. Difficulties with these types of tasks serve as early warning signs of risk for reading problems. Additional information regarding phonological awareness can be obtained by administering Test 7: Sound Blending and (from the WJ IV COG) Test 5: Phonological Processing, which includes the Word Access, Word Fluency, and Substitution subtests. Comparing the results of these tests to those of the WJ IV ACH Word Attack test may help determine whether problems are due to limitations in phonological awareness, phoneme/grapheme knowledge, or difficulties with both.

Score Comparison Procedures

There are several score comparison procedures available for the WJ IV OL. The intra-oral language variation procedure explores significant differences among a person's oral language abilities, and thus is helpful in determining a pattern of strengths and weaknesses in language functions. The oral language-achievement comparison procedure documents any significant discrepancies between an oral language predictor and achievement performance. The Comparative Language Index (CLI) is generated when the parallel Spanish and English tests have been administered so that a comparison can be made between English and Spanish language proficiency. In addition, Cognitive Academic Language Proficiency (CALP) levels for specific clusters can be selected for inclusion in the score report. All of these options are available when the Online Scoring and Reporting System is used.

Intra-Oral-Language Variation Procedure

The intra-oral-language variation procedure is a norm-based method for evaluating the presence of significant strengths or weaknesses among an individual's linguistic abilities. To calculate this variation procedure, a minimum of four tests (Tests 1–4) must be administered. The individual's performance on one test is then compared to his or her predicted performance, which is based on the average performance on the other three tests. For example, when a person's performance on Test 1: Picture Vocabulary is being evaluated, the average of the other three tests (Test 2: Oral Comprehension, Test 3: Segmentation, and Test 4: Rapid Picture Naming) is used to obtain the predicted score. The actual score is then compared to the predicted score. If the actual score is higher than predicted, a positive difference is obtained. If the actual score is lower than predicted, a negative difference is obtained. Depending on the magnitude of the positive (or negative) difference, the person may have a relative strength (or weakness) in a specific area. If, for example, Picture Vocabulary is significantly higher than predicted, the person exhibits a relative strength in vocabulary knowledge. If the person's actual Picture Vocabulary score is significantly lower than predicted, he or she exhibits a relative weakness in vocabulary knowledge. This type of information is valuable in documenting a pattern of strengths and weaknesses or determining a specific area of weakness rather than generalized low performance. Additionally, Tests 5–8 can be included in the variation procedure, along with any cluster that results from the tests administered. Three tests from the WJ IV COG (Test 1: Oral Vocabulary, Test 5: Phonological Processing, and Test 12: Nonword Repetition) and the Vocabulary and Auditory Processing clusters are also entered into the intra-oral-language variation procedure when administered. Whenever additional tests or clusters are included in the variation procedure, it is called the Extended variation.

Oral Language Ability–Achievement Comparison Procedure

The WJ IV OL provides an option to use oral language as a predictor score in the ability/achievement comparison calculation. The Broad Oral Language cluster may be used to predict levels of achievement from the individual's level of oral language development.

If testing is completed in Spanish, the Amplio lenguaje oral cluster may be used as the predictor. This allows the individual's oral language ability in Spanish to predict his or her ability to perform academically in English. For Spanish-dominant bilingual students, this may be an important comparison to make because oral language ability in Spanish can suggest the level of academic performance a student may be able to attain, in English, if provided with intensive English language instruction and appropriate Spanish-language supports (Gersten et al., 2007; Lindholm & Aclan, 1991; Short & Fitzsimmons, 2007).

Within this comparison procedure, the standard score from the Broad Oral Language cluster, composed of three tests, may be used to predict achievement on any of the achievement cluster scores. Individuals with a significant negative discrepancy (e.g., ≥ -1.50) between oral language ability and achievement exhibit relative strengths in oral language with weaknesses in one or more achievement areas (for this example, a discrepancy of this size will occur about 6 out of 100 times).

As noted by Stanovich (1991a, 1991b), use of an oral language measure to predict reading and writing is often preferable to use of a general intelligence score because it is more in line with the concepts of so-called "potential" and "unexpected" failure. He further explains that using oral language ability as the aptitude measure moves us closer to a more principled definition of reading disability because it provides a more accurate estimate of what the person could achieve if the reading problem were entirely resolved. Essentially, what distinguishes the individual with a reading disability from other poor readers is that listening comprehension ability is higher than ability to decode words (Rack, Snowling, & Olson, 1992), and thus the difficulty is "unpredicted." However, it is important to note that an individual with a learning disability may or may not exhibit an oral language ability–achievement discrepancy. For example, an older student with reading difficulties may have depressed performance in oral language because of his or her limited experiences with text. This lack of exposure to print contributes to reduced knowledge and vocabulary.

Comparative Language Index

The CLI is a unique comparison procedure available when any of the three parallel English and

Spanish clusters have been administered. The CLI is available when the following clusters are compared: Oral Language to Lenguaje oral, Broad Oral Language to Amplio lenguaje oral, and Listening Comprehension to Comprensión auditiva.

The CLI is presented as a ratio of the individual's RPI numerators on the two clusters being compared, one in Spanish and one in English. The CLI is helpful in determining language dominance and proficiency. For example, when an individual is administered Tests 1, 2, and 6 in English and Tests 10–12 in Spanish, the Broad Oral Language and Amplio lenguaje oral clusters are obtained. Here is an example: Antonio, a fifth-grade student, had an RPI for Broad Oral Language of 45/90 and an RPI for Amplio lenguaje oral of 90/90. The CLI is expressed with the Spanish numerator first and the English numerator second, resulting in a CLI of 90/45. This CLI indicates that Antonio has 90% proficiency on the Spanish cluster and 45% proficiency on the parallel English cluster.

Cognitive Academic Language Proficiency

Another interpretive feature of the WJ IV involves the CALP levels that may be reported. If selected in the Online Scoring and Reporting System, all administered clusters that yield a CALP score are reported in a separate section of the score report. For the WJ IV OL, CALP levels can be reported for the following clusters: Oral Language, Broad Oral Language, Oral Expression, Listening Comprehension, and the three Spanish-language clusters (Lenguaje oral, Amplio lenguaje oral, and Comprensión auditiva). Labels attached to the CALP levels describe the individual's proficiency. For example, a person's proficiency on a task may be described as *advanced*, *fluent*, or *limited*. In all, six levels of CALP are available, plus two regions that fall between the levels.

WJ IV TESTS OF ACHIEVEMENT

The WJ IV ACH (Schrank, Mather, & McGrew, 2014a) provides examiners with a comprehensive instrument for evaluating academic achievement. The WJ IV ACH is a companion battery to the WJ IV COG and the WJ IV OL.

Organization of the WJ IV ACH

The WJ IV ACH has 20 tests that are organized into five main areas: reading, mathematics, written language, academic knowledge, and cross-domain clusters. The cross-domain clusters include tests from three different curricular areas (reading, mathematics, and writing). For example, the Academic Fluency cluster includes Sentence Reading Fluency, Math Facts Fluency, and Sentence Writing Fluency.

All of the tests are contained in two easel test books, the Standard Battery (Tests 1–11) and the Extended Battery (Tests 12–20). The Standard Battery has three forms (Forms A, B, and C), and there is one form of the Extended Battery. The Standard Battery includes the most commonly administered tests, so having three forms provides alternate and equivalent tests to avoid overexposure to the same set of test items. The Extended Battery, which can be used with any of the three forms of the Standard Battery, includes tests that provide greater breadth and depth of coverage. Figure 14.4 shows the organization of the WJ IV ACH, which applies to all forms of the Standard Battery and the Extended Battery.

The areas of reading, mathematics, and written language each include measures of basic skills, fluency or automaticity, and application or higher-level skills. The Academic Knowledge cluster includes individual tests of Science, Social Studies, and Humanities, which respectively sample an individual's knowledge of the biological and physical sciences; history, geography, government, psychology, and economics; and art, music, and literature. Table 14.14 provides an overview of the content and task demands of each of the 20 achievement tests.

How to Administer the WJ IV ACH

In many cases, tests will be administered in the order they are presented in the easel test books, particularly the core set of tests (Tests 1–6). The tests have been ordered so that tasks alternate between different formats and achievement areas (e.g., writing vs. math). However, the tests may be administered in any order.

Administration Time

As a general rule, experienced examiners require about 40 minutes to administer the core set of tests (Tests 1–6). The Writing Samples test requires approximately 15 minutes to administer, whereas the other tests, on average, require about 5 minutes each. The tests in the Extended Battery require an additional 5–10 minutes each. The amount of time varies, depending on an examinee's particular characteristics, age, and speed of response.

			Reading						Mathematics				Writing				Cross-Domain Clusters					
			Reading	Broad Reading	Basic Reading Skills	Reading Comprehension	Reading Fluency	Reading Rate	Mathematics	Broad Mathematics	Math Calculation Skills	Math Problem Solving	Written Language	Broad Written Language	Basic Writing Skills	Written Expression	Academic Skills	Academic Fluency	Academic Applications	Academic Knowledge		Brief (or Broad) Achievement

Testing Materials

The testing materials required for administration of the WJ IV ACH include the test books (for the Standard Battery and Extended Battery), a test record, a response booklet, the audio CD, appropriate audio equipment, pencils, and a stopwatch.

Summary of Key Administration and Scoring Points

Most tests use suggested starting points and basal and ceiling rules; responses are scored 1 or 0. Table 14.15 summarizes key administration and scoring points for each test.

Special Administration and Scoring Considerations

Although the WJ IV ACH examiner's manual (Mather & Wendling, 2014a) and test book provide detailed rules for test by test administration, this section presents important reminders about tests that have special administration or scoring rules.

Tests Requiring a Response Booklet

The following tests require a response booklet: Test 3: Spelling, Test 5: Calculation, Test 6: Writing Samples, Test 9: Sentence Reading Fluency, Test 10: Math Facts Fluency, Test 11: Sentence

TABLE 14.14. Content and Task Demands of the 20 WJ IV ACH Tests

Test name	Description	Task demands
	Reading	
Test 1: Letter–Word Identification	Measures an aspect of reading decoding.	Requires identifying and pronouncing isolated letters and words.
Test 4: Passage Comprehension	Measures reading comprehension of contextual information.	Requires reading a short passage and supplying a key missing word.
Test 7: Word Attack	Measures aspects of phonological and orthographic coding.	Requires applying phonic and structural analysis skills to pronounce phonically regular nonsense words.
Test 8: Oral Reading	Measures word-reading accuracy and prosody.	Requires reading sentences aloud that gradually increase in difficulty.
Test 9: Sentence Reading Fluency	Measures reading rate.	Requires reading and comprehending simple sentences, and then deciding if each statement is true or false by marking "Yes" or "No" (3-minute time limit).
Test 12: Reading Recall	Measures reading comprehension and meaningful memory.	Requires reading a passage silently one time and then retelling the story orally.
Test 15: Word Reading Fluency	Measures vocabulary knowledge and semantic fluency.	Requires marking two words that go together in a row of four words (3-minute time limit).
Test 17: Reading Vocabulary	Measures reading vocabulary and comprehension.	Requires reading and providing synonyms or antonyms.
	Mathematics	
Test 2: Applied Problems	Measures the ability to analyze and solve practical math problems, mathematical reasoning.	Requires comprehending the nature of the problem, identifying relevant information, performing calculations, and recording solutions.
Test 5: Calculation	Measures the ability to perform mathematical computations.	Requires calculation of simple to complex mathematical facts and equations.
Test 10: Math Facts Fluency	Measures aspects of number facility and math achievement.	Requires rapid calculation of single-digit addition, subtraction, and multiplication facts (3-minute time limit).
Test 13: Number Matrices	Measures quantitative reasoning.	Requires providing the missing number from a matrix.
	Written Language	
Test 3: Spelling	Measures the ability to spell dictated words.	Requires writing the correct spelling of words presented orally.
Test 6: Writing Samples	Measures quality of meaningful written expression and ability to convey ideas.	Requires writing sentences in response to a series of demands that increase in difficulty.
Test 11: Sentence Writing Fluency	Measures aspects of automaticity with syntactic components of written expression.	Requires formulating and writing simple sentences rapidly (5-minute time limit).

(continued)

TABLE 14.14. *(continued)*

Test name	Description	Task demands
Test 14: Editing	Measures the ability to identify and correct errors in spelling, usage, punctuation, and capitalization.	Requires identifying errors in short written passages and correcting them orally.
Test 16: Spelling of Sounds	Measures aspects of phonological/orthographic coding.	Requires spelling nonsense words that conform to conventional English spelling rules.
	Academic Knowledge	
Test 18: Science	Provides a survey of knowledge in science, including biology, chemistry, geology, and physics.	Requires providing an oral response to orally presented questions. Many items provide visual stimuli, and early items require a pointing response only.
Test 19: Social Studies	Provides a survey of knowledge in social studies, including history, psychology, geography, government, and economics.	Requires providing an oral response to orally presented questions. Many items provide visual stimuli, and early items require a pointing response only.
Test 20: Humanities	Provides a survey of knowledge in humanities, including art, music, and literature.	Requires providing an oral response to orally presented questions. Many items provide visual stimuli, and early items require a pointing response only.

Writing Fluency, Test 15: Word Reading Fluency, and Test 16: Spelling of Sounds. In addition, the response booklet contains a worksheet to use with Test 2: Applied Problems and Test 13: Number Matrices. The examiner must maintain control of the response booklet, presenting it to the examinee and removing as directed by instructions in the test book.

Timed Tests

The following tests are timed: Test 9: Sentence Reading Fluency, Test 10: Math Facts Fluency, Test 11: Sentence Writing Fluency, and Test 15: Word Reading Fluency. The time limit is 3 minutes each for Sentence Reading Fluency, Math Facts Fluency and Word Reading Fluency, and 5 minutes for Sentence Writing Fluency.

A stopwatch or the stopwatch feature on a smartphone is required to administer these tests. If a stopwatch is unavailable, a watch or clock with a second hand should be used. In this case, the examiner should write down the exact starting and stopping times in minutes and seconds in the spaces provided in the test record, rather than depending on memory. The examiner enters the times and numbers correct in the Online Scoring and Reporting System to generate the scores for these tests. The exact finishing time for each test must be entered because earlier finishers who do well will receive a higher score than individuals who continue to work for the full time limit.

