Consider the test question provided in Figure 15.2. Solving the problem requires that the relationships among the shapes in the 2 × 2 matrix are understood. The examinee must understand that the difference between the left and right columns is shading, and that between the top and bottom rows is shape. The same kind of thinking is needed to solve a verbal analogy like "Man is to boy as woman is to ____________." That is, the relationships between the people must be understood, but in addition, the item requires *knowledge* of verbal concepts (*girl, woman, boy,* etc.). Furthermore, the examinee needs to understand that a girl becomes a woman and, similarly, a boy becomes a man. The relationships between the younger and older persons need to be comprehended to arrive at the correct answer. The same kind of thinking and knowledge components are involved when a student is asked, "What number comes next in this series: 1, 4, 7, __?" The relationships between the first and second numbers, as well as the second and third numbers, must be determined. In these last two examples, the student must know certain facts in order to understand the relationships among the words or numbers. In the example in Figure 15.2, in which only shapes are provided, the relationships among the shapes must be understood to answer the question, but knowledge of the names of the shapes is not needed. What is needed is *thinking about the relationships* between the shapes in the top and bottom rows. What distinguishes the different tasks is the fact that answering the verbal and math questions requires knowledge, whereas responding to the item presented with shapes requires very little knowledge. This distinction is the basis of interpretation of the CAS2 scores as well as scores from any other tests, especially tests of academic skills.

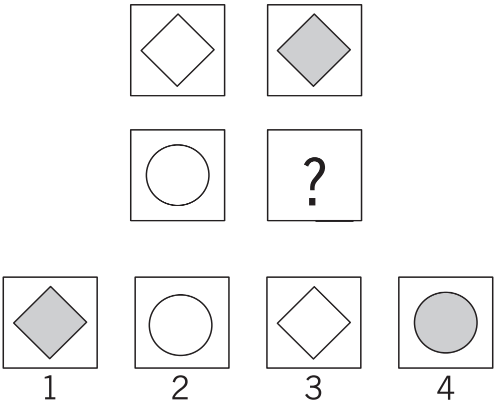

FIGURE 15.2. Illustration of a test item that demands simultaneous processing.

The cognitive demands of each CAS2 subtest on its respective PASS scale measure thinking (the PASS processes) with a minimum amount of knowledge. A person's CAS2 scores will often be compared, for example, to some test scores that may require a considerable amount of knowledge (e.g., reading, math, and writing). It is essential that examiners understand the relative contributions of knowledge and thinking to ability test scores when they are relating PASS scores to those from achievement tests and/or to reports of academic or behavioral problems in school or at home.

Overview of CAS2 Interpretation

In the remainder of this section on interpretation, we describe how to translate the PASS scores into theory-based explanation of a child or adolescent's neurocognitive processing abilities. We explain how to examine the scores for the CAS2, CAS2: Español, CAS2: Brief, and CAS2: Rating Scale from a normative basis (comparing the student to the standardization sample) and from an ipsative perspective (i.e., making comparisons within the individual's own set of scores). This analysis includes a method for determining whether there is a pattern of strengths and weaknesses that has relevance to educational programming, eligibility determination, and differential diagnosis, as well as intervention planning.

The CAS2 is unique among ability tests in that it was conceived in terms of and based upon the PASS neurocognitive theory, which provides the foundation for interpretation of the test scores. The focus of interpretation is on the child's ability to use the PASS neurocognitive concepts when thinking. Emphasis is placed on the four PASS scales' scores, which provide the most important information about the examinee. Indeed, we argue that the scores corresponding to the four PASS scores are *more* important than the Full Scale or the subtest scores. The CAS2 Full Scale (like the CAS2: Brief and CAS2: Rating Scale Total Scores) provides a very reliable overall description of a child's neurocognitive processing abilities, but it does not provide information regarding strengths or weaknesses according to PASS theory.

Interpretation of PASS profiles is the key to understanding a student's successes and difficulties in school and social/interpersonal situations, determining that student's eligibility for services, and planning appropriate interventions. Similarly, individual subtest score variability has little value, and efforts to reinterpret subtests from informally derived perspectives should be avoided. The purpose of having multiple subtests in the CAS2 is not to measure different abilities, but rather to provide highly reliable PASS scale scores by using subtests that measure each of the neurocognitive processes in a slightly different manner. For example, the Simultaneous subtests involve memory, verbal content, and reasoning with diagrams. The varying content of these complementary measures provides a broad evaluation of Simultaneous processing. When subtest scores are significantly different, they should only be interpreted when the additional data are compelling. Having one subtest score different from the others in that scale does not necessarily mean that the score for that scale is not interpretable; this phenomenon is more fully discussed later in this chapter. Even in such cases, the focus of interpretation of the CAS2 is on the PASS scale level.

Interpretation of PASS Scales

To be clear, the CAS2, CAS2: Español, and CAS2: Brief all measure planning, attention, simultaneous, and successive neurocognitive processing abilities in slightly different ways. These are briefly described as follows:

- *Planning.* This neurocognitive ability is used to create, apply, self-monitor, and self-correct thoughts and actions so that effective solutions to problems can be achieved. Planning provides the means to solve novel problems when no solution is immediately apparent, and often involves retrieval of information and use of the other PASS abilities to process information. All the CAS2 Planning subtests involve the use of strategies for efficient performance and the application of these strategies to novel tasks of relatively reduced complexity.
- *Attention.* This neurocognitive ability is used to focus selectively on a specific aspect of a complex stimulus while inhibiting responses to competing aspects. Successful performance on the Attention subtests requires attention to be focused, selective, sustained, and sometimes quite effortful. All CAS2 Attention subtests present tasks that require focus on one stimulus and resistance to responding to distractions over time.
- *Simultaneous.* This neurocognitive ability is used to understand how separate elements fit together into a conceptual whole. This ability is often applied to visual–spatial content, but can also be used to comprehend logical–grammatical verbal statements. Simultaneous processing subtests require perception of parts as a single whole, understanding of relationships, and synthesis of parts into integrated groups; all this occurs either through examination of the stimuli during the activity or through recall of the stimuli.
- *Successive.* This neurocognitive ability is used to integrate information into a specific order, where each element is only related to those that precede it. Successive processing involves working with stimuli in sequence, ordering thoughts and ideas, and forming sounds and movements in order. Some Successive processing subtests require recognition and reproduction of the serial order of information; others require comprehension of complex linear relationships.