Audio-Recorded Tests

Test 16: Spelling of Sounds is the only WJ IV ACH test that is presented with an audio recording. Use of the test's audio recording is expected, and headphones are recommended unless the person being tested resists wearing headphones or has difficulty attending to a recorded presentation.

Qualitative Observation Checklists

Each of the 11 tests in the Standard Batteries (Forms A, B, C) has a Qualitative Observation Checklist in the test record. These checklists are designed to document an examinee's performance on the test through qualitative observations, or in the case of Test 8: Oral Reading, a quantitative observation. Although optional, use of these checklists can provide important insights about how the individual completed the task.

TABLE 14.15. Summary of WJ IV ACH Test Administration and Scoring Rules

Test name	Item scoring rule	Sample items?	Basal/ceiling rules?[a]	Administration notes	Extra materials required for administration
			Standard Battery tests (Forms A, B, C)		
Test 1: Letter–Word Identification	1, 0	No	Yes; 6/6	Suggested starting points are available; word must be pronounced smoothly to receive credit.	
Test 2: Applied Problems	1, 0	No	Yes; 5/5	Suggested starting points are available.	Response booklet
Test 3: Spelling	1, 0	No	Yes; 6/6	Suggested starting points are available.	Response booklet
Test 4: Passage Comprehension	1, 0	Yes (PreK)	Yes; 6/6	Suggested starting points are available.	
Test 5: Calculation	1, 0	Yes (Pre-G1)	Yes; 6/6	Suggested starting points are available.	Response booklet
Test 6: Writing Samples	2, 1.5, 1, 0.5, 0	No	No; ceiling determined by score on block of items	Suggested starting points are available; scoring is based on specific block of items administered	Response booklet
Test 7: Word Attack	1, 0	Yes (G3–adult)	Yes; 6/6	Suggested starting points are available; word must be pronounced smoothly to receive credit.	
Test 8: Oral Reading	2, 1, 0	No	No; ceiling determined by continuation instructions	Suggested starting points are available; be familiar with the types of reading mistakes that count as errors.	
Test 9: Sentence Reading Fluency	1, 0	Yes	No; 3-minute time limit	All begin with sample items, then proceed to item 1; use scoring guide overlay.	Stopwatch (timed test); response booklet
Test 10: Math Facts Fluency	1, 0	No	No; 3-minute time limit	All begin with item 1; use scoring guide overlay.	Stopwatch (timed test); response booklet
Test 11: Sentence Writing Fluency	1, 0	Yes	No; 5-minute time limit	All begin with sample items, then proceed to item 1.	Stopwatch (timed test); response booklet

			Extended Battery tests		
Test 12: Reading Recall	1 for each correctly recalled element	No	No; ceiling determined by continuation instructions	Suggested starting points are available; direct examinee to read the story once silently.	
Test 13: Number Matrices	1, 0	Yes	Yes; 6/6	Choose appropriate sample item; then use suggested starting points.	Response booklet; stopwatch to monitor response time
Test 14: Editing	1, 0	Yes	Yes; 6/6	All begin with sample items; then use suggested starting points.	
Test 15: Word Reading Fluency	1, 0	Yes	No; 3-minute time limit	All begin with sample items; then proceed to item 1.	Stopwatch (timed test); response booklet
Test 16: Spelling of Sounds	1, 0	Yes	Yes; 6/6	Suggested starting points are available; scoring is based on written response only.	Audio; response booklet
Test 17: Reading Vocabulary				Both subtests must be administered.	
17A: Synonyms	1, 0	Yes	Yes; 5/5	All begin with sample items; then use suggested starting points.	
17B: Antonyms	1, 0	Yes	Yes; 5/5	All begin with sample items; then use suggested starting points.	
Test 18: Science	1, 0	No	Yes; 6/6	Suggested starting points are available.	
Test 19: Social Studies	1, 0	No	Yes; 6/6	Suggested starting points are available.	
Test 20: Humanities	1, 0	No	Yes; 6/6	Suggested starting points are available.	

[a] May be modified by complete-page rule.

Test 6: Writing Samples

The examiner administers the appropriate block of items as indicated on the table in the test book on the page after the Writing Samples tab. If it is apparent that the examinee is experiencing undue ease or difficulty with the assigned block of items, it may be necessary to administer additional items to obtain a better estimate of writing ability. This can be done immediately, or because the test is scored after testing is completed, it may be necessary to administer the additional items at a convenient time within the next few days.

The Writing Samples scoring table in the test record allows the examiner to determine whether the most appropriate block of items has been administered. If the individual's raw score falls within one of the seven shaded areas on the scoring table, the additional items noted in the Adjusted Item Block chart on page 7 in the test record should be administered. This chart also indicates the block of items to use for calculating the raw score.

If an examinee's response to an item is illegible or difficult to read, the person can be asked to write as neatly as possible—*but not, however, to read aloud what was written for scoring purposes*. Illegible responses are scored as 0. If requested by the examinee, the examiner may read any words during this test or repeat the instructions. When an examinee asks whether spelling is important or how to spell a word, the examiner should encourage the examinee just to do the best he or she can.

Writing Samples is scored after the testing is completed. Items 1–6 are scored 1 or 0. Items 7 and higher may be scored 2, 1.5, 1, 0.5, or 0 points, according to a modified holistic procedure that requires examiner judgment. Because scoring of this test is more involved and subjective than the scoring of other WJ IV ACH tests, special rating and scoring procedures are provided in Appendix B of the examiner's manual that accompanies the test.

Test 8: Oral Reading

Oral Reading is composed of a set of sentences that gradually increase in difficulty. The examinee reads each sentence orally from the test book. The examiner uses the sentences printed in the test record and marks each error with a slash mark at the point in a sentence the error occurs. Examiners must familiarize themselves with the types of errors that are marked: mispronunciations, omissions, insertions, substitutions, hesitations of 3 seconds or more, repetitions, transpositions, and ignoring punctuation. Oral Reading uses continuation instructions to determine when to continue or discontinue testing. A multipoint scoring system is used to score the examinee's oral reading of each sentence: 2 (no errors), 1 (one error), or 0 (2 or more errors).

Test 9: Sentence Reading Fluency

The score for Sentence Reading Fluency is based on both the number of correct responses and the number of incorrect responses. Both totals must be entered into the Online Scoring and Reporting System.

Test 12: Reading Recall

Reading Recall requires the examinee to read a story silently one time and then retell the story. The scoring is based on the number of story elements the examinee recalls correctly during the retelling. The test is administered in two-story sets, and continuation instructions are used to determine when to administer additional stories and when to discontinue testing. The administration and scoring of this test are similar to those for WJ IV COG Test 6: Story Recall.

Test 16: Spelling of Sounds

Spelling of Sounds requires the examinee to write the spelling of a given sound or nonsense word. The examinee is asked to say the sound or word aloud before writing, but the scoring is based solely on the written response. All correct responses are shown in the test book and represent the only spellings that can be scored a 1.

Reliability and Validity

Following is a summary of reliability and validity information for the WJ IV ACH. For more complete information, consult the WJ IV technical manual (McGrew et al., 2014) and the discussion of CHC theory in the introductory section of this chapter.

Median reliability coefficients for the WJ IV ACH tests are reported in Table 14.16. With the exception of the timed tests, coefficients of stability are reported as median internal-consistency (r_{11}) and median *SEM* values. For the four timed tests, test–retest values (r_{12}) were used as the most appropriate coefficient of stability. Mosier's (1943) formula was used to calculate reliabilities for tests

TABLE 14.16. WJ IV ACH Median Test Reliability Statistics

Test	Median r_{11}	Median *SEM* (SS)	Median r_{12}
	Standard Battery		
Test 1: Letter–Word Identification	.94	5.21	—
Test 2: Applied Problems	.92	4.75	—
Test 3: Spelling	.92	4.86	—
Test 4: Passage Comprehension	.89	6.08	—
Test 5: Calculation	.93	4.99	—
Test 6: Writing Samples	.90	4.74	—
Test 7: Word Attack	.90	5.03	—
Test 8: Oral Reading	.96	3.35	—
Test 9: Sentence Reading Fluency	—	—	.93
Test 10: Math Facts Fluency	—	—	.95
Test 11: Sentence Writing Fluency	—	—	.83
	Extended Battery		
Test 12: Reading Recall	.92	2.62	—
Test 13: Number Matrices	.92	3.75	—
Test 14: Editing	.91	4.85	—
Test 15: Word Reading Fluency	—	—	.92
Test 16: Spelling of Sounds	.88	5.89	—
Test 17: Reading Vocabulary	.88	6.36	—
Test 18: Science	.84	7.39	—
Test 19: Social Studies	.87	6.76	—
Test 20: Humanities	.87	7.96	—

Note. r_{11}, internal-consistency reliability; r_{12}, test–retest reliability for speeded tests.

with subtests, such as ACH Test 17: Reading Vocabulary. Because the WJ IV ACH Standard Battery has three parallel forms (A, B, and C), alternate-form equivalence was studied. The empirical evidence supports the equivalence of the alternate forms.

Table 14.17 contains the median cluster reliability coefficients (r_{cc}) and median standard errors of measurement for obtained cluster standard scores, or *SEM* (SS), as calculated via Mosier's formula. All of the WJ IV ACH clusters exceed the commonly referenced professional standard of .90 for decision-making purposes. Although the test reliabilities support use and interpretation of the test-level scores as single indicators of an ability, the WJ IV ACH clusters are preferred for most decision-making purposes, due to their higher reliabilities.

Table 14.18 contains a summary of correlations for the WJ IV ACH reading, math, and written language clusters with other measures of achievement, including the Kaufman Test of Educational Achievement—Second Edition (KTEA-2; Kaufman & Kaufman, 2004b), the Wechsler Individual Achievement Test—Third Edition (WIAT-III; Pearson, 2009), and the Oral and Written Language Scales: Written Expression (OWLS-WE; Carrow-Woolfolk, 1996). The significant correlations support the validity of the WJ IV ACH clusters as valid measures of reading, mathematics, and written language.

Interpretation

The WJ IV ACH provides measures for evaluating six of the eligibility areas for specific learning disabilities listed in IDEA (2004): basic reading skills, reading comprehension, reading fluency, math calculation skills, math problem solving, and written expression. The other two areas, oral expression and listening comprehension, are evaluated with the WJ IV OL.

Within the framework of CHC theory, the WJ IV ACH tests are primarily measures of reading–writing ability (Grw) or quantitative knowledge (Gq). The reading and written language tests provide measures of Grw, defined by Newton and McGrew (2010) as "the breadth and depth of a person's acquired store of declarative and procedure reading and writing skills and knowledge" (p. 628). The WJ IV ACH mathematics tests provide measures of a broad quantitative knowledge (Gq) construct, or "the breadth and depth of a person's acquired store of declarative and procedural quantitative or numerical knowledge" (Newton & McGrew, 2010, p. 628). The three tests in the Academic Knowledge cluster, Science, Social Studies, and Humanities, are primarily measures of domain-specific knowledge (Gkn), defined as depth, breadth, and mastery of specialized knowledge (Schneider & McGrew, 2012).

However, the WJ IV ACH tests are cognitively complex tasks requiring the application of one or more narrow abilities and dynamic cognitive processes (McGrew, Schrank, & Woodcock, 2007). Table 14.19 outlines the narrow abilities defined by CHC theory for each of the WJ IV ACH tests. Table 14.20 provides a summary of selected interventions and accommodations for each WJ IV ACH test. As in the WJ IV COG and WJ IV OL, the identified narrow abilities and inferred cognitive processes are used to provide a link between WJ IV ACH test scores and evidence-based interventions.

TABLE 14.17. WJ IV ACH Median Cluster Reliability Statistics

Cluster	r_{cc}	Median *SEM* (SS)
Reading	.95	4.24
Broad Reading	.97	3.35
Basic Reading Skills	.95	3.97
Reading Comprehension	.93	4.24
Reading Comprehension—Ext.	.96	3.00
Reading Fluency	.96	3.00

Academic Knowledge	.95	4.24
Phoneme–Grapheme Knowledge	.94	4.24
Brief Achievement	.97	3.35
Broad Achievement	.99	2.12

Basic Reading Skills

Test 1: Letter–Word Identification and Test 7: Word Attack constitute the Basic Reading Skills cluster and provide a broad view of an individual's basic word-reading skills, including sight word recognition and phonic skills. The dual-route theory (Coltheart, 1980, 2007) suggests that two pathways are involved in learning words: a *lexical* procedure and a *nonlexical* procedure. The lexical procedure is engaged when the person is reading real words, whereas the nonlexical procedure involves converting letters to phonemes and aids in using phonics and reading nonwords. Comparing the results of the two tests in this cluster helps determine whether word recognition skills, phonic skills, or both are limited and require remediation. Analysis of errors made on both tests can help target specific instructional elements. Table 14.20 provides examples of interventions.

If an individual has trouble decoding words, few resources are left for comprehension. Slow, labored reading with many errors will have a negative impact on comprehension. Analyzing an individual's performance on the Basic Reading Skills tests is important to the interpretation of the Reading Comprehension tests. The examiner must be sure to consider the effect of decoding problems before identifying a problem in reading comprehension.

Test 1: Letter–Word Identification

Letter–Word Identification requires the individual to read aloud isolated letters and words presented in a list. It is a measure of reading decoding (word recognition), including reading readiness skills. Knowledge of word meanings is not required to perform this task. Individuals with good word

TABLE 14.18. Correlations for Select WJ IV ACH Measures and Other Measures of Achievement

Other measure	Broad Reading	Reading Fluency	Broad Math	Broad Written Language
Kaufman Test of Educational Achievement—Second Edition (KTEA-2)[a]				
Reading	.92	.86	.78	.85
Decoding Fluency	.83	.80	.62	.79
Math	.73	.70	.91	.68
Written Language	.79	.75	.71	.84
Wechsler Individual Achievement Test—Third Edition (WIAT-III)[b]				
Total Reading	.89	.87	.67	.83
Reading Comprehension and Fluency	.82	.80	.58	.68
Mathematics	.73	.71	.90	.72
Written Expression	.75	.76	.63	.77
Oral and Written Language Scales: Written Expression (OWLS-WE)[c]				.70

Note. Samples used in studies varied by age or grade as noted.

[a] Ages 8–12.

[b] Grades 1–8.

[c] Ages 7–17.

recognition skills recognize the letters and words rapidly and with little effort. In other words, they demonstrate automaticity at the word-reading level, which facilitates reading performance.

Low performance on this test may be due to inefficient or limited strategies for word identification. Individuals who lack automaticity of word identification skills may identify several words accurately, but require increased time and greater attention to phonic analysis to determine the correct response. These individuals tend to read slowly and make numerous errors. They may be easily frustrated or unwilling to try for fear of making an error. The results of this test can be compared with those of Test 7: Word Attack, the other test in the Basic Reading Skills cluster. Other helpful comparisons include Test 4: Passage Comprehension, Test 8: Oral Reading, Test 9: Sentence Reading Fluency, Test 12: Reading Recall, Test 15: Word Reading Fluency, and Test 17: Reading Vocabulary. These comparisons can provide insights into the individual's level of reading skills with and without the context of meaning. Although all of the tests require word identification, these other tests also require knowledge of word meanings, sentence structure, and comprehension.

Use of an explicit, systematic, synthetic phonics program is one of the most effective interventions for developing basic reading skills (Brady, 2011; National Reading Panel, 2000). High-frequency words should be taught in conjunction with a structured phonics program to help develop word recognition skills.

Test 7: Word Attack

Word Attack requires the individual to read phonically regular nonsense words orally. It measures aspects of both phonological and orthographic coding. Phoneme–grapheme knowledge is necessary to perform well on this test because the words are not real words and cannot be recognized or recalled from memory. The reader must apply phoneme–grapheme knowledge in order to translate a written word that is not stored in memory into speech (Berninger & Richards, 2010).

Low performance on Word Attack may result from poor phonological processing, limited phoneme–grapheme knowledge, poor decoding skills and strategies, or a lack of fluency. Impaired decoding is frequently thought to be the basis of reading problems. Analyzing the types of errors

TABLE 14.19. WJ IV ACH Tests: CHC Broad and Narrow Abilities Measured

Test name	Primary broad CHC ability	*Narrow ability*
Test 1: Letter–Word Identification	Reading and writing ability (Grw)	*Reading decoding* (RD)
Test 2: Applied Problems	Quantitative knowledge (Gq)	*Mathematical achievement* (A3)
	Fluid reasoning (Gf)	*Quantitative reasoning* (RQ)
Test 3: Spelling	Reading and writing ability (Grw)	*Spelling ability* (SG)
Test 4: Passage Comprehension	Reading and writing ability (Grw)	*Reading comprehension* (RC)
Test 5: Calculation	Quantitative knowledge (Gq)	*Mathematical achievement* (A3)
Test 6: Writing Samples	Reading and writing ability (Grw)	*Writing ability* (WA)
Test 7: Word Attack	Reading and writing ability (Grw)	*Reading decoding* (RD)
	Auditory processing (Ga)	*Phonetic coding* (PC)
Test 8: Oral Reading	Reading and writing ability (Grw)	*Reading comprehension* (RC) *Verbal (print) language comprehension* (V)
Test 9: Sentence Reading Fluency	Reading and writing ability (Grw)	*Reading comprehension* (RC) *Reading speed* (RS)
	Processing speed (Gs)	
Tet 10: Math Facts Fluency	Quantitative knowledge (Gq)	*Mathematical achievement* (A3)
	Processing speed (Gs)	*Number facililty* (N)
Test 11: Sentence Writing Fluency	Reading and writing ability (Grw)	*Writing ability* (WA) *Writing speed* (WS)
	Processing speed (Gs)	
Test 12: Reading Recall	Reading and writing ability (Grw)	*Reading comprehension* (RC)
	Long-term storage and retrieval (Glr)	*Meaningful memory* (MM)
Test 13: Number Matrices	Fluid reasoning (Gf)	*Quantitative reasoning* (RQ)
Test 14: Editing	Reading and writing ability (Grw)	*English usage* (EU)
Test 15: Word Reading Fluency	Reading and writing ability (Grw)	*Reading comprehension* (RC) *Reading speed* (RS)
	Processing speed (Gs)	
Test 16: Spelling of Sounds	Reading and writing ability (Grw)	*Spelling ability* (SG)
	Auditory Processing (Ga)	*Phonetic coding* (PC)
Test 17: Reading Vocabulary	Reading and writing ability (Grw)	*Reading comprehension* (RC)
	Comprehension–knowledge (Gc)	*Lexical knowledge* (VL)
Test 18: Science	Domain-specific knowledge (Gkn)	*General science information* (K1)
	Comprehension–knowledge (Gc)	*General (verbal) information* (K0)
Test 19: Social Studies	Domain-specific knowledge (Gkn)	*Knowledge of culture* (K2) *Geography achievement* (A5)
	Comprehension–knowledge (Gc)	*General (verbal) information* (K0)
Test 20: Humanities	Domain-specific knowledge (Gkn)	*Knowledge of culture* (K2)
	Comprehension–knowledge (Gc)	*General (verbal) information* (K0)

TABLE 14.20. Examples of Interventions, Strategies, and Accommodations Related to Limitations in Performance on WJ IV ACH Tests

Test	Brief intervention, strategy, or accommodation
Test 1: Letter–Word Identification	Explicit, systematic synthetic phonics instruction; teaching word recognition strategies; teaching high-frequency words.
Test 2: Applied Problems	Combining direct instruction and strategy instruction; teaching schema-based problem solving; use of modeling and verbal rehearsal.
Test 3: Spelling	Use of the write–say method; teaching common irregular words; teaching morphology; having student keep a dictionary of words commonly used in his or her writing; reducing number of words on spelling tests.
Test 4: Passage Comprehension	Activating prior knowledge; use of graphic organizers; teaching self-monitoring strategies; use of books on audio to ensure access to content.
Test 5: Calculation	Developing number sense; sequential direct instruction; employing concrete–representational–abstract teaching sequence; use of computer-assisted instruction.
Test 6: Writing Samples	Creating a literate, motivating, risk-free environment; teaching the writing process; providing daily practice; teaching text structures; increasing time to complete writing tasks; decreasing number of writing assignments; use of technology to support writing (e.g., word processor, spell-checker, voice recognition).
Test 7: Word Attack	Teaching phoneme–grapheme mapping, using letter tile or Elkonin boxes; explicit, systematic, synthetic phonics instruction; use of decodable texts.
Test 8: Oral Reading	Modeling fluent oral reading; for practice, use of texts on which the student is accurate; cueing of phrase boundaries (e.g., use of slash marks or scoops to identify phrases).
Test 9: Sentence Reading Fluency	Use of repeated readings with error correction procedure; providing frequent practice; previewing passages and practicing words in isolation.
Test 10: Math Facts Fluency	Practicing with math facts charts; use of explicit timings and graph progress; use of computer programs for drill and practice.
Test 11: Sentence Writing Fluency	Use of word, phrase, and sentence fluency-building activities; teaching the mechanics of writing; permitting use of word processor.
Test 12: Reading Recall	Teaching use of mental imagery strategies while reading; providing instruction and practice with a self-monitoring strategy; reciprocal teaching; having student summarize passages after reading.
Test 13: Number Matrices	Teaching number patterns and core math concepts; counting by increments; use of manipulatives; developing a sense of numerical quantity; use of math talk.
Test 14: Editing	Teaching proofreading skills; employing peer editing; use of technology.
Test 15: Word Reading Fluency	Conducting 1-minute speed drills of word lists; teaching word recognition skillls; use of word webs.
Test 16: Spelling of Sounds	Instruction in orthography and morphology; use of multi-sensory techniques; teaching use of computerized spell-checker.
Test 17: Reading Vocabulary	Use of semantic feature analysis; encouraging reading for different purposes; teaching synonyms, antonyms, and multiple-meaning words.
Test 18: Science	Frequent exposure to and practice with words and concepts related to science; increasing experiences (e.g., visits to museums, conducting experiments); use of semantic maps.
Test 19: Social Studies	Frequent exposure to and practice with words and concepts related to social studies; increasing experiences (e.g., visits to museums, community services); reading in the content area.
Test 20: Humanities	Frequent exposure to and practice with words and concepts related to humanities; increasing experiences (e.g., visits to art museums/concerts, reading different genres aloud).

the individual makes on this test not only helps to plan the most appropriate instructional program, but also helps determine whether further testing is indicated. In addition to explicit and systematic instruction in phonics, teaching structural analysis skills (e.g., six syllable types or onsets–rimes) improves the individual's ability to decode words (Ehri, 2000).

Reading Comprehension

The Reading Comprehension cluster is composed of Test 4: Passage Comprehension and Test 12: Reading Recall. This cluster provides a broad view of the individual's reading comprehension skill. Reading comprehension is a complex cognitive process that requires intentional interaction between the reader and the text to construct meaning (Durkin, 1993). Both tests in this cluster measure comprehension in the context of connected discourse. Reading Recall also has a meaningful memory component (the ability to encode, consolidate, or store meaningful representations of the story details), requiring subsequent reconstruction of the passage that was read. Because of the retelling aspect of Reading Recall, expressive language demands are increased and must be considered when interpreting results.

The Reading Comprehension—Extended cluster includes Passage Comprehension and Reading Recall, but adds a third test, Test 17: Reading Vocabulary. Reading Vocabulary measures comprehension in a decontextualized format—that is, understanding of word meanings in isolation. Comparing the results of the three tests in this cluster helps determine whether a meaningful context helps or interferes with an individual's comprehension.

Other helpful comparisons include comparing the results of the Reading Comprehension cluster to those of the Basic Reading Skills cluster, the Academic Knowledge cluster, the WJ IV OL Listening Comprehension cluster, and the WJ IV COG General Information test. Low performance on Reading Comprehension tasks may result from low basic reading skills or limited oral language or background knowledge. Considering the impact of these various factors helps determine the most appropriate instructional program for the individual. See Table 14.20 for examples of interventions.

Test 4: Passage Comprehension

Passage Comprehension requires the individual to read a short passage silently, comprehend the information, and provide a missing word. It is a measure of reading comprehension and lexical knowledge. This modified cloze task requires the ability to use both syntactic and semantic clues in comprehending text.

Low performance on Passage Comprehension may result from limited basic reading skills, comprehension difficulties, or both. Analysis of the types of errors made helps determine the most appropriate instructional plan. One effective intervention for improving reading comprehension is to teach a variety of comprehension strategies (National Reading Panel, 2000). The seven most effective strategies identified by the National Reading Panel are these: comprehension monitoring, cooperative learning, use of graphic and semantic organizers, question answering, question generating, story structures, and summarization.

The results from Passage Comprehension can be compared to those of WJ IV OL Test 2: Oral Comprehension, a similar task that does not require reading, to help determine whether the problem is with reading alone or involves limited language comprehension. If the individual does well on the oral test, then language comprehension is not likely to be the reason for poor performance on the reading test. If the individual does poorly on the oral test, then any limitations in language comprehension must also be considered as a contributing factor to poor reading performance.

Test 12: Reading Recall

Reading Recall requires the individual to read a story and then reconstruct the elements of that story. Both reading and expressive language skills are required to perform this story-retelling task. Reading Recall measures reading comprehension, meaningful memory, and language development. Poor attention, poor memory consolidation, poor decoding, limited vocabulary, low expressive language, or limited comprehension may negatively affect performance on this test. Performance on the Reading Recall test can be compared to that on WJ IV COG Test 6: Story Recall, a similar task that does not require reading. If performance is higher on Reading Recall than Story Recall, this suggests that comprehension is stronger when the examinee is reading silently than when attending to orally imparted discourse. If performance is higher on Story Recall than on Reading Recall, this suggests that the problem is not with memory consolidation or attention, but rather with reading skills.

One intervention to improve comprehension is to teach the reader to visualize while reading.

Visualization requires the reader to be actively engaged with the text and to think deeply about the content. Individuals who have difficulty visualizing the information provided by the text struggle with comprehension (Gersten, Fuchs, Williams, & Baker, 2001). Explicit instruction in how to visualize while reading may be required. Teachers can ask specific questions about a text to evoke imagery, and can also model how to use visualization through a think-aloud process.

Test 17: Reading Vocabulary

Reading Vocabulary has two parts: 17A Synonyms and 17B Antonyms. The individual is required to read words and to supply (orally) synonyms and antonyms, respectively. Low performance on this test may result from poor basic reading skills, limited vocabulary, or both. An individual who reads the stimulus words correctly, but provides incorrect responses, may be better at decoding than comprehending. An individual who misreads the stimulus words, but provides the correct responses, may be better at comprehending than decoding.

Reading Vocabulary performance can be directly compared to the individual's performance on WJ IV COG Test 1: Oral Vocabulary, a similar task that does not require reading. If the individual's performance is higher on the oral task than on the reading task, then the focus of instruction should be on developing basic reading skills. If the individual's performance is low on both the oral task and the reading task, then the focus of instruction should be on developing oral vocabulary, as well as basic reading skills. Use of semantic feature analysis (Anders & Bos, 1986; Pittelman, Heimlich, Berglund, & French, 1991) helps increase vocabulary by exploring similarities, differences, and connections between words and concepts.

Reading Fluency

Reading fluency is often described as the bridge between word identification and comprehension, and is considered the best predictor of reading comprehension (Chall, 1996; Chard, Vaughn, & Tyler, 2002). The National Reading Panel (2000) identified reading fluency as one of the five critical areas of reading assessment and instruction, which led to the addition of reading fluency as one of the eight areas of eligibility for specific learning disabilities (IDEA, 2004). The Reading Fluency cluster contains two tests: Test 8: Oral Reading, an untimed measure of oral reading, and Test 9: Sentence Reading Fluency, a timed measure of silent reading. Although the Oral Reading test is not timed, a person's ease of reading, accuracy, and expression (prosody) can be observed as the sentences are read aloud. The number and type of errors the person makes while reading can also be recorded in the Qualitative Observation Tally located in the test record. This type of information helps inform instructional planning. Sentence Reading Fluency is a timed silent reading task that requires comprehending simple sentences quickly. An examiner comparing the individual's performance on the two tests in this cluster should consider how the differences in task and response demands may have influenced performance. See Table 14.20 for suggested interventions.

Test 8: Oral Reading

The Oral Reading test requires oral reading of a set of sentences that gradually increase in complexity. The test provides information about the individual's decoding skill, automaticity with reading, and prosody (reading with appropriate expression and attention to punctuation). The Qualitative Observation Tally in the Test Record can be used to code the type of errors an individual makes while reading the sentences and can lead to specific instructional implications. Both explicit modeling of fluent reading and repeated reading practice with corrective feedback have been identified as highly effective interventions for improving reading fluency (Chard et al., 2002).