The scores obtained with the CAS2: Rating Scale reflect behaviors a teacher can observe in the classroom that are associated with the PASS neurocognitive constructs. For planning, the goal is to estimate the extent to which behaviors associated with planning can be detected through observations of the strategies, organizational skills, and problem solving that a student may exhibit in the classroom. Attention is inferred from how well the student can focus on a task, resist distractions, and pay attention when dealing with everyday school activities. A student's ability to see relationships among concepts or physical objects, work with visual materials, and recognize faces can be informative about simultaneous processing. Finally, how well the student works with information in a sequence, remembers words or numbers in order, and can spell long words tells us about successive processing. It is important to note, however, that environmental factors can influence the PASS-related behaviors a student shows in the classroom. Instruction that discourages or encourages strategy use, for example, can influence classroom behaviors that would be related to planning.

Analytical Support for Interpretation Based on the PASS Scales

Interpretation of all the CAS2 measures thus begins with examination of the four PASS scores. This emphasis on the multidimensional theoretical level of analysis was supported by Naglieri and Rojahn's (2004) finding that the four PASS scale scores cumulatively accounted for more of the variance on an achievement test than the CAS Full Scale score in a sample of 1,559 students between the ages of 5 and 17. This study, in conjunction with those showing distinct PASS profiles for students with different disabilities (see Chapter 6, this volume), strengthens this emphasis on the separate neurocognitive abilities. Interpretation of PASS scores was also supported by Canivez (2011), who found that compared to subtests in other tests of intelligence, CAS subtests measured less general factor variance; the Planning, Attention, Simultaneous, and Successive factors had sufficient specific variance.

Recent CFA results are provided in the CAS2 and CAS2: Rating Scale manuals and provide support for focusing on the four PASS scales. The subtest-to-PASS-scale configuration was tested with individuals in the normative sample at four age intervals (ages 5–7, 8–10, 11–13, and 14–18 years), using maximum-likelihood CFA. Several models were tested, including models with one factor (PASS scales), two factors (Planning/Attention and Simultaneous/Successive), three factors (Planning/Attention, Simultaneous, and Successive), and four factors (Planning, Attention, Simultaneous, and Successive). The findings reported in the CAS2 manual indicated that for the four age groups, the four-factor PASS model was the best fit, thereby supporting the relative importance of the PASS scales versus the subtests (see the manual for more details).

Similar results were obtained from the analysis of the CAS2: Rating Scale. The correspondence of items to PASS scales on the CAS2: Rating Scale was studied by using CFA to test one-factor (no PASS scales), two-factor (Planning/Attention and Simultaneous/Successive), three-factor (Planning/Attention, Simultaneous, and Successive), and four-factor (Planning, Attention, Simultaneous, and Successive) models. The various fit statistics across the four different models improved as the number of factors increased, indicating that the four-factor PASS model was the best fit. These findings support the assignment of items to the four PASS scales. Perhaps most importantly, the results from these analyses of the assignment of *behavioral* items observed by teachers from the CAS2: Rating Scale and the correspondence of *subtests* from the CAS2 both support the structure of these measures based on the PASS theory. These results lend still more support to the interpretation of these tests at the PASS level, as well as the interpretation of the overall scores.

Steps for Interpreting the CAS2, CAS2: Brief, and CAS2: Rating Scale

Step 1: Interpreting the PASS Profile

The interpretation of the CAS2, CAS2: Brief, and CAS2: Rating Scale should begin with an examination of the four PASS scales and their associated confidence intervals, percentile ranks, and categorical labels. These derived scores are found in the standard score conversion tables in the CAS2, CAS2: Brief, and CAS2 Rating Scale manuals. Determining whether the PASS scores differ significantly is accomplished by comparing each PASS scale score with the average of the student's four PASS scores. This method is known as an *ipsative* comparison, which has been used often in intelligence testing (see Kaufman, 1994; Naglieri, 1999, 2011) because it can be used to determine whether any of the four PASS scores deviate from the student's level of functioning. This method thus provides a way to determine if the student's profile of neurocognitive processes is reliable. The values needed to use this approach for the CAS2, CAS2: Brief, and CAS2: Rating Scale are provided in the respective manuals and in Naglieri and Otero (2017).

However, the ipsative approach to determining whether any PASS scores differ significantly from the student's average is not sufficient to define a weakness or strength that can be used for diagnostic purposes (Naglieri, 1999; Naglieri & Otero, 2017). A second rule is needed for a better understanding of any high or low scores that may be found. For instance, a PASS score that is significantly lower than the person's average *must* *also* fall below the national average (at least below a standard score of 90) to be considered a weakness appropriate for eligibility determination or diagnosis. Table 15.5 provides several examples that are useful for using this approach.

Example 1 in Table 15.5 provides a scenario in which the Planning score of 84 is significantly lower than the student's average PASS score of 96.8, *and* that score falls below the average range. This meets our definition of a weakness because (1) it is low for this individual and (2) it is low in relation to the norm (i.e., the standardization sample). Similarly, the Simultaneous score is interpreted as a strength because it is significantly *above* the student's average and *above* the 84th percentile rank. This profile is often found for individuals who have been diagnosed with ADHD (Naglieri & Otero, 2012) and who lack control of their behavior and thinking. We suggest that scores above or below the average (90–109), or, to be stricter, scores corresponding to plus or minus one standard deviation from the average (standard score of 85/16th percentile and standard score of 115/84th percentile), be considered scores that are sufficiently unusual. There is no perfect cutoff score, so ultimately it is the clinician's decision.