Test 9: Sentence Reading Fluency

Sentence Reading Fluency requires the individual to read simple sentences quickly and indicate if each statement is true or false by circling "Yes" or "No." It is a measure of reading speed and automaticity. Low performance on Sentence Reading Fluency may be a result of difficulty sustaining attention, limited basic reading skills, slow processing speed, or comprehension difficulties. An individual's orthographic processing, perceptual speed, or processing speed (as assessed with the WJ IV COG Cognitive Processing Speed cluster or Perceptual Speed cluster) may facilitate or inhibit performance on this test.

The speed and fluency with which an individual performs basic skills can influence performance on higher-level skills. Sentence Reading Fluency can be compared with Test 15: Word Reading Fluency, to see whether performance is similar on both these timed tests. If the Sentence Reading Fluency score is higher than the Word Reading

Fluency score, it suggests that increased context improves word recognition and comprehension. Speed drills and monitoring progress are two interventions for building reading speed. When instruction is focused on rate, it is important to use materials on which the individual has a 95–98% accuracy level.

Other Reading Clusters

There are three additional reading clusters available: Reading Rate, Reading, and Broad Reading.

Reading Rate

The Reading Rate cluster consists of Test 9: Sentence Reading Fluency and Test 15: Word Reading Fluency. Both of these tests are timed and read silently. Sentence Reading Fluency requires comprehension of simple sentences, whereas Word Reading Fluency involves the understanding of vocabulary and the semantic relationships among pairs of words. Results on this cluster can be compared to those on Basic Reading Skills, as well as Reading Comprehension. In addition, the examiner may wish to investigate how the person performs on other timed measures (e.g., Math Facts Fluency and Sentence Writing Fluency), as well as on measures of processing and perceptual speed on the WJ IV COG. In some cases, the results of this cluster, when substantiated with additional information, can be used to help document a need for extended time on tests.

Test 15: Word Reading Fluency. Test 15 is a timed test that requires the examinee to silently and quickly read groups of four words and mark the two in each group that share a semantic relationship. Low performance on this test may result from poor basic reading skills, limited vocabulary, or slow processing speed. An individual's processing speed may facilitate or inhibit performance on this test.

Reading

The Reading cluster consists of two tests: Test 1: Letter–Word Identification, a measure of word recognition skill; and Test 4: Passage Comprehension, a measure of reading comprehension. The cluster does not include a timed reading test, so it provides an overall measure of reading accuracy and comprehension that does not include the effects of reading speed.

Broad Reading

The Broad Reading cluster is composed of three tests—Test 1: Letter–Word Identification, Test 4: Passage Comprehension, and Test 9: Sentence Reading Fluency. This cluster provides a broad overview of the individual's overall reading level. Because it is a mix of three different aspects of reading (basic skills, comprehension, and fluency), interpretation of this cluster is most meaningful when performance is similar on all three tests.

Math Calculation Skills

The Math Calculation Skills cluster is composed of two tests, Test 5: Calculation and Test 10: Math Facts Fluency. It provides a measure of basic math skills, including computational skills and automaticity with basic math facts. Relative ease with computations is an important factor in predicting math performance. The results of the two tests in this cluster can be compared, to help determine whether fluency with basic math facts or calculation skill is affecting performance. Table 14.20 provides a selection of interventions.

Test 5: Calculation

The Calculation test requires the individual to perform a variety of calculations ranging from simple addition and subtraction to complex calculus. Tasks progress in this order: (1) basic addition, subtraction, multiplication, and division; (2) advanced calculations of each operation with regrouping; (3) advanced calculations of each operation with negative numbers (except division); (4) fractions; (5) percentages; (6) algebra; (7) trigonometry; (8) logarithms; and (9) calculus. Calculation measures the ability to perform mathematical computations that are fundamental to more complex math reasoning and problem solving. Fluency with basic math skills is fundamental to more complex math (Geary, 2007). Low performance may result from limited basic math skills, weaknesses in short-term working memory or memory span, limited fluency or automaticity with math facts, poor or limited instruction, or difficulty with attention.

The examiner should observe the examinee's behaviors; categorize errors that are made; note which concepts are known and unknown; and interview the examinee, if needed. Effective instruction should be direct and explicit, with cumulative review (Fuchs et al., 2008). Combining direct instruction with strategy instruction yields more positive results than using either method alone (Karp & Voltz, 2000; Swanson, 2001).

Test 10: Math Facts Fluency

Math Facts Fluency requires the individual to solve simple addition, subtraction, and multiplication tasks quickly. Poor math fact retrieval is often described as a primary characteristic of individuals with a specific math disability (Andersson, 2008; Geary, 2007). Low performance on this test may result from poor attention, limited basic math skills, lack of automaticity, or slow perceptual speed. Some individuals work slowly and accurately, whereas other individuals work very quickly and make many errors. If numerous errors are made, an examiner should attempt to determine the reasons for the mistakes. As examples, a student may be confused or not pay careful attention to the signs, may not know multiplication facts, or may be confused about the properties of zero (e.g., 6 + 0 = 0). Related interventions for low performance on math facts fluency include developing number sense (Berch, 2005; Griffin, 2004) and use of explicit timings to increase speed of performance (Miller & Hudson, 2007; Rathvon, 1999).

Math Problem Solving

The Math Problem Solving cluster is composed of two tests, Test 2: Applied Problems and Test 13: Number Matrices. It provides a measure of mathematical knowledge and quantitative reasoning. Results of this cluster can be compared to those of the Math Calculation Skills cluster, to help determine whether or not limited basic math skills are affecting performance in math problem solving. In addition, the results of this cluster can be compared to those of the Oral Language cluster if the WJ IV OL is used, and to those of the Comprehension–Knowledge (Gc) and Fluid Reasoning (Gf) clusters if the WJ IV COG is used. Individuals with low oral language skills may have difficulty with quantitative terminology or math vocabulary. Individuals with low comprehension–knowledge may lack prerequisite knowledge for acquiring and identifying mathematical concepts. Individuals with low fluid reasoning may have difficulty identifying and thinking through the various steps of a mathematical problem. See Table 14.20 for suggested interventions.

Test 2: Applied Problems

Applied Problems requires the individual to analyze and solve practical math problems. It is a measure of quantitative reasoning, math achievement, and math knowledge. Applied Problems requires the construction of mental models (Johnson-Laird, Byrne, & Schaeken, 1992) to solve problems through the application of insight or quantitative reasoning. Solutions to these problems require access to complex cognitive processes and the calculation abilities that depend on them (Ashcraft, 1995). Because no reading is required, low performance will most likely be related to limitations in mathematical knowledge, attention, fluid reasoning, basic math skills, or oral language comprehension.

Difficulties with vocabulary, working memory, and perceptual speed can also impair performance on Applied Problems. Results on this test can be compared to those on reading and writing clusters, to determine whether the individual does better when no reading is required. Analyzing the individual's errors may help provide ideas for instructional planning. Interventions related to low performance on Applied Problems include schema-based strategy instruction (Fuchs & Fuchs, 2007; Xin, Jitendra, & Deatline-Buchman, 2005) and use of the concrete–representational–abstract (CRA) instructional sequence (e.g., Morin & Miller, 1998).

Test 13: Number Matrices

The task in Number Matrices requires the individual to look at a matrix of numbers, figure out the pattern, and then provide the missing number. This test requires a foundation in mathematics knowledge (i.e., access to the category-specific verbal and visual codes, such as knowledge of the number line). The solution to each item is obtained by mapping the relationship deduced from the completed part of the item onto the incompleted part of the item, thereby completing a serial relationship. Because the solution must work both ways (horizontally and vertically), a correct response must also produce a number matrix. It is a measure of deductive and inductive quantitative reasoning (aspects of fluid reasoning) and also requires attentional control in working memory and perceptual speed.

Low performance on this test may result from limited fluid reasoning, especially the narrow ability of quantitative reasoning. In addition, limited attention, working memory capacity, and perceptual speed may have an impact on performance. Related interventions involve explicit instruction in seriation and number reasoning skills (High/Scope Educational Research Foundation, 2003; Kroesbergen & Van Luit, 2003).

Other Math Clusters

There are two additional math clusters: Mathematics and Broad Mathematics.

Mathematics

The Mathematics cluster consists of two tests, Test 2: Applied Problems and Test 5: Calculation. The cluster does not include a timed test, so it provides a level of math development without the influence of speed.

Broad Mathematics

The Broad Mathematics cluster is composed of three tests—Test 2: Applied Problems, Test 5: Calculation, and Test 10: Math Facts Fluency. It provides a broad, comprehensive view of the individual's math achievement level. The Broad Mathematics cluster measures computational skill, automaticity with math facts, and problem solving and reasoning. Because this cluster measures three different aspects of math ability, interpretation of the cluster is most accurate when performance is similar on all three of the tests.

Written Expression

The Written Expression cluster includes two tests, Test 6: Writing Samples and Test 11: Sentence Writing Fluency. It provides a measure of meaningful written expression and automaticity with writing. Expressing oneself in writing is a highly complex task that requires executive functions, such as attention, working memory, planning, and self-regulating behaviors. Ineffective or inconsistent use of executive function capacities can affect any aspect of the writing process and may be at the core of many written language problems (Dehn, 2008; Hale & Fiorello, 2004; McCloskey, Perkins, & Van Divner, 2009). Multiple cognitive abilities are related to written expression, including auditory processing, long-term storage and retrieval, cognitive processing speed, crystallized intelligence, short-term working memory, and fluid reasoning (Flanagan, Ortiz, & Alfonso, 2013).

Comparing the results of this cluster to those of the Reading Comprehension and Basic Writing Skills clusters, or the WJ IV OL Oral Expression cluster, can be helpful in pinpointing the underlying cause of limits in written expression as well as determining instructional objectives. Low performance may result from low oral language skills or limited basic writing skills. See Table 14.20 for suggested interventions for each writing test.

Test 6: Writing Samples

The Writing Samples test requires the individual to produce meaningful written sentences in response to a variety of tasks. In several items, the individual must make bridging inferences in working memory to integrate the initial and final sentences into a well-formed passage. These items require planning, or tailoring the target sentence to the lexical and semantic information that is conveyed in the other portions of the sample (Ferreira, 1996). Low performance may result from limits in oral language, vocabulary, organizational ability, working memory, or spelling skill. Although errors in spelling are not penalized on this test unless the response is illegible, an individual's spelling difficulties may limit the quality of his or her written output. For example, the person's writing may be restricted to words he or she can spell. The individual's attitude toward writing may also influence performance. Weaknesses in key abilities required for writing may result in a poor attitude toward and avoidance of writing tasks, whereas strengths in those abilities may create a positive attitude and a willingness to complete writing tasks. Important qualitative information can be gained through a careful analysis of the individual's responses. Writing Samples results can be compared to results on measures of oral language, to see whether writing ability is commensurate with levels of receptive and expressive language ability.

Interventions for limited proficiency on Writing Samples include teaching of text structures (Englert, 2009) and use of strategy instruction, such as the self-regulated strategy development approach developed by Harris, Graham, and colleagues over the past two decades.

Test 11: Sentence Writing Fluency

Sentence Writing Fluency requires the individual to produce, in writing, legible, simple sentences with acceptable English syntax. This test measures the narrow abilities of writing ability and writing speed. It requires quick formulation of constituent structures, or fluency of combining words into phrases (Gazzaniga et al., 1998).

Low performance on this test may result from poor attention, poor motor control/handwriting, limited spelling or reading skills, slow cognitive processing speed, or a response style that interferes with performance (e.g., slow and accurate, fast and inaccurate, slow and inaccurate). The results on this test can be compared to those on other timed measures, to see if the person generally works slowly or has a particular difficulty with writing speed. Possible interventions related to limited performance on Sentence Writing Fluency include explicit instruction in the mechanics of writing (Graham, Berninger, Abbott, Abbott, & Whitaker, 1997) and use of technology (MacArthur, 1996).

Other Written Language Clusters

There are three additional clusters available in written language: Basic Writing Skills, Written Language, and Broad Written Language.

Basic Writing Skills

The Basic Writing Skills cluster consists of two tests, Test 3: Spelling and Test 14: Editing. It provides a measure of basic writing skills in isolated and context-based formats. Task demands include writing letters, spelling single words, and identifying and correcting errors in spelling, usage, capitalization, and punctuation. Because Editing requires the examinee to read the items and then identify and correct the error, the impact of the examinee's reading ability on performance must be considered. The results of this cluster can be compared with those of the Written Expression cluster to determine if basic writing skills are affecting performance. Mastery of basic skills is a fundamental part of complex, meaningful written expression. Error analysis of the two tests in this cluster may also help identify any problems related to spelling.

Test 3: Spelling. The Spelling test requires the individual to produce, in writing, single letters or words in response to oral prompts. Several factors that may influence performance include fine motor skill, handwriting, phonological coding, and orthographic coding. This test measures prewriting skills and spelling. A careful analysis of errors can often result in specific instructional recommendations.

Test 14: Editing. The Editing test requires the ability to identify and correct errors in punctuation, capitalization, spelling, and usage in short written passages read by the examinee. Low performance may result from limited instruction, lack of knowledge of writing conventions, failure to self-monitor or self-correct errors, or poor reading skill.

Written Language

The Written Language cluster contains two tests, Test 3: Spelling and Test 6: Writing Samples. Because it includes a measure of basic writing skills and a measure of written expression, this cluster may be used to estimate a person's general writing ability. This cluster does not include a timed test, so it provides a measure of written language that does not include the effects of speed.

Broad Written Language

The Broad Written Language cluster includes three tests—Test 3: Spelling, Test 6: Writing Samples, and Test 11: Sentence Writing Fluency. It provides a broad, comprehensive view of the individual's written language achievement. Task demands include spelling single-word responses, expressing ideas to various tasks, and writing simple sentences quickly. The results from this cluster can be compared to the results on the Broad Reading cluster and on the Oral Language cluster from the WJ IV OL, to help determine the impact of oral language and/or reading skills on written language performance.

Cross-Domain Clusters

The cross-domain clusters are made up of tests from different achievement domains. The seven clusters are Academic Skills, Academic Fluency, Academic Applications, Academic Knowledge, Phoneme–Grapheme Knowledge, Brief Achievement, and Broad Achievement.

Academic Skills

The Academic Skills cluster is composed of the three basic skill tests—Test 1: Letter–Word Identification, Test 3: Spelling, and Test 5: Calculation. It provides a general, basic skills achievement composite and can help determine whether the individual's level of basic skills is similar or variable across the three academic areas. The examiner should consider whether basic skills facilitate or inhibit the individual's performance. Low performance may suggest particular curricular adaptations, such as use of books on CD during reading time, or a calculator during math activities. Examinees with low performance in one or more areas often require direct, explicit instruction to improve the accuracy of skills.

Academic Fluency

The Academic Fluency cluster is composed of the three timed tests—Test 9: Sentence Reading Fluency, Test 10: Math Facts Fluency, and Test 11: Sentence Writing Fluency. It provides a general academic fluency composite and can help determine if the individual's level of automaticity with basic skills is facilitating or inhibiting academic performance. The examiner should note whether the individual's speed of performance is similar or variable across the three academic areas. For example, a person may work slowly on reading and writing tasks, but at an average rate on measures of mathematics. In many cases, low performance on this cluster when contrasted with measures of Gc, such as the Academic Knowledge cluster, may suggest a need for extended time or shortened assignments. Additional information can be obtained by comparing the Academic Fluency cluster to the Perceptual Speed (P) and the Cognitive Processing Speed (Gs) clusters in the WJ IV COG. This may help determine if any limitation in academic fluency is related to a cognitive function or if performance in one or more academic areas is slowed because of low basic skills.

Academic Applications

The Academic Applications cluster is composed of the three application tests—Test 2: Applied Problems, Test 4: Passage Comprehension, and Test 6: Writing Samples. It provides a general measure of an individual's ability to reason and apply academic knowledge. As with the other cross-domain clusters, the examiner should note whether the individual's performance on the tests in this cluster is similar or variable, and should also consider the impact of basic skills, fluency, and oral language proficiency when interpreting this cluster. Low performance may suggest a need for adjusting the difficulty level of the instructional materials. Individuals with low Academic Applications scores often need adjustment in the difficulty levels of instructional tasks.

Academic Knowledge

The Academic Knowledge cluster contains three tests—Test 18: Science, Test 19: Social Studies, and Test 20: Humanities. In the WJ IV ACH, these three tests were expanded to be full-length tests, rather than subtests as they were in the WJ III ACH. Because of this change, individual test scores are available in addition to the cluster score. Each of these tests measures acquired curricular knowledge, an aspect of comprehension–knowledge. The tasks require the individual to respond orally to questions, although early items require only a pointing response.

Low performance on any of these tests may result from limits in vocabulary, reading, or exposure to curricular areas, or from lack of experiences related to science, social studies, or humanities. This cluster can provide valuable insights into the individual's interests, as well as the level of crystallized intelligence. Because no reading is required, the results can help determine whether the individual's acquired knowledge base is affecting performance in the other academic areas. If the WJ IV COG has been administered, results from this cluster can be compared to those from the Comprehension–Knowledge (Gc) cluster. If the WJ IV OL has been administered, results can be compared to those from the Oral Language and Listening Comprehension clusters. In addition, the Academic Knowledge cluster score can be used as the ability score in an ability–achievement comparison procedure available within the WJ IV ACH. This comparison procedure is designed to help determine whether an individual's performance in reading, writing, and/or mathematics is consistent with his or her level of acquired knowledge.

Test 18: Science. The Science test measures an individual's knowledge of the sciences including anatomy, biology, chemistry, geology, medicine, and physics.

Test 19: Social Studies. The Social Studies test contains items testing an individual's knowledge of history, economics, geography, government, and psychology.

Test 20: Humanities. The Humanities test measures an individual's knowledge of art, music, and literature.

Phoneme/Grapheme Knowledge

The Phoneme/Grapheme Knowledge cluster is a combination of two tests, Test 7: Word Attack and Test 16: Spelling of Sounds. It may be used to evaluate the individual's proficiency in using phonics for reading and spelling. The tasks require the individual to decode (read) and encode (spell) pseudowords or nonsense words. Although they have no meaning, these words all use possible English spelling patterns (orthography). Low performance may result from poor phonological skills, limited orthographic skills, or both. A low score may also be attributable to poor or limited instruction. To help understand the reasons for an individual's low performance, the examiner should compare this cluster to the Auditory Processing (Ga) cluster in the WJ IV COG or the Phonetic Coding cluster in the WJ IV OL. The Phoneme/Grapheme cluster can be especially useful in documenting specific reading disabilities (dyslexia).

Test 16: Spelling of Sounds. The Spelling of Sounds test requires the individual to spell nonsense words that conform to conventional phonics and spelling rules. Both phonological coding and orthographic coding are measured by this test. Low performance may result from poor attention, poor phonological processing, poor orthographic awareness, or low phoneme–grapheme knowledge. An examiner can compare results from this test to results from the Word Attack test or various WJ IV OL tests (Segmentation, Sound Blending, and Sound Awareness), to help determine whether difficulties result from phonological problems or limited knowledge of phoneme–grapheme relationships. An analysis of errors can be particularly valuable on this test.

Brief Achievement

The Brief Achievement cluster is a combination of three tests—Test 1: Letter–Word Identification, Test 2: Applied Problems, and Test 3: Spelling. This cluster provides a quick screening of the person's levels of performance in reading, writing, and math that does not include the effects of performance under timed conditions

Broad Achievement

The Broad Achievement cluster is composed of nine tests in the Standard Battery. These nine tests are used to create the Broad Reading, Broad Mathematics, and Broad Written Language clusters. The purpose of the Broad Achievement cluster is to provide a general index of an examinee's academic proficiency and fluency with academic tasks. The cluster can be used to identify students with very limited or advanced performance levels across curricular areas. It is also helpful when a global view of an individual's overall performance across the various achievement domains is needed. The tests required for obtaining the Broad Achievement cluster also yield the four additional cross-domain clusters (Academic Skills, Academic Fluency, Academic Applications, and Brief Achievement) described previously.

Score Comparison Procedures

The WJ IV ACH provides two variation procedures and one comparison procedure. The primary purpose of the variation procedures is determination of relative strengths and weaknesses, whereas the primary function of the ability–achievement comparison procedure is prediction of achievement.

Intra-Achievement Variation

The intra-achievement variation allows an examiner to analyze an individual's academic test and cluster scores and to explore relative strengths and weaknesses. For example, a person may have a relative strength in math, but a relative weakness in reading. These variations within achievement can help determine the person's present educational needs. The examiner can calculate intra-achievement variations for three curricular areas (reading, mathematics, and writing) if Tests 1–6 have been administered. Additional tests and clusters can be added to this variation procedure. Individuals who have relative achievement strengths or weaknesses, such as significantly higher math skills relative to the average of all other achievement areas, exhibit an intra-achievement variation.

Academic Skills–Fluency–Applications Variation

Nine WJ IV ACH tests are required for this variation procedure: three in reading (Letter–Word Identification, Passage Comprehension, Sentence Reading Fluency), three in written language (Spelling, Writing Samples, Sentence Writing Fluency), and three in mathematics (Applied Problems, Calculation, Math Facts Fluency). The person's performance in skills, fluency, and applications is compared across the academic areas of reading, written language, and mathematics.

Three more clusters can be added to this variation procedure: Reading Rate from the WJ IV ACH, and Cognitive Processing Speed or Perceptual Speed from the WJ IV COG.

Academic Knowledge–Achievement Comparison Procedure

Because Academic Knowledge is a strong measure of acquired knowledge and does not require reading, writing, or math, it serves as a good predictor of academic ability. This procedure allows the examiner to determine whether current achievement levels are commensurate with the individual's store of acquired curricular knowledge. As described above, the Academic Knowledge cluster consists of Test 18: Science, Test 19: Social Studies, and Test 20: Humanities. The standard score for this cluster is used to calculate predicted scores for expected achievement. The individual's predicted achievement is then compared to his or her actual achievement. Examinees with predicted scores significantly higher than their actual achievement scores exhibit an ability–achievement discrepancy in one or more areas of achievement. Additionally, two clusters from the WJ IV OL (Phonetic Coding and Speed of Lexical Access) can be included in this comparison procedure.

SUMMARY

The WJ IV consists of three co-normed batteries, the WJ IV COG, the WJ IV OL, and WJ IV ACH, providing a comprehensive system for identifying an individual's cognitive, linguistic, and academic levels and determining relative strengths and weaknesses. There are 18 tests in the WJ IV COG, 12 tests in the WJ IV OL, and 20 tests in the WJ IV ACH. Interpretation of the WJ IV is based on contemporary CHC theory and an accumulation of knowledge about the structure of, and interplay among, cognitive abilities and neurocognitive functions—particularly in the domains of working memory and attentional control, memory consolidation and retrieval, and auditory intelligence. To enhance ecological validity, cognitive complexity is increased in several new tests and clusters.

The narrow abilities identified by CHC theory and external neurocognitive research combine to form a theoretical and conceptual basis for suggested links between the WJ IV tests and evidence-based educational interventions. The WIIIP operationalizes the link between WJ IV test results and instructional interventions, providing a seamless method for making evaluations instructionally relevant. Together, the WJ IV and the WIIIP represent a comprehensive evaluation system that is useful for diagnosis, eligibility determinations, and instructional planning.

NOTE

1. A "wrong turn at Albuquerque" is a catchphrase popularized in the Bugs Bunny™ cartoons; it humorously refers to an incorrectly perceived juncture (sometimes caused by trying to follow an overly complicated set of directions or a poor map) that lands a traveler in an unintended place. Bugs Bunny is a registered trademark of Warner Brothers Entertainment, Inc., Burbank, California.

CHAPTER 15

The Cognitive Assessment System—Second Edition

From Theory to Practice

Jack A. Naglieri
Tulio M. Otero

In this chapter, we describe a suite of instruments to measure *planning, attention, simultaneous, and successive* (PASS) neurocognitive processes. This suite includes the Cognitive Assessment System—Second Edition (CAS2; Naglieri, Das, & Goldstein, 2014a), the CAS2: Brief (Naglieri, Das, & Goldstein, 2014b), the CAS2: Rating Scale (Naglieri, Das, & Goldstein, 2014c) and the CAS2: Español (Naglieri, Moreno, & Otero, 2017). These measures extend the approach taken with the original CAS (Naglieri & Das, 1997a, 1997b) to accommodate a wider range of professionals of different qualification levels, as well as a wider array of contexts. These measures provide multiple ways to evaluate the four PASS neurocognitive processes, which we have most recently described in Chapter 6 of this book, and more thoroughly elsewhere (Naglieri & Otero, 2017). The strength of this theory as measured by these instruments lies in the fact that this approach dramatically changes the very concept of intelligence from that developed by the U.S. military in the early 1900s, and by others such as Alfred Binet, to a neurocognitive conceptualization. In practical terms, this means that the CAS2 battery, like the CAS before it, provides a way to do the following:

- Detect the neurocognitive variability that improves our understanding of individuals with, for example, specific learning disabilities (SLD), autism, and attention-deficit/hyperactivity disorder (ADHD) (Naglieri, 2012; Naglieri & Goldstein, 2011).
- Fairly assess neurocognitive abilities across races (Naglieri, Rojahn, Matto, & Aquilino, 2005) and ethnicities (Naglieri, Rojahn, & Matto, 2007).
- Equitably assess PASS across languages (Naglieri, Otero, DeLauder, & Matto, 2007; Naglieri, Taddei, & Williams, 2013; Naglieri et al., 2017; Otero, Gonzales, & Naglieri, 2013).
- Use PASS scores reflecting patterns of strengths and weaknesses for instructional planning and intervention (Naglieri & Otero, 2017; Naglieri & Pickering, 2010).

The strength of the CAS2 suite of measures is that it provides a way to evaluate neurocognitive abilities (i.e., basic psychological processes), using a specific theory (PASS theory) based on Luria's (1966a, 1966b, 1973, 1980, 1982) conceptualization of brain function (see Chapter 6, this volume, for further information). The subtests were explicitly designed to measure the four PASS constructs. In other words, the theory of human neurocognitive function came first; then ways to measure each construct were developed, tested, and validated for specific purposes. Importantly, this approach to test development provides clarity about interpretation of scores and what they mean. The theory defines the constructs that are represented by the test's scores. This approach is a unique way to develop a measure of ability because of its reliance on a specific neurocognitive theory that (1) measures a wider range of abilities than traditional IQ; (2) does not rely on verbal and quantitative test questions, which require knowledge rather than thinking; (3) provides a fair way to assess diverse populations; and (4) has instructional implications. These key differences have a considerable impact on the validity of the CAS2, as well as the utility of the information it yields.

DESCRIPTION OF THE MEASURES

The CAS and CAS2 represent ongoing efforts to operationalize the PASS theory. These efforts began on February 11, 1984, when J. P. Das and Jack A. Naglieri first decided to develop a different kind of intellectual ability test that would be based on Luria's conceptualization of the brain, easy to administer and score, straightforward to interpret, capable of detecting learning strengths and weaknesses, accessible to a wide variety of students, and helpful for teachers to maximize learning. At the initial meeting, it was determined that each subtest would have a clear correspondence to the theoretical framework now known as PASS. Development of the subtests was accomplished by following a carefully prescribed sequence of item generation, experimental research, test revision, and reexamination until the instructions, items, and other dimensions were refined over a series of pilot tests, research studies, national tryouts, and national standardizations. This process resulted in subtests that provided an efficient way to measure each of the processes (Das, Naglieri, & Kirby, 1994; Naglieri & Das, 1997b). Descriptions of the tasks that became the CAS and now the CAS2 subtests, and efforts to evaluate their practical utility and validity, are available in many published papers and several books (see Das et al., 1994; Naglieri & Das, 1997a; Naglieri & Otero, 2012, 2017). The most recent advancement in the assessment of PASS neurocognitive processes and related behaviors is represented by the various versions of CAS2 (see Figure 15.1), which can be used in different contexts and by different professionals.