Interventions for a student such as the one described in Example 1 should focus on having the student using the strength in simultaneous processing when learning, as well as on encouraging the use of strategies. The student can be taught that learning is most efficient when the big pic-

TABLE 15.5. Illustrations of PASS Profile Interpretations

PASS scale	Score	Difference from average score	Significant?	Weakness or strength?
		Example 1		
Planning	84	–12.8	Yes	Weakness
Simultaneous	116	19.3	Yes	Strength
Attention	95	–1.8	No	
Successive	92	–4.8	No	
Average	96.8			
		Example 2		
Planning	90	–1.5	No	
Simultaneous	103	11.5	Yes	
Attention	95	3.5	No	
Successive	78	–13.5	Yes	Weakness
Average	91.5			
		Example 3		
Planning	93	–13.5	Yes	
Simultaneous	104	–2.5	No	
Attention	111	4.5	No	
Successive	118	11.5	Yes	Strength
Average	106.5			
		Example 4		
Planning	86	–4.5	No	(Weakness)
Simultaneous	102	11.5	Yes	
Attention	95	4.5	No	
Successive	79	–11.5	Yes	Weakness
Average	90.5			

Note. Significance of the difference between each PASS score and the average PASS score for each case was tested at $p = .05$. A cutoff score of 85 was used.

ture is clear. The teacher can use handouts from Naglieri and Pickering (2010) that encourage the use of manipulatives, such as Cuisenaire Rods (pp. 114–115) for math, and that rely on simultaneous processing, such as the Summarization Strategy (p. 83) for reading comprehension. To encourage the use of planning processes, the Planning Facilitation (pp. 111–112) method for math and Plans for Reading Comprehension (p. 85) are good resources. The ultimate goal is to help the student use plans more frequently and to develop a repertoire of strategies that can be skillfully applied whenever needed.

Example 2 illustrates how a weakness can give the impression of a strength. In this case, the Simultaneous score of 103 is above the child's average PASS score by 11.5 points, and the difference is statistically significant—but because this score is within the average range (90–109), it would not be described as a strength. However, it would be appropriate to describe the Simultaneous score as the student's strongest area of ability, and to emphasize this neurocognitive ability when identifying or developing instructional methods that emphasize a big-picture perspective on information (e.g., Story Maps and Webbing, from Naglieri & Pickering, 2010). The Planning scale score of 90 is close to the average of 91.5, and the Attention score of 95 is 3.5 points above the child's average, indicating that neither of these is a strength or weakness. The Successive score of 78 is 13.5 points below the child's average, which is statistically significant *and* would be considered a weakness because the score is well below the average range. This finding indicates that the student has considerable difficulty working with information (words, numbers, motor movements, thoughts) arranged in a specific order. This profile is often found for students with SLD in reading decoding; they struggle in working with letters, sounds, and words arranged in a specific order (Naglieri & Otero, 2012).

Interventions for a student with a good score on the Simultaneous scale and an identified weakness on the Successive scale should focus on improving sequencing by organizing the information in groups—a strategy that brings in simultaneous processing. Naglieri and Pickering (2010) suggest using methods they describe, such as Chunking for Reading Decoding (p. 86) and Word Sorts for Improving Spelling (pp. 98–99), because they help a student learn to use simultaneous processing (the focus is on the bigger picture) to manage the sequence of information more easily. They also urge the student to recognize when a task requires successive processing (see the handout entitled Successive Processing Explained, p. 61) as a cue to use these intervention methods.

Example 3 illustrates that a relatively low score on the Planning scale (93), which is 13.5 points below the child's average but still within the average range, would not be considered a weakness. This does *not* mean that the score is unimportant, however: Because the Planning score is the lowest of the four scores, it has implications for the child's educational planning and self-esteem. Parents, teachers, and the student should be mindful that limited planning ability may be the reason the student does not perform his or her best when tasks demand developing and using strategies, organizing ambiguous tasks, and figuring out how to get things done. This suboptimal performance will be particularly apparent in contrast to tasks that demand getting the big picture (simultaneous), sequencing (successive), or sustaining focus and resisting distractions (attention). In fact, the Successive score of 118 is 11 points above the child's average and a strength, indicating that the student is likely to do well working in situations where the solutions are clearly spelled out in a logical, linear manner.

Interventions for a student with a strength on the Successive scale (above the PASS mean and the average range), and a score on the Planning scale that is at the bottom of the average range, should focus on the strength and encourage the student to be mindful about the value of strategy use. This is a student who needs to know that he or she may be prone to act impulsively at times, without careful consideration of the consequences. Teaching the student about the importance of being thoughtful and strategic will be very important, and handouts from Naglieri and Pickering (2010) such as Planning Explained (p. 55) and How to Be Smart: Planning (p. 63) should be utilized. The handout Successive Processing Explained (p. 61) should be used to inform the student of his or her strongest way to think, and to explain that seeing the whole (simultaneous) and focusing while resisting distractions (attention) are also important.

Example 4 presents a situation in which analysis of the PASS profile demands that rules be flexibly applied. The Simultaneous scale score of 102 is significantly above the child's average PASS score by 11.5 points—but as in Example 2, it would not be described as a strength because this score is within the average range. Nevertheless, as in Example 2, it would be reasonable to describe the Simultaneous score as reflecting the student's strongest ability and to recommend instructional methods that emphasize a big-picture perspective on information (e.g., Story Maps and Webbing, from Naglieri & Pickering, 2010). The Successive scale score of 79 is 11.5 points below the child's average, which is statistically significant; importantly, because the score is below the average range, this score is also considered a weakness. This weakness has educational and diagnostic implications. The Planning score of 86 is 4.5 points below the child's PASS average, and although not significantly different from the child's average PASS score, it is below the average range. In this case, it would be reasonable to interpret the Planning score as a weakness. The detection of Successive and Planning weaknesses like these has considerable implications for a student, especially in the early elementary grades, in which tasks that require sequencing are emphasized; when the student is unsure how to do something, he or she will have limited ability to use strategies to be successful. The intervention considerations for these processes described in the previous cases would also apply.

Step 2: Examining the Full Scale or Total Score

The next step is to interpret the Full Scale (CAS2) or Total Score (CAS2: Brief and CAS2: Rating Scale). The important question to consider with every case is this: Does the Full Scale or Total Score represent all four PASS scores? When significant variability in the four PASS scales is *not* found, the overall score can be considered an adequate description of the child or adolescent across the four scales. In contrast, when significant PASS score variability is found, it should be clearly stated that the Full Scale or Total Score will not be representative of all of the four PASS scales. In these instances, it is necessary simply to deemphasize the Full Scale or Total Score.