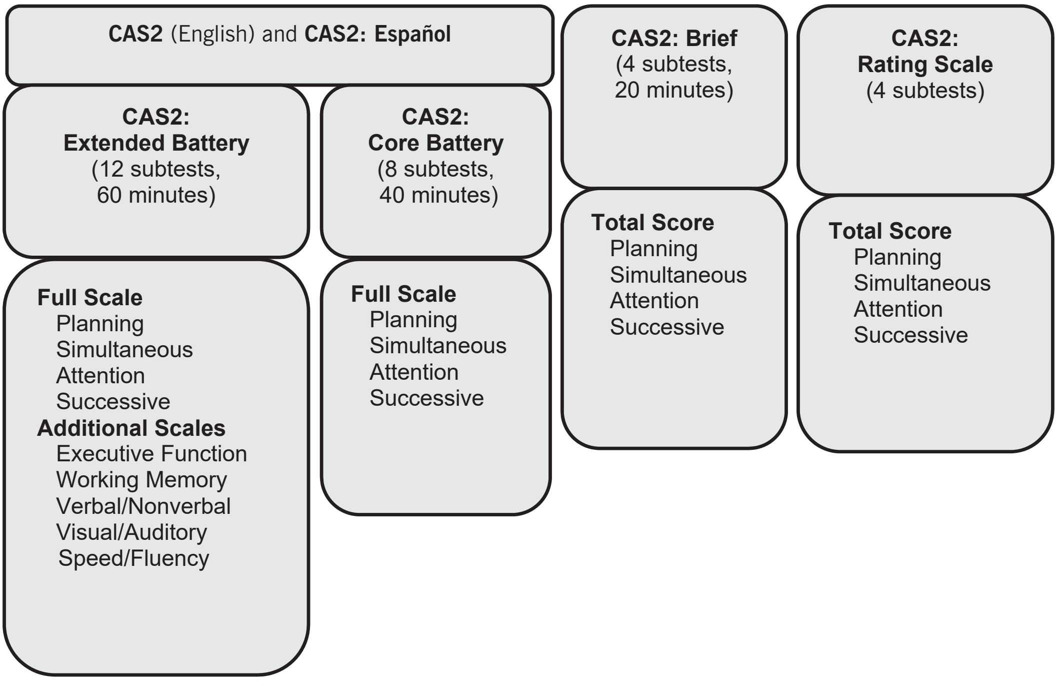

FIGURE 15.1. The CAS2 comprehensive system for assessment of PASS neurocognitive abilities and behaviors.

The CAS2 Suite as a Comprehensive System of Assessment

The CAS2, the CAS2: Brief, the CAS2: Español, and the CAS2: Rating Scale all provide scores for the four PASS neurocognitive processes. The PASS scale scores are combined into a Full Scale score (the CAS2 in English and the CAS2: Español) or Total Score (the CAS2: Brief and the CAS2: Rating Scale), both expressed as standard scores with a mean of 100 and standard deviation of 15. The PASS scores are computed on the basis of the subtest scaled scores included in each respective scale or the rating scale items for each neurocognitive ability. These scales represent a child's cognitive processing in specific areas and are used to examine cognitive strengths and/or weaknesses. It is important to note that the subtests vary in content (some are verbal, some involve memory, etc.), but each is an effective measure of a specific PASS process. In addition, the CAS2, CAS2: Brief, and CAS2: Rating Scale subtests are sometimes similar across the tests, but not identical, and the CAS2: Rating Scale's items focus on behaviors a teacher can observe. The subtests or items for these CAS2 measures of PASS are shown in Table 15.1 and more fully described in the sections that follow.

The CAS2

The CAS2 was designed to meet the need for a comprehensive evaluation of basic neurocognitive processes for children and adolescents ages 5 years, 0 months through 18 years, 11 months. Both the 8-subtest Core Battery (40-minute administration time) and the 12-subtest Extended Battery (60-minute administration time) provide a thorough evaluation of the four PASS constructs, using measures that vary by content, modality, and other demands. This individually administered test was normed on a sample of 1,342 cases representative of the U.S. population on several essential demographic variables (see the CAS2 interpretive and technical manual for more details). The two versions yield standard scores for the Full Scale and the Planning, Attention, Simultaneous, and Successive (PASS) cognitive processing scales. Subtest scores are reported as scaled scores, with a mean of 10 and a standard deviation of 3. The 12-subtest Extended Battery also includes scales to measure Working Memory, Executive Function (with and without Working Memory), Verbal Content, Nonverbal Content, Visual/Auditory, and Speed/Fluency. The CAS2 scales and their subtests are described more fully below.

Planning Scale

What the Scale Measures

The purpose of the Planning scale is to measure the student's ability to devise and apply strategies to solve novel problems (Naglieri & Otero, 2017). Planning is essential to all tasks where the examinee intentionally and independently decides to use some method to solve a problem. Better scores are obtained on these tasks if there is awareness of the need for a solution, monitoring for effectiveness of the chosen solution, consideration of alternative methods that might be appropriate, and evaluation of the relative value between continuing with the method or using a different one (Shadmehr, Smith, & Krakauer, 2010). Planning processing is also important when there is self-reflection on the results of a completed task, recognition of what worked and what did not work, and consideration of other possible solutions in the future. These unique human functions recruit activity within frontal lobes of the brain (Goldberg, 2009), as well as several neural networks (see Chapter 6, this volume).

How Planning Is Measured

To measure Planning, a test score *must* reflect how well a child has solved a novel problem for which there is no previously known strategy. To achieve this essential goal, the instructions for administration focus on *what* the student is to do, but the examiner provides no direction about *how* to complete the task. All of the Planning subtests on the CAS2, CAS2: Brief, and CAS2: Español (Naglieri et al., 2014a, 2014b, 2017) are solved via strategies selected by the examinee. The instructions explain the demands of the task, and the student is told to complete the task *in any way* that seems best. For this reason, the test scores reflect efficiency, measured by how long it takes to complete the task with the largest number of correct choices.

Planning Subtests (in Order of Administration)

- *Planned Codes*. The items on the Planned Codes subtest require the examinee to write specific codes (e.g., A, B, C, D to OX, XX, OO, XO) that correspond to letters (e.g., A, B, C, D) in empty spaces arranged in four rows and eight col-

TABLE 15.1. Subtests or Items Included in the Various CAS2 Measures

CAS2 Extended Battery (12 subtests)	CAS2 Core Battery (8 subtests)	CAS2: Español (12 subtests)	CAS2: Brief (4 subtests)	CAS2: Rating Scale (40 items)
		Planning		
Planned Codes	Planned Codes	Códigos planificados	Planned Codes	Planning items
Planned Connections	Planned Connections	Conexiones planificadas		
Planned Number Matching		Planificación de números pareados		
		Simultaneous

Number Detection	Number Detection	Detección de numeros		
Receptive Attention		Atención receptiva		
		Successive		
Word Series	Word Series	Serie de palabras	Successive Digits	Successive items
Sentence Repetition/ Sentence Questions	Sentence Repetition/ Sentence Questions	Repetición de oraciones Preguntas a oraciónes		
Visual Digit Span		Retención visual de dígitos		

umns of letters without the codes. Students have 60 seconds per item to complete as many empty code boxes as possible. Each item is organized in a manner that requires a new strategy on each page.

- *Planned Connections.* The Planned Connections subtest requires the examinee to connect a series of numbers, alternating numbers, and letters of increasing length and difficulty in a specified order as quickly as possible within a time limit.
- *Planned Number Matching.* Each Planned Number Matching item presents the student with a page of eight rows with six numbers on each row. The student is required to find and underline the two numbers in each row that are the same within a time limit. This subtest is not included in the eight-subtest Core Battery.

Simultaneous Scale

What the Scale Measures

The Simultaneous scale measures how well a child or adolescent can combine separate stimuli into a conceptual whole (Naglieri & Otero, 2017). The spatial aspect of simultaneous ability involves perceiving stimuli as a group, seeing patterns in diagrams, recognizing a whole shape, and the formation of visual images. Simultaneous processing is also measured with items that require the comprehension of word relationships, prepositions, and spatial orientation. This ability is associated with the parietal, occipital, and temporal brain regions.

How Simultaneous Processing Is Measured

The distinguishing characteristic of the CAS2, CAS2: Brief, and CAS2: Español (Naglieri et al., 2014a, 2014b, 2017) subtests designed to measure simultaneous processing is that the correct answer to each item can only be obtained if the information that is provided is organized into a coherent whole. There is considerable variability in the content of the subtests, which illustrates the varied contexts in which simultaneous processing is used. For example, one of the subtests contains nonverbal visual–spatial content, while another is highly verbal; still another requires memory.

Simultaneous Subtests

- *Matrices.* The Matrices subtest utilizes shapes and geometric placements that are interrelated through spatial or logical organization. Students analyze the relationship among the parts of each item and solve for the missing part to choose the best of six options. This subtest is similar to other tests involving progressive matrices (e.g., the Naglieri Nonverbal Ability Test—Third Edition [NNAT3]; Naglieri, 2017).
- *Verbal–Spatial Relations.* Verbal–Spatial Relations is a six-item multiple-choice subtest in which each item consists of six drawings and a printed question at the bottom of each page. The examiner reads the question aloud, and the child is required to select the option that matches the verbal description. For example, the student may be asked, "Which picture shows a circle above a triangle to the left of a square under a triangle?"
- *Figure Memory.* This subtest requires a student to identify a familiar geometric shape (e.g., a triangle, a three-dimensional box) within a more complex design. The items are presented in a specific sequence. First, the examiner shows the student a geometric figure for 5 seconds. Then the stimulus is removed, and the student is asked to identify the original figure embedded in a larger, more complex geometric pattern. This subtest is not included in the eight-subtest Core Battery.

Attention Scale

What the Scale Measures

The purpose of the Attention scale is to determine how well a child or adolescent can focus on a specific stimulus and inhibit responding to distractions. The goal is to measure complex forms of attention, which involve "selective recognition of a particular stimulus and inhibition of responses to irrelevant stimuli" (Luria, 1973, p. 271). The ability to attend is demonstrated when a student can remain focused, selective, and effortful over time. Focused attention involves directed concentration toward a particular activity; selective attention provides the inhibition of responses to distracting stimuli; and sustained attention refers to the variation of performance over time, which can be influenced by the different amount of effort required to solve the test. Several brain structures, such as the reticular formation and the attention networks (see Chapter 6, this volume), allow an individual to focus selective attention toward a stimulus over time without the loss of attention to other competing stimuli.

How Attention Is Measured

Attention is measured in the CAS2, CAS2: Brief, and CAS2: Español (Naglieri et al., 2014a, 2014b, 2017) by subtests that demand focused, selective, sustained, and effortful activity. The subtest demands require the examinee to focus and resist distractions at different points. For example, in the Expressive Attention subtest, the most difficulty is experienced at the point of speaking. In contrast, the attentional demands of the Receptive Attention subtest are greatest when the stimuli are compared and a decision (match or no match) is made. The variety of task demands and content illustrates how attention can be measured in different ways.

Attention Subtests

- *Expressive Attention.* This subtest has two different versions. Children ages 5–7 years are given three pages consisting of seven rows that each contain six pictures of common animals, with each picture depicted as either big (1 inch × 1 inch) or small (½ inch × ½ inch). On each of the three pages, the student is required to identify whether the animal depicted is big or small in real life, ignoring the relative size of the picture on the page. On the first page, the pictures are all the same size. On the second page, big animals are depicted with big pictures, and small animals are depicted with small pictures. On the third page, the realistic size of the animal often differs from its printed size. For students ages 8–18 years the task is as follows: On page 1, students are asked to read the words BLUE, YELLOW, GREEN, and RED printed in black ink. On page 2, students are asked to name the colors of four colored rectangles (printed in blue, yellow, green, and red). On page 3, the four color words from page 1 are printed in the colors from page 2, but the word names and the colors do not match. In this item, students are required to name the color of the ink in which the word is printed, rather than to read the word.

- *Number Detection*. Each item presents the student with a page of 18 rows and 12 numbers per row. The task is to identify by underlining specific numbers on a page (ages 5–7 years) or specific numbers in a particular font (ages 8–18 years). The ratio of targets to distractors is carefully controlled by row and maintained across pages.
- *Receptive Attention*. This subtest consists of four sets of items, each containing 60 picture pairs (ages 5–7 years) or 180 letter pairs (8–18 years). The task is to underline pairs of objects or letters that either are identical in appearance or are the same from a lexical perspective (i.e., they have the same name). This subtest is not included in the eight-subtest Core Battery.

Successive Scale

What the Scale Measures

Successive processing is a neurocognitive ability that is used to work with information arranged in a specific serial order. This ability is required for recognition, recall, and reasoning when success on any task demands appreciation of a sequence. For example, successive processing is involved in the decoding of unfamiliar words, production of syntactic aspects of language, sequencing of non-automatized motor movements, and speech articulation. For this reason, successive processing is involved in activities such as phonological skills and the syntax of language (Das et al., 1994). This ability is associated with the temporo-parietal junctions of both the right and left hemispheres.

How Successive Processing Is Measured

Successive processing is measured on the CAS2, CAS2: Brief, and CAS2: Español (Naglieri et al., 2014a, 2014b, 2017) with tasks that vary in their content and complexity. Recall of words in order is a simple task, but repeating sentences made up only of color words or answering questions about the meaning of these statements demands appreciation of the syntactic relationships. The Successive scale's content also varies by modality; both auditory and visual stimuli are used. The use of various modalities illustrates that the content of the test is secondary to the basic cognitive processing demand.

Successive Subtests

- *Word Series*. This subtest utilizes nine single-syllable, high-frequency words: *book, car, cow, dog, girl, key, man, shoe,* and *wall*. The examiner reads aloud a series of two to nine of these words, at the rate of one word per second. The student is required to repeat the words in the same order as stated by the examiner.
- *Sentence Repetition or Sentence Questions*. The Sentence Repetition subtest, which is only administered to examinees ages 5–7 years, requires a child to repeat syntactically correct sentences containing little meaning, such as "The blue is yellowing." The Sentence Questions subtest is administered to examinees ages 8–18 years. For the items on this version, the child or adolescent answers a question by using words that are syntactically correct but contain little meaning. For example, the student is read the sentence "The blue is yellowing," and is then asked the following question: "Who is yellowing?"
- *Visual Digit Span*. The student is asked to recall a series of numbers in the order in which they were shown in the stimulus book. Items that are two to five digits in length are exposed for the same number of seconds as there are digits. Items with six digits or more are all exposed for a maximum of 5 seconds. This subtest is not included in the eight-subtest Core Battery.

CAS2: Español

The CAS2: Español is made up of the same 8- or 12-subtest versions as the CAS2 in English for students ages 5 years, 0 months through 18 years, 11 months. The test yields PASS and Full Scale scores, as well as additional scale scores to measure Working Memory, Executive Function, Verbal Content, and Nonverbal Content. We describe the translation and adaptation of the CAS2 into Spanish, as well as the rationale for this version, below.

Spanish Translation and Adaptation

The translation and cultural adaptation process was conducted by a team of psychologists from diverse geographical regions where Spanish is spoken and was organized by Mary Moreno, with Tulio M. Otero as consultant. The goal was to obtain equivalence between the original CAS2 and the Spanish version, based on a comprehensive cultural equivalence methodology for the translation and cultural adaptation proposed by Chávez and Canino (2005). This approach integrates the *emic–etic* perspective in an overall research methodology that is both culturally valid and generalizable. The *emic* perspective involves the evaluation of the phenomenon under study from within the culture and its context, while the *etic* perspective is basically comparative.

The back-translation method was used for the translation and adaptation of the CAS2: Español. In this method, a test is translated from English to Spanish, and then it is translated back from Spanish to English. This method was also used to translate the administration and scoring manual, the stimulus book, and the record form. The 12 CAS2 subtests were divided into two equal groups, and each group was assigned to a pair of translators. Each translator in each pair independently completed work on six subtests, and when they were finished, the two translators compared their results. They discussed the disagreements and, when necessary, consulted a translator on the other team. When they reached an agreement on the translation of their six subtests, one translator from each team also determined the consistency of the vocabulary used in the whole test. Once completed, the product was presented to two psychologists with broad experience in instrument translation, and they in turn checked for coherence between the English and Spanish versions.

The Spanish version of the CAS2 is more than a literal English–Spanish translation because it represents an adaptation of the original instrument. For example, the Word Series subtest in English is composed of one-syllable words that, when literally translated into Spanish, often contained more than one syllable. To ensure that the Spanish version of the subtest was not more difficult, one-syllable Spanish words familiar to 5-year-old participants were selected for this subtest. Similarly, modifications were made to the Sentence Repetition and Sentence Questions subtests to maintain the original intention of each subtest, so that the syntactic structure of the items was maintained. Finally, the vocabulary used in the Spanish version of the CAS2 took into account the diversity of concepts used by different Spanish-speaking cultural populations. For more information on the translation and adaptation of the CAS2 to the CAS2: Español, please see the CAS2: Español manual (Naglieri et al., 2017).

Rationale for the Spanish Edition

The CAS2: Español was developed to meet the need for assessment of children and adolescents with limited or no knowledge of English, and of English-language learners with limited cognitive academic language proficiency in both English and Spanish. Our goal was to provide a tool that can be effectively used with students who are learning English or who have limited educational opportunity. This goal is consistent with the position of Ceci (2000), Fagan (2000), Naglieri (2015), and Suzuki and Valencia (1997), all of whom believe that neurocognitive tests relying less on knowledge (vocabulary, information, etc.) are more appropriate for assessment of culturally and linguistically diverse populations.

There is evidence that the PASS neurocognitive processes can be assessed across language and cultures. Naglieri, Rojahn, and Matto (2007) examined the utility of the PASS theory with Hispanic children by comparing performance on the CAS of Hispanic and white non-Hispanic children from the standardization sample (N = 2,200). The study showed that the two groups differed by 4.8 standard score points when demographic differences were statistically controlled for. They also found that the correlations between achievement and the CAS scores did not differ significantly for the Hispanic and white non-Hispanic samples (Naglieri, Rojahn, & Matto, 2007). Similar results were reported for the CAS2 Full Scale scores in the test manual (Naglieri et al., 2014a). Without controls for demographic differences, Hispanics and non-Hispanics differed on the CAS2 Full Scale scores by 4.5 points; with such controls, the difference was 1.8 points. Very similar results are reported in the CAS2: Brief manual (Naglieri et al., 2014b). These findings suggest that measuring neurocognitive abilities rather than traditional IQ results in smaller differences between Hispanic and white non-Hispanic groups.

Other research involving Hispanics provided additional insights into the value of PASS theory as measured by the CAS. Naglieri, Otero, and colleagues (2007) compared PASS standard scores obtained on the CAS when administered in English and Spanish to bilingual children referred for reading problems. The children earned similar Full Scale scores on the English and Spanish versions of the CAS, and these scores were highly correlated (r = .96). As a group, this sample had a very low score on the Successive scale when given in English or Spanish. This finding was consistent with other research suggesting that children with reading decoding problems perform poorly in successive processing. Importantly, more than 90% of children who had a weakness on the English version of the CAS also had the same weakness on the Spanish version of the CAS. This study was followed by another (Otero et al., 2013) with a group of students referred for reading problems. Otero and colleagues (2013) found CAS Full Scale scores that differed by less than 1 point and, again, a high correlation between the scores (r = .94).

These findings are further supported by researchers who have used the PASS scales in other countries. Natur (2009) compared Arabic-speaking Palestinian students using the Arabic version of the CAS to a matched sample of children from the United States using the CAS in English. He found a very small difference between the Palestinian students' Full Scale mean of 101.0 and the U.S. Full Scale mean of 102.7 when the U.S. norms were used. Similarly, Naglieri and colleagues (2013) found that Italian children's (N = 809) Full Scale standard score of 100.9 on the Italian version of the CAS (Naglieri & Das, 2006) was very similar to the Full Scale standard score of 100.5 for a matched sample of U.S. children (N = 1,174) from the original standardization sample. Both samples' CAS standard scores were based on the U.S. norms. Importantly, multigroup confirmatory factor analysis (CFA) results supported the configural invariance of the CAS factor structure between Italians and Americans for the 5- to 7-year-old and 8- to 18-year-old age groups.

These research findings led us to conclude that although it would be optimal if scores for the CAS2: Español were based on separate norms collected on Spanish-speaking children in various countries and in the United States, the test can be used if appropriate actions are taken by the clinician. That is, the clinician should explicitly state that the scores obtained on the CAS: Español were obtained by comparing the child's performance to that of English-speaking students in the United States. We do expect, however, that this version of the CAS2 is likely to provide a good option for assessment of PASS processes. Of course, we anticipate more research on the utility of this approach to measuring these four neurocognitive processes.

There is, however, another important reason to use the CAS2: Español. The barrier posed by language-based measures of ability was the focus of findings in *McFadden v. Board of Education for Illinois School District U-46* (2013). This case involved Hispanic parents' concerns that their students were significantly underrepresented in gifted education classes. Over 40% of the students in the Elgin School District (U-46) were Hispanic, but only 2% of the students in the district's mainstream elementary school gifted program were Hispanic. The district required all students, including those who were learning the English language, to obtain high scores on a measure of ability that demands considerable verbal knowledge and quantitative skills (e.g., the Cognitive Abilities Test, Form 6 [CogAT6]; Lohman & Hagen, 2001), even if they had a very high score on a nonverbal measure of ability (the NNAT-2; Naglieri, 2008). The Court ruled that the use of tests requiring knowledge of English contributed to the underrepresentation of Hispanic students in gifted education. Judge Gettleman ruled that gifted children for whom English is a second language would be likely to score lower on a verbally demanding test than on the nonverbal, culturally neutral NNAT-2, which the plaintiffs' expert testified identified gifted students without a bias toward those students with higher English verbal skills. The judge further decided that the civil rights of the Hispanic students were violated in large part by the use of test questions demanding knowledge (traditional subtests like Vocabulary, Similarities, Information, and Arithmetic) to measure ability. The implications are clear: Using test questions that require knowledge should be avoided for those with limited verbal and quantitative skills. Because the language demands (particularly expressive language demands) made by the CAS2 are far less than those made by traditional tests of ability, and because the test is less reliant on previously acquired knowledge, it can be used in a manner consistent with fair and equitable assessment practices.

The CAS2: Brief

The CAS2: Brief is intended to be used as a short measure (administration time is 20 minutes) of PASS processes for children and adolescents. This version is appropriate for use in a prereferral evaluation of an initial concern, in a reevaluation, or in the decision-making process regarding educational programming.

The CAS2: Brief is a four-subtest, individually administered measure of PASS neurocognitive processing for students ages 4 years, 0 months through 18 years, 11 months. It was normed on a sample of 1,417 students representative of the U.S. population on a number of important demographic variables (see the examiner's manual for more details). The CAS2: Brief yields standard scores with a mean of 100 and a standard deviation of 15 for the four PASS scores and the Total Score. The subtests used in the CAS2: Brief are similar to, but not the same as, those used in the CAS2. Each PASS scale includes just one subtest, as described below.

Planning

The Planned Codes subtest is used on the CAS2: Brief to measure planning. This subtest, like its counterpart in the CAS2, contains four items, each with its own set of codes and particular arrangements of rows and columns. A legend at the top of each page shows which numbers (1, 2, 3, 4) correspond to different codes (a combination of O's and X's). The items differ from those in the CAS2 in the correspondence of numbers rather than letters and in the position of the numbers on the page. The test was designed to provide an examinee with the opportunity to complete the task more efficiently by using any strategy he or she may devise.

Simultaneous

The CAS2: Brief's Simultaneous Matrices subtest is a 44-item multiple-choice subtest composed of items different from those used in the CAS2 Matrices subtest. Simultaneous processing is measured with items composed of geometric shapes and designs that are interrelated through spatial or logical organization. The CAS2: Brief items have a different color scheme (yellow, blue, teal, and black) from those in the CAS2 (yellow, blue, and black). Like the CAS2, the items are composed like those in the NNAT-2 (Naglieri, 2008).

Attention

A modified version of the Expressive Attention subtest on the CAS2 is used to measure Attention in the CAS2: Brief. For children ages 5–7 years, the task is to identify the pictures of animals as either large or small, regardless of their relative size on each page. On the first page, all the animals are the same size. On the second page, the animals are sized relative to actual size. The item on the third page is the most sensitive to attention because the animals are usually sized opposite to their actual size. The orientation of the pictures is different from that in the CAS2, but the same pictures are used. The second set of items is administered to children ages 8–18. There are also three items in this version. First, the child reads words such as *blue* and *yellow;* second, the child identifies colors of a group of rectangles; and third, the child identifies the ink color in which words are printed. It is the last page that is sensitive to attention because the child must focus on one variable (specifically, the color), while inhibiting the more automatic response of word reading. All the stimuli are arranged differently for the CAS2: Brief than for the CAS2; the same images are used, but the color green is excluded in this version.

Successive

In the CAS2: Brief measure of successive processing, recall of numbers in order is used instead of recall of words (as on the CAS2). The Successive Digits subtest requires that the examinee repeat a series of numbers in the same order presented by the examiner. The numbers, which include numbers one through nine, are presented orally. There is a condition requiring the examinee to repeat the numbers in reverse order because, as found by Schofield and Ashman (1986), reversing the order of digits was equally correlated with both successive and planning processing.

CAS2: Brief and Identification of Gifted and Talented Students

Identification of gifted and talented students, like special education classification, has its own controversies that center on definitions and criteria for eligibility. These controversies are mostly attributable to the fact that there is no universally accepted definition of *gifted and talented,* which explains why nearly every U.S. state has its own definition. The National Association for Gifted Children (NAGC) defines *gifted* individuals as those students who demonstrate outstanding levels of aptitude, which can be explained as an exceptional ability to reason and learn. The NAGC defines *talented* individuals as those students with documented performance or achievement levels (e.g., mathematics, music, language) and/or sensory–motor skill levels (e.g., painting, dance, sports) in the top 10% of their age group. These definitions are similar to those proposed by Gagné (1985). According to Gagné, *giftedness* refers to natural abilities called *aptitudes* or *gifts* in at least one aspect of ability that fall in the top 10% of an individual's peer group, whereas *talent* indicates the superior mastery of knowledge and skills, as indicated by performance in the upper 10% of age peers. What is apparent in all these definitions is the view that gifted and talented students are those with a natural ability to perform above the 89th percentile, or those with the *potential* to perform at such a high level.

Given that identification of giftedness requires comparing a child's performance to that of a same-age norm group, the critical question becomes this: performance on which IQ test? A traditional IQ test actually assesses a mixture of ability (in those sections that *do not* require knowledge) and talents (in those sections that *do* require knowledge). Naglieri, Brulles, and Lansdowne (2008) and Naglieri and Ford (2015) proposed that gifted students with high ability can be identified with nonverbal tests that do not include verbal and quantitative measures, whereas talented students can be identified by measures of academic achievement. They also stressed that nonverbal tests help identify *all* gifted students, especially members of diverse populations that have been traditionally underrepresented (Ford, 2010, 2013). The importance of measuring ability without using verbal and quantitative tests found on IQ tests like the Wechsler scales or the CogAT6 (Lohman & Hagen, 2001) was recently tested in the *McFadden* legal case, as discussed above. We have taken the same position in our work on PASS theory. That is, measurement of intelligence is achieved more purely when the test questions have minimal knowledge demands.

Using PASS theory as measured by the CAS2: Brief to identify gifted students provides a way to measure cognitive ability rather than knowledge or achievement. For this reason, the CAS2: Brief meets the need for a short measure of ability that requires minimal verbal and math skills, but instead emphasizes neurocognitive abilities. Importantly, measuring cognitive constructs as defined in PASS theory would also result in the measurement of *more* abilities than would be assessed with a typical nonverbal test. For this reason, we suggest that the CAS2: Brief is a good tool for identification of gifted students, especially because it is appropriate for diverse populations of students. Of course, if a more comprehensive approach is warranted or desired, the CAS2 Core or Expanded Battery may be used.

Fair Assessment Using the CAS2, CAS2: Espanol, and CAS2: Brief

According to the Individuals with Disabilities Education Improvement Act of 2004 (IDEA, 2004), evaluators must use measures of intelligence that are considered nondiscriminatory (see Chapter 6, this volume), and fair assessment should also be viewed as a social justice issue. Padilla and Borsato (2008) explained that although tests can be technically sound, their content may privilege one group over another because knowledge is culturally embedded and the content of assessment tools may reflect the cultural values of the test developers. For this reason, Stobart (2005) argued that fairness or equity in assessment is fundamentally a sociocultural issue, and therefore equitable assessment is also a social justice issue (Gipps, 1999). Although test developers are now using more diverse norming samples that reflect the true diversity of the United States, obtaining more diverse samples is insufficient if the items on a measure are not appropriate for those diverse groups.