Step 3: Comparing the CAS2 or CAS2: Brief Scores with CAS2: Rating Scale Scores

Comparing scores from the CAS2 or CAS2: Brief with those obtained from the CAS2: Rating Scale allows for an examination of how PASS neurocognitive abilities can be contrasted to behaviors observed in the classroom. The values needed for significance when comparing the CAS2 and CAS2: Brief with the CAS2: Rating Scale are provided in Naglieri and Otero (2017). It is important to recognize that like any observational measure, the CAS2: Rating Scale is more influenced by the environment than PASS neurocognitive abilities measured by student performance on the CAS2 subtests. For this reason, PASS scores from the CAS2 and those from the CAS2: Rating Scale may differ because of the impact of environment, especially schooling. For example, a student may have good planning ability, yet may not demonstrate behaviors related to planning in the classroom if he or she has been taught to follow a specific method of solving a math question rather than to devise several ways of completing a problem. In this case, instruction reduces the role of planning and increases the need to remember the exact solution taught by the teacher. The underlying message to the student is to think less about possible ways of doing things and remember more of what is being taught (Meltzer, 2010). In such instances, the CAS2 or CAS2: Brief score may be different from the CAS2: Rating Scale score. This information is valuable, especially in devising interventions.

Step 4: Comparing PASS Scores to Achievement Test Scores

A key component of a comprehensive assessment is the comparison of scores on tests of cognitive ability and academic achievement. Comparing PASS scores to achievement test scores helps us understand if a cognitive processing weakness corresponds to an academic weakness, and if a cognitive processing strength corresponds to an academic strength. The statistical significance of the difference between scores on the CAS2 and a variety of achievement tests can be determined by using the same method as that for comparing CAS2 with CAS2: Rating Scale scores (Anastasi & Urbina, 1997). The values needed for significance provided in Naglieri and Otero (2017) were computed by using the standard errors of measurement reported in the technical manuals of the Kaufman Test of Educational Achievement, Third Edition (Kaufman & Kaufman, 2014), the Wechsler Individual Achievement Test—Third Edition (WIAT-III; Pearson, 2009), the Woodcock–Johnson IV Tests of Achievement (McGrew, LaForte, & Schrank, 2014), the Feifer Assessment of Reading (Feifer, 2015), the Feifer Assessment of Mathematics (Feifer, 2016), and the Bateria-III Woodcock–Muñoz (Muñoz-Sandoval, Woodcock, McGrew, & Mather, 2005). This method provides an efficient way to determine whether PASS strengths and weaknesses correspond to academic strengths and weaknesses.

Analyzing the Scores

The comparison of the CAS2 scores with achievement test scores should focus on the four PASS scales. The Full Scale should only be included if the four PASS scales are not significantly different and there is some requirement to contrast achievement with a total score. The emphasis, however, should be on comparison of the PASS scales to specific areas of achievement. To illustrate, if a child has earned scores of 90 on Planning, 102 on Simultaneous, 96 on Attention, and 77 on Successive on the CAS2 Extended Battery, these scores can be compared to subtest and composite scores from an achievement test. If the student has earned scores of 80 and 77 on the WIAT-III Pseudoword Decoding subtest and Basic Reading composite, respectively, these scores would be significantly lower (at $p = .10$) than the Simultaneous and Attention scores. However, the Pseudoword Decoding and Basic Reading scores would *not* be significantly different from the Successive score. The differences among the PASS scales (i.e., Successive score significantly below the child's average PASS score); the differences between the high ability scores (Simultaneous and Attention) in contrast to low achievement; and the similarity between the low Successive score and low achievement form the basis of the discrepancy–consistency model for SLD determination, which is described next. In this illustration, the CAS2 Full Scale score is not needed, nor does it help explain the relationship between PASS neurocognitive and achievement scores.

Determining Patterns of Strengths and Weaknesses: The Discrepancy–Consistency Method for SLD Identification

Naglieri (1999) first introduced the idea that a pattern of strengths and weaknesses in neurocognitive scores could be used as part of the process of identifying SLD. Similar approaches have also been suggested (Flanagan, Ortiz, & Alfonso, 2007; Hale & Fiorello, 2004). These authors' shared view that a pattern of strengths and weaknesses in cognitive ability scores can be used to identify SLD is sometimes referred to as a "third option" (Zirkel & Thomas, 2010). We propose that the discrepancy–consistency method should be used for the identification of SLD, based on a systematic examination of the variability of PASS scores from the CAS2 and academic achievement test scores. This method is based on evidence of one or more PASS weaknesses (as described in Step 1 above) and of variability in achievement test scores corresponding to PASS strengths and weaknesses. The results are two discrepancies and one consistency:

- A discrepancy between high and low PASS scale scores.
- A discrepancy between high PASS scores and low achievement test scores.
- A consistency between the PASS weakness(es) and low achievement test scores.

When these two discrepancies and a consistency are found, there is evidence that the child has what IDEA calls "a disorder in one or more of the basic psychological processes" involved in learning, and thereby that this student can be identified as having an SLD (Naglieri, 1999, 2005, 2011). An example of a decision tree for identifying a pattern of strengths and weaknesses, and making an SLD eligibility determination via the discrepancy–consistency method, is provided in Figure 15.3; a graphic representation of the findings is found in Figure 15.4.

Evidence of "a disorder in one or more of the basic psychological processes" referred to in IDEA is found in the successive processing weakness; when this evidence is combined with similarly low reading scores and with academic failure, eligibility for services is supported. This kind of a weakness in sequencing information underlies the inability to decode words successfully, as especially noted in the Pseudoword Decoding task. The consistency between the low Successive scale score and reading scores for this illustration provides evidence of a cause of the academic failure (assuming adequate instruction, motivation to learn, etc.). The significant difference between the high PASS scores and the two low reading scores further suggests that the student's achievement is below the ability to work with information that forms a whole, as well as to attend, shift focus, and resist distraction. This evidence, in conjunction with other relevant data and when other inclusionary–exclusionary conditions are also met, supports the student's eligibility for SLD services.