It is important that educators and parents understand the relationship of fair assessment to social justice in an often unjust educational system (as reflected in the *McFadden* case, described earlier). Equitable assessment is a form of social justice because a fair, appropriate assessment can prevent social problems and/or ensure access to resources (Mpofu & Ortiz, 2009). According to the *Standards for Educational and Psychological Testing* (American Educational Research Education [AERA], American Psychological Association, & National Council on Measurement in Education, 1999, as quoted in Mpofu & Ortiz, 2009, p. 57), "equitable assessment provides examinees an equal opportunity to display the requisite assessment processes, skills, and expectancies, as well as a fair chance to achieve the same level as others with equal ability on a given construct under measurement." The *Standards* also remind us that if a person has had limited opportunities to learn the content in, for example, a test of intelligence, that test may be considered unfair if it penalizes students for not learning content that is included in a test, even if the norming data do not demonstrate psychometric bias. Test developers are encouraged to use universal test design to ensure that "tests are as usable as possible for all test takers regardless of gender, age, language background, socioeconomic status or disability" (quoted in Mpofu & Ortiz, 2009, p. 57).

Poor test performance can have significant consequences because it is often used to make high-stakes decisions such as placement in special education, assignment to educational tracks, admission to college, and employment. The typical focus on finding a deficit is balanced when the emphasis is on understanding an examinee's current resources and assets in order to improve his or her well-being. In this way, assessment can embody a social justice perspective. We believe that the various CAS2 measures provide ways to assess children in a manner consistent with social justice tenets. These measures allow children's neurocognitive (PASS) assets as well as challenges to be determined, for the purpose of developing intervention plans that ultimately increase their access to the curriculum and to their own resources.

CAS2: Rating Scale

The CAS2: Rating Scale measures behaviors associated with the four PASS abilities for students ages 4 years, 0 months through 18 years, 11 months. The scale contains 40 items (10 for each PASS scale), which are rated by a teacher. It was normed on a sample of 1,383 students representative of the U.S. population on a number of key variables (see the examiner's manual for more details). Like the CAS2 and the CAS2: Brief, the CAS2: Rating Scale yields standard scores for the four PASS scales and a Total Score (mean of 100 and standard deviation of 15). The administration directions for the CAS2: Rating Scale are included in the record form. The CAS2: Rating Scale can be used whenever a teacher's evaluation of classroom behaviors related to PASS processes is desired. The information can be used for instructional planning, for screening, or (when paired with the CAS2: Brief or CAS2) as part of a larger evaluation.

Planning

The Planning scale is composed of items that ask about how well the student makes decisions about how to do things. These include questions that ask whether the student thinks before acting, controls impulses, devises new solutions when necessary, and determines the extent to which actions matched intentions. An example of a Planning scale item is "During the past month, how often did the child or adolescent . . . have a good idea about how to complete a task?"

Simultaneous

The Simultaneous scale includes items that describe how well the student understands interrelationships among ideas and objects. The questions determine whether a child can understand relationships among physical objects as well as verbal concepts. An example of a Simultaneous scale item is "During the past month, how often did the child or adolescent figure out . . . how parts of a design go together?"

Attention

The Attention scale items evaluate how well a student can focus attention and resist distractions, concentrate in noisy settings, and sustain attention over time. An example of an Attention scale item is "During the past month, how often did the child or adolescent work without getting distracted?"

Successive

The Successive scale evaluates the student's ability to work with information arranged in a specific order that includes remembering words, numbers, letters, and ideas in order, as well as blending sounds of words in the correct sequence. An example of a Successive scale item is "During the past month, how often did the child or adolescent follow three to four directions given in order?"

THEORETICAL BASIS OF THE CAS2 MEASURES

It is historically true that intelligence tests were not explicitly based on a specific theory of intelligence, which is why the definition "Intelligence is what intelligence tests measure" is so revealing. Neither Alfred Binet's (1890) nor David Wechsler's (1939) approach was theory-based. Instead, their tests were collections of tasks thought to have some relevance to the goal of categorizing people on a scale of ability, typically defined by the content of the tests (verbal, quantitative, and performance). The first test authors who intentionally developed an intelligence test with consideration of theory were Alan and Nadeen Kaufman when they published the Kaufman Assessment Battery for Children (K-ABC) in 1983. The first test authors to base a different kind of intelligence test on a specific neurocognitive theory were Naglieri and Das when they published the original CAS in 1997.

The CAS, like the CAS2, was unique in that it contained scales corresponding to Luria's (1973) view of neurocognitive abilities instead of the traditional verbal, quantitative, and nonverbal configuration. The goal was to provide a new way of defining ability based on a cognitive and neuropsychological theory, and to develop a test to measure these basic psychological processing abilities. The authors of the K-ABC and the CAS shared the intention to emphasize theory in the construction of the tests, and the view that this emphasis would stimulate an evolutionary step in the field of intelligence testing. Building a test on theory, rather than attaching theories or models to previously published tests, defines these "second-generation" approaches, and the research summarized in Naglieri and Otero (2017) illustrates the advantages.

In Chapter 6 of this volume, we summarize what we have learned about the validity of PASS theory, which leads us to suggest that the theory has a very strong research foundation that continues to grow. Consider these examples:

- Individuals with distinct disabilities such as SLD and ADHD have specific PASS profiles (Naglieri, 2012; Naglieri & Goldstein, 2011).
- Researchers found only small differences between PASS scores across races (Naglieri, Rojahn, et al., 2005) and ethnicities (Naglieri, Rojahn, & Matto, 2007).
- Only small differences between PASS scores have been found when the tests are administered in English or Spanish (Naglieri, Otero, et al., 2007; Otero et al., 2013).
- Only small differences between PASS scores were found when the Italian and English versions of the CAS were compared (Naglieri et al., 2013).
- PASS scores have shown to be strongly correlated with academic achievement scores (Naglieri & Rojahn, 2004).
- PASS scores have been successfully used for instructional planning and intervention (Naglieri & Conway, 2009; Naglieri & Feifer, in press).

ADMINISTRATION AND SCORING

Administration

The directions for administration are provided in the administration and scoring manual for the CAS2 (Naglieri et al., 2014a) and the CAS2: Español (Naglieri et al., 2017), and in the examiner's record form for the CAS2: Brief and the CAS2: Rating Scale. The instructions include general administration guidelines and scoring rules, as well as verbal statements and nonverbal actions to be used by the examiner. The combination of verbal and nonverbal communication is designed to ensure that all children understand each task.

The subtests on the CAS2, CAS2: Brief, and CAS2: Español are carefully sequenced to ensure the integrity of the subtests and to reduce the influence of extraneous variables on a student's performance. The Planning subtests are administered first because the child is given flexibility to solve the subtest in any manner. Attention subtests are presented after the Planning subtests because they must be completed in the prescribed order (i.e., left to right, top to bottom).

All Planning subtests include strategy assessment, which is conducted during and after the administration of each Planning subtest in two ways. First, observed strategies are those seen by the examiner through carefully watching the child completing the items; reported strategies are obtained following completion of an item. The examiner obtains this information by asking, "How did you find what you were looking for?" or "Tell me how you did these," or the like. The child can communicate the strategies by either verbal or nonverbal (gesturing) means. Strategies are recorded in the "Observed" and "Reported" sections of the Strategy Assessment Checklist included in the record form.

The administration directions were carefully written to ensure that each student fully understands the demands of the subtests. For example, sample and demonstration items are included, as well as opportunities for the examiner to clarify the requirements of the task. If, however, a child does not understand the demands of the subtest or appears in any way confused or uncertain, the examiner is instructed to provide a brief explanation if necessary. This instruction gives the examiner the freedom to explain what the child must do, in whatever terms are considered necessary to ensure that the child understands the task. The content of the help is determined by the examiner and can be given in any form, including gestures, as well as the use of a language other than English. However, it is important to remember that these alternative instructions are meant to ensure that the child understands what to do; they are not intended to teach the child how to complete the test.

Hand Scoring

The CAS2, CAS2: Brief, and CAS2: Español are scored via a standard conversion method of using the sum of the subtest raw scores to convert to subtest scaled scores; the subtest scaled scores are summed and converted to standard scores for the four PASS scales, the CAS2 Full Scale or Total Score (CAS2: Brief), or the Supplemental scales (CAS2). The CAS2 and CAS2: Español subtest raw scores are calculated in various ways: the total number correct (Nonverbal Matrices, Verbal–Spatial Relations, Figure Memory, Word Series, Sentence Repetition, Sentence Questions, and Visual Digit Span); time in seconds (Planned Connections); or ratio scores that combine time and number correct (Matching Numbers, Planned Codes, and Expressive Attention) or time, number correct, and number of false detections (Number Detection and Receptive Attention). *False detections* are defined as the number of times a child underlines a stimulus that is not a target. The examiner converts the raw scores to subtest scaled scores, using the appropriate table for the student's chronological age in years, months, and days. The PASS and Full Scale or Total Score standard scores are obtained from the sum of the subtests on either the Extended (12-subtest) or Core (8-subtest) Battery.

Online Scoring and Report Writing

Conversions of raw to standard scores and generation of a narrative report are made easier by use of the CAS2: Online Scoring and Report System (Naglieri, 2014). This online portal provides conversion of item level raw scores on the CAS2 and CAS2: Español to raw scores (and ratio scores) for each subtest; sums the subtest scores; and calculates all subtest scaled scores, as well as the PASS, Full Scale, and Supplemental scale standard scores. In addition, the system computes all the values needed to make comparisons among CAS2 scores for determining a pattern of strengths and weaknesses.

The CAS2: Online Scoring and Report System is a record-form-based program designed on the premise that computer scoring, interpretation, and report generation should be managed in a clear and easily understood environment. When the online program is opened, the first page that appears is one that looks very much like the first page of the CAS2 record form. Data entry requires the examiner to enter actual item data. For example, when time scores and number correct are entered for each Matching Numbers page, the program computes the ratio score, and then the sum of the ratio scores is calculated automatically. Alternatively, subtest raw scores can be entered directly on the front of the record form. Once the subtest raw scores are entered, the subtest scaled scores and PASS and Supplemental Scales' standard scores are computed, and analysis of the scores is completed. A text description of the results is provided, as are handouts for teachers and parents that describe the four PASS scales. The program performs all the interpretive tasks described by Naglieri and Otero (2017), and it also provides some of the intervention handouts included in the book *Helping Children Learn: Intervention Handouts for Use in School and at Home* (2nd ed.; Naglieri & Pickering, 2010).

PSYCHOMETRIC PROPERTIES

Standardization

The CAS2 scales were standardized, and norming was based on a total sample of 4,142 children and adolescents ages 4–18 years. The samples for the CAS2 (N = 1,342), CAS2: Brief (N = 1,417), and CAS2: Rating Scale (N = 1,383) were carefully chosen to match the 2013 U.S. census data on the variables of age, gender, geographic region, and ethnicity. Specific procedures used for data collection and norming, as well as details regarding representation by geographic region, gender, race, ethnicity, family income, educational level of parents, and educational classification of the three samples, are fully described in the respective manuals. Some important psychometric qualities are summarized below.

Reliability

The CAS subtests and scales have high reliability and meet or exceed minimum values suggested by Bracken (1987). The average reliability for the Extended Battery Full Scale is .97, and average reliabilities for the PASS scales are .88 (Planning and Attention) and .93 (Simultaneous and Successive). The Core Battery reliabilities are as follows: Full Scale, .87; Planning, .85; Simultaneous, .90; Attention, .84; and Successive, .90.

The average reliability coefficients for all age groups for the CAS2 measures are provided in Table 15.2 for the CAS2 subtests, Table 15.3 for all the scales on the CAS2, and Table 15.4 for the CAS2: Brief and CAS2: Rating Scale. The CAS2 subtest reliabilities range from .80 (Planned Connections) to .91 (Verbal–Spatial Relations) and illustrate that these subtests have good reliability overall. Importantly, when these subtests were combined into PASS scales, the reliability coefficients were very high, ranging from .84 (Attention) to .93 (Simultaneous) for the 8-subtest Core Battery and from .90 (Attention) to .94 (Simultaneous) for the 12-subtest Extended Battery. The Full Scale reliabilities were .95 and .97 for the CAS2 Core and Extended Batteries, respectively. The PASS scale and Total Score reliability coefficients for the CAS2: Brief were also high, ranging from .88 (Simultaneous) to .93 (Planning) with a .94 on the total score. The CAS2: Rating Scale reliability coefficients were high as well, ranging from .93 (Simultaneous) to .96 (Attention), with .98 on the Total Score. These reliability results were also similar across gender, race, ethnicity, and special education categories (see the respective CAS2 manuals).

TABLE 15.2. Coefficient Alpha Reliabilities for the CAS2 Subtests

Subtest	Alpha
Planned Codes	.88
Planned Connections	.80
Planned Number Matching	.82
Matrices	.88
Verbal–Spatial Relations	.91
Figure Memory	.85
Expressive Attention	.82
Number Detection	.80
Receptive Attention	.83
Word Series	.83
Sentence Repetition	.83
Sentence Questions	.85
Visual Digit Span	.86

TABLE 15.3. Reliability Coefficients for the CAS2 PASS Scales, Full Scale, and Supplemental Scales

CAS2 Scales	Alpha
Core Battery (8 subtests)	
Planning	.90
Simultaneous	.93
Attention	.86
Successive	.89
Full Scale	.95
Extended Battery (12 subtests)	
Planning	.92
Simultaneous	.94
Attention	.90
Successive	.92
Full Scale	.97
Supplemental scales	
Executive Function without Working Memory	.86
Executive Function with Working Memory	.91
Working Memory	.92
Verbal Content	.91
Nonverbal Content	.92

INTERPRETATION

Two Critical Questions

As emphasized throughout this chapter, the interpretation of the CAS2, CAS2: Brief, and CAS2: Rating Scale scores is based on the view that PASS scores are measures of neurocognitive processes or "thinking" processes. These processes are inferred through the performance of a child or adolescent

TABLE 15.4. Coefficient Alpha Reliabilities for the CAS2: Brief and CAS2: Rating Scale

Scale	Alpha for CAS2: Brief	Alpha for CAS2: Rating Scale
Planning	.93	.95
Simultaneous	.88	.93
Attention	.89	.96
Successive	.86	.94
Full Scale	.94	.98

on a particular test or behaviors observed by a parent. Later in this section, we explain how the scores from the CAS2 for the four types of thinking according to PASS theory can be understood when compared to achievement test scores, behavior ratings, and other measures of ability. A key requirement of this analysis, however, is understanding the PASS processing demand(s) of a test score from any measure. To do so, we need to ask two critical questions about a question from any test. First, what does the student have to know to answer the question (i.e., achievement)? Second, how does the student have to think to answer the question (i.e., PASS)?