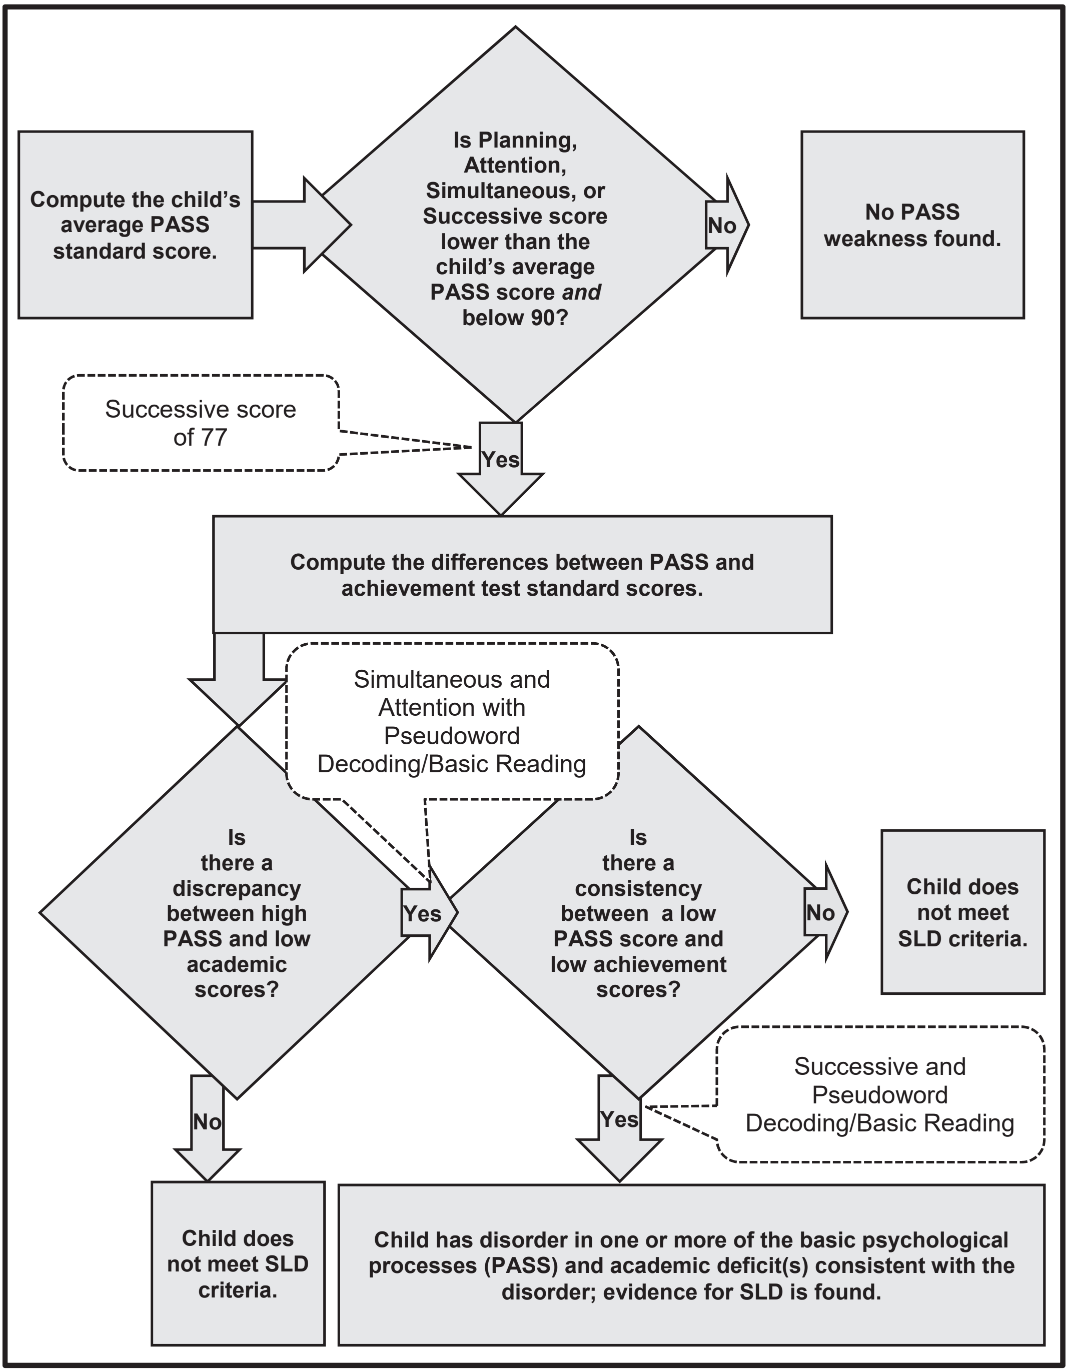

FIGURE 15.3. An example of using the discrepancy–consistency method for SLD eligibility determination.

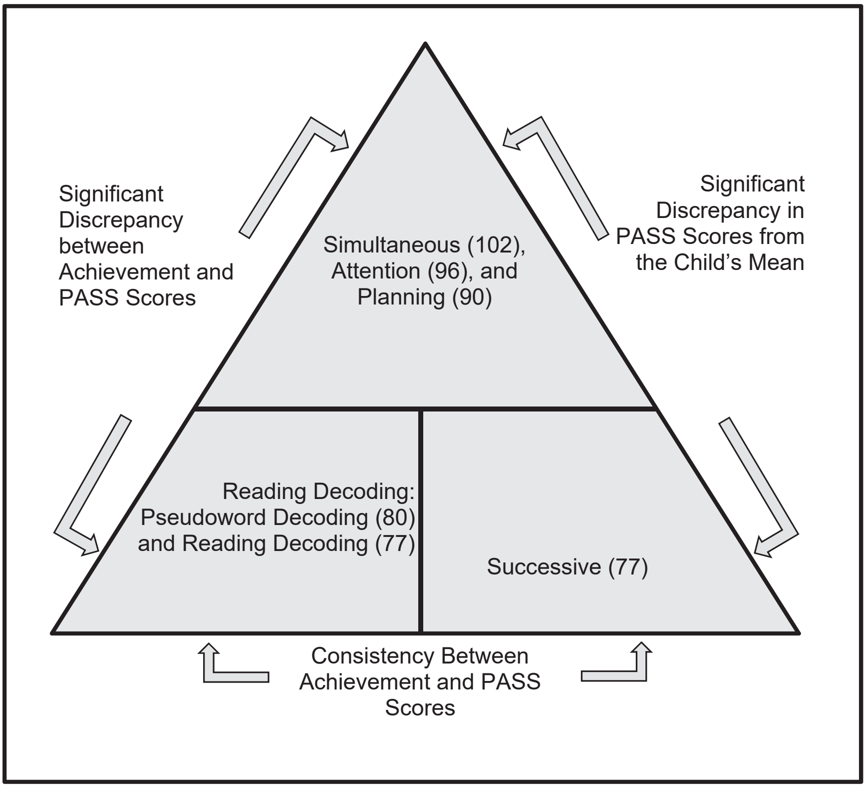

FIGURE 15.4. PASS and achievement scores for the discrepancy–consistency method.

Step 5: Examining the CAS2 Supplemental Scales

The CAS2 Extended Battery of 12 subtests includes Supplemental scales. These scales provide a way to integrate CAS2 results with measures of executive function, working memory, and speed/fluency, or of other concepts such as verbal–nonverbal and visual–auditory skills. These scores are thus useful for comparing results on the CAS2 to results obtained from other tests included in a comprehensive assessment battery. Even though our view is that PASS scores constitute the most valid way to interpret the CAS2, connecting this test's scores with other commonly used concepts is important. When doing so, practitioners should follow a few guidelines.

PASS scales represent the best way to understand the CAS2 subtests, which is why the theory drives interpretation. However, the Supplemental scales provide information that assists the clinician in incorporating other tests' data with CAS2 data during the interpretation. For example, it may be useful to relate findings from a rating scale of executive function, such as the Comprehensive Executive Function Inventory (CEFI; Naglieri & Goldstein, 2013), to some of the CAS2 subtests that also measure this construct. There are two different ways of looking at executive function, based on different combinations of CAS2 subtests; one CAS2 Supplemental scale includes, while another excludes, a measure of working memory.

Executive Function Scales

There is little agreement about the definition of executive function(s), the number of components it may have, and the role of working memory within it (Goldstein, Naglieri, Princiotta, & Otero, 2014). The two Supplemental scales on the CAS2 for assessing executive function are titled Executive Function without Working Memory and Executive Function with Working Memory. The Executive Function without Working Memory score is based on the scores obtained on the Planned Connections and Expressive Attention subtests, which are most closely aligned with the research on the executive functioning concept. The selection of these subtests is supported by Weyandt and colleagues (2014), who reported that the trail-making test (our Planned Connections) and the Stroop test (our Expressive Attention) are the most widely used measures of executive functioning. These tests measure two important components of executive function: shifting and inhibition (Georgiou, Das, & Hayward, 2008), respectively.

The Executive Function with Working Memory composite includes the Planned Connections, Expressive Attention, Verbal–Spatial Relations, and Sentence Repetition (for ages 5–7 years) or Sentence Questions (for ages 8–18 years) subtests. This combination of subtests adds the working memory concept, which is described by Baddeley and Hitch (1974) and is central to some theories of executive functioning.

The CAS2 Executive Function scales can be easily compared to the scores on the CEFI (Naglieri & Goldstein, 2013) because both measures use the same metric (i.e., mean of 100 and standard deviation of 15), where higher scores indicate better performance. The values needed for significance when comparing scores on CEFI and the CAS2 are provided in Naglieri and Otero (2017). This comparison will help determine whether a student's ability to think, devise a plan, apply the solution, evaluate its effectiveness, modify the plan as needed, and successfully complete the tasks on the CAS2 is consistent with behaviors observed by a parent or teacher or reported by the student. It is important to note that it is not assumed that these scores should be similar because behaviors will be greatly influenced by the environment within which the student functions. For example, if the student's educational experiences have consisted largely of explicit instructions in how to complete assignments, then the student's opportunity to think about different ways to solve problems may be inhibited. This possibility may explain why a child or adolescent with good scores on the Executive Function scales of the CAS2 has low scores on the CEFI.

Working Memory Scale

Georgiou and colleagues (2008) described *working memory* as the capacity to store information for a short period of time and manipulate that information using the *phonological loop* and *visuospatial sketchpad,* which are two concepts introduced by Baddeley and Hitch (1974). The visuospatial sketchpad refers to the person's use of mental images with visual and spatial features, and the phonological loop refers to retention of information from speech-based systems that are particularly important when order of information is required (Engle & Conway, 1998). The Verbal–Spatial Relations and Sentence Repetition or Sentence Questions subtests have cognitive demands similar to those of the visuospatial sketchpad and phonological loop, respectively, which is why these subtests were selected to comprise the Working Memory scale on the CAS2.

The CAS2 Working Memory scale can be compared to the Working Memory Index in the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014). The values needed for significance for testing any score differences are provided by Naglieri and Otero (2017). This comparison between scales that have the same name but are part of different tests must take into account the differences between the subtests used to measure this concept. For example, the CAS2 subtests that make up the Working Memory scale closely represent the concepts of the visuospatial sketchpad and phonological loop (Baddeley & Hitch, 1974; Engle & Conway, 1998). In contrast, the WISC-V Working Memory Index consists of the Digit Span and Picture Span subtests. We can assume that Digit Span Forward (like the CAS2 Sentence Repetition and Sentence Questions subtests) has a strong successive processing demand, but that Digit Span Backward involves successive and planning processes (Schofield & Ashman, 1986). The contribution of PASS processes to digit sequencing (reproducing the string of numbers in ascending order) was not evaluated by Schofield and Ashman, as this task postdates their original work. Because the task does involve mental manipulation and resequencing, we believe that this too would recruit successive and planning processes. It is not clear what processes are involved in the WISC-V Picture Span subtest, although we suspect that this test may involve some successive processing.

Verbal and Nonverbal Scales

Verbal Scores. The use of *verbal* and *performance* (i.e., nonverbal) test content as a way to define scales on measures of ability was initiated by Wechsler (1939) and based on the 1917 U.S. Army Alpha and Beta tests (Naglieri, 2015). The verbal (Army Alpha) tests were intended for those who had been educated, and the nonverbal (Army Beta) tests were intended for those who were illiterate. In fact, Yoakum and Yerkes (1920) stated that the purpose of the Beta (nonverbal) tests was "to avoid injustice by reason of unfamiliarity in English" (p. 19) and that the Alpha (verbal) tests would *not* measure intelligence reliably for those with a limited knowledge of English (p. 51). Not only did the Alpha and Beta tests set the stage for the Verbal and Performance scales on the Wechsler–Bellevue scale (Wechsler, 1939), but the U.S. Army's tests became embedded in both individual and group-administered tests of intelligence.

The WISC-V (Wechsler, 2014) still includes verbal and nonverbal subtests, although the publisher has created new scales and different names. The Verbal Comprehension Index is made up of subtests (Vocabulary and Similarities) intended to measure "verbal concept formation and abstract reasoning" and "word knowledge and verbal concept formation" (p. 7); "a child's ability to acquire, retain, and retrieve general factual knowledge" (p. 8); and "verbal reasoning and conceptualization, verbal comprehension and expression, the ability to evaluate and use past experience, and the ability to demonstrate practical knowledge and judgment" (p. 8). These subtests clearly require verbal skills and especially knowledge. It is important to recognize that verbal tests that contain considerable knowledge will be influenced by the student's opportunity to learn, just as Yoakum and Yerkes (1920) suggested.

The CAS Verbal scale differs from scales with similar names in traditional IQ tests. The Verbal scale on the CAS2 was created to measure thinking with verbal content, but with questions requiring as little factual knowledge as possible and very limited expressive language skills. The intent of the Verbal scale on the CAS2 is thus to measure verbal reasoning, but with less of a demand on language and on general knowledge. The CAS2 Verbal scale consists of Verbal–Spatial Relations, Receptive Attention, and Sentence Repetition (ages 5–7 years) or Sentence Questions (ages 8–18 years), which are derived from the Simultaneous, Attention, and Successive scales, respectively. This means that scores obtained on the CAS2 Verbal scale are likely to differ from those obtained on Verbal Comprehension measures found on the WISC-V and other traditional cognitive tests, especially for individuals with limited opportunity to acquire verbal knowledge.

The CAS2 Verbal scale demands the use of language across three of the four PASS scales and meets the objective described by Suzuki and Valencia (1997), as well as Naglieri and Bornstein (2003): to create a measure of ability with greatly reduced English demands and general factual knowledge demands, but one that still assesses thinking with language. Comparing the WISC-V Verbal Comprehension Index and the CAS2 Verbal scale, using the values presented by Naglieri and Otero (2017), allows the practitioner a way to determine if the child can work with the English language; by contrast, interpreting the WISC-V Verbal Comprehension Index score in isolation will reflect how much the child *knows,* as well as his or her ability to work with English.

Nonverbal Scores. Wechsler (1939) adapted the Army Beta tests and called his version the Performance Scale. That scale has been split into the Visual Spatial Index and the Fluid Reasoning Index in the WISC-V. These scales have also been described as nonverbal measures, which have gained popularity as the U.S. population has become more diverse (see Bracken & McCallum, 2009; Naglieri & Brunnert, 2009). These tests typically demand that the student solve problems using shapes that are arranged in a 2 × 2 or 3 × 3 matrix. The solution to each problem demands that the logic is understood in terms of changes in shape, color, and rotation.

The CAS2 Matrices, Figure Memory, and Planned Codes subtests constitute a Nonverbal scale that requires reasoning, has minimal language requirements, has a visual–spatial memory component, and provides the examinee with the opportunity to use strategies in solving a task. This scale involves simultaneous and planning processes. In addition to the two index scores mentioned above, the WISC-V has an ancillary Nonverbal Index that consists of six subtests: Block Design, Matrix Reasoning, Coding, Figure Weights, Visual Puzzles, and Picture Span. We suggest that this Nonverbal Index involves simultaneous processing (Block Design, Visual Puzzles and Matrix Reasoning), perhaps some successive processing (Picture Span), and some quantitative knowledge (Figure Weights). Practitioners should recognize that differences between scores on the CAS2 Nonverbal scale and the WISC-V Nonverbal Index may reflect the different cognitive and academic demands of the subtests in these scales.

Visual versus Auditory Subtest Comparisons

The idea that visual or auditory demands may have a significant impact on a student's performance has been studied since the early 1970s. Despite the limited support for interventions based on sensory modality (Dehn, 2014), interest in this area persists. Assessment of the difference in scores obtained from visual and auditory tests is typically confounded by differences in the intellectual requirements of the tasks. For example, WISC-V Block Design and Digit Span scores might be used when comparing visual and auditory stimuli, respectively, but this comparison is confounded by differences in the processing demands. That is, Block Design can be interpreted as a simultaneous processing task, while Digit Span has a strong successive processing requirement (Naglieri, Kamphaus, & Kaufman, 1983). This problem is circumvented in the CAS2 by comparing two subtests on the Successive scale.

Specifically, the CAS2 provides a means of directly comparing performance on tasks with auditory versus visual demands through evaluation of scores on the Word Series and Visual Digit Span subtests. Both these subtests demand the same neurocognitive ability (i.e., successive processing), but use visual (Visual Digit Span) versus auditory (Word Series) information. If the two subtests' scores differ by 3 points (one standard deviation), then the difference is statistically significant (see the CAS2 interpretive manual, Table B.3), and the difference in the modalities of stimuli may be an important factor to consider.

Speed/Fluency Scale

The concept of speed of processing, or how fast a person responds to highly learned stimuli, can be understood in terms of PASS theory by referring to Goldberg's (2009) description of the right and left hemispheres of the brain. In his book *The New Executive Brain,* Goldberg states that when a task is new, brain activity is maximized—especially in the frontal lobes, where planning takes place. When the task has been well learned, the functioning of the brain shifts from thinking about how to perform the task to solving the task with automaticity. Fluency is the result of the interaction of many factors, such as instruction, motivation, intention, and opportunity—but especially PASS abilities because they provide a foundation for learning. The transition from putting forth greater effort to putting forth less effort represents not only a change in hemispheric dominance from right to left (Goldberg, 2009), but also greater vertical organization of the brain. That is, as any task is learned, there is a shift to subcortical dominance, with greater involvement of the cerebellum. The cerebellum drives the speed, force, and accuracy of the expression of what is learned.

Speed/fluency can be measured with the first two pages of the Expressive Attention subtest on the CAS2. These initial two pages of Expressive Attention items require that the student respond to very well-known stimuli (either identifying the size of well-known animals, or reading the same words or naming the same set of basic colors) as quickly as possible. These items are used to prime the examinee for the final page that measures attention, but the scores on these pages are *not* used to measure attention. Naming sizes of animals, colors, or words requires speedy and fluent retrieval of knowledge, but little attention. Thus the first two pages of the Expressive Attention subtest are used to provide the Speed/Fluency scale score.

Step 6: Examining the Subtest Scores within Each of the Four PASS Scales

Determining whether there is variation among the CAS2 subtests is different for the 12-subtest Extended Battery and the 8-subtest Core Battery. The subtest scores from the Extended Battery on each of the four PASS scales are compared to the mean of the three subtest scores for each PASS scale. The differences are tested for significance via the ipsative comparison method (see Naglieri & Otero, 2017, for the values needed) *and* compared to the average subtest score range (8–12) via the same approach as that used for the PASS scales. That is, these differences need to be significant, *and* the subtest score must be below 8 (weakness) or above 12 (strength). These subtest score variations should be interpreted within the context of the PASS theory, with consideration of strategy use and other relevant variables.

Subtest variability, when interpreted within the context of PASS theory, may have potential value. For example, a child may have a low score on the Planned Connections subtest because an ineffective plan or no plan has been used. If the child has used strategies on the other two Planning subtests, the low score and observation of no plan would indicate that inconsistent strategy use is the problem. Similarly, a low score on Planned Codes may reflect a lack of self-correction if the child completes a page using a strategy that was appropriate on a previous page, without recognizing that the arrangement has changed. Similarly, a child with a very low Attention score may have problems shifting focus from letters to numbers as required on the Planned Connections subtest, resulting in a very low score on that subtest, despite average scores on the other two Planning subtests. In this example in which one subtest score on a PASS scale (Planning) is influenced by a problem with a different process (Attention), that low subtest score should not be included in the calculation of the overall Planning scale score, and a prorating approach should be applied.

A pairwise comparison method is used to examine subtest variation within each PASS scale for the eight-subtest Core Battery. The examiner should calculate the difference between the two subtests on each PASS scale (ignoring the sign) and compare the result to the values in Naglieri and Otero (2017) to determine when two subtests within each of the four PASS scales differ significantly. If the difference is equal to or greater than that found in the table, then the difference is significant. If a significant difference is found and a student has obtained a higher score on the Word Series subtest than the Sentence Repetition subtest, for example, the examiner look to see if the higher score is associated with a chunking strategy. If so, then it is likely that the use of a plan has influenced the results on the Successive scale. In such an instance, the difference between the two subtest scores illustrates the potential improvement on tasks requiring successive processing when a strategy is used. The best estimate of successive processing is the lower score, however, because it is less confounded by other processing abilities. This information is very useful for intervention: A teacher can simply encourage the use of plans when the student is completing work, especially work that demands successive processing (see Naglieri & Pickering, 2010).

Using the CAS2: Online Scoring and Report System

The CAS2: Online Scoring and Report System (Naglieri, 2014) provides an efficient way to convert all raw scores to derived scores; complete all scoring and comparisons of scales within the CAS2; and provide a narrative report describing each scale, the scores obtained, and what they mean. Item scores or subtest raw scores can be entered in the online program, using an interface that looks like the CAS2 record form. The report is provided as either a .pdf or a Word document. Two report formats are available: the Score Summary and the Scoring and Interpretive Report. The Scoring and Interpretive Report provides all the results that can be included within a comprehensive report; the user can modify and/or add information as needed.

INTERVENTION

One of the greatest strengths of the CAS2 is that this assessment approach gives a practitioner a way to understand how a student learns best (i.e., a PASS strength), and whether there are any obstacles to learning (i.e., a PASS weakness), so that a path to maximize learning is apparent. This information is most valuable when it is shared with the student, teachers, and parents. Fortunately, the four PASS neurocognitive abilities are easy to explain. One way to do this is to describe when PASS abilities are used, as follows:

"Planning is used when you think about how to do something before you act."

"Attention is used when you focus your thinking on something and resist distractions."

"Simultaneous processing is used when you think about how ideas or things go together."

"Successive processing is used when you must think of things in a specific order."

These four PASS neurocognitive processes underlie everything we do, and are most apparent in relation to academic success and difficulties. A PASS weakness can pose a substantial obstacle to learning (Naglieri, 2000). Conversely, if someone has a strength in one of the PASS processes, that strength can form the basis of success. It is essential that we communicate information about strengths and weaknesses to the students we assess, to maximize their likelihood of success in school and in life. This is an important initial step in the intervention process, but we begin here by explaining our view of intervention, and of how it differs from instruction.

We use the term *intervention* to indicate a specific way of teaching that is selected or developed with consideration of a student's PASS cognitive processing profile. *Instruction* is the application of any method of teaching, such as a phonics or whole-language curriculum, regardless of the learner's PASS profile. The use of an instructional method without consideration of the student's PASS and academic profiles is *not* an intervention. Ordinary instruction becomes an intervention when it is based on the results of an assessment that includes information about PASS processes and other relevant factors, such as mental health, previous educational history, home environment, and so on. The more informed we are about the characteristics of the student, the more efficient the selection of an instructional method will be, and the more likely it becomes that the intervention will be successful.

Informing the Student

The student who has been evaluated with the CAS2 is the most important person to inform about the results, in terminology appropriate for the student's age and ability to understand. When a comprehensive evaluation is conducted, we can expect that this student's difficulties at school have affected his or her self-concept. Just as success in school is often associated with being "smart," the lack of success can lead a student to doubt his or her ability. Thoughts such as "I am not very capable of learning" can lead a student to have limited expectations for success. Therefore, the first step in the intervention process is to inform the student of his or her PASS strengths as well as weaknesses, in a manner that is age-appropriate. Importantly, the examiner should clearly describe observed strengths, while also emphasizing that observed weaknesses can be managed with thoughtful effort. The goal is to change the student's attitude toward learning by helping him or her understand that the areas of strength can be used to overcome the observed weaknesses. This objective can be facilitated by handouts for students (as well as teachers and parents) provided by Naglieri and Pickering (2010), which explain each PASS processing ability as well as academic interventions. This strategy can also help change the student's mindset about the future, which is a key to acceptance of any interventions.

Teaching a student with a PASS processing disorder about his or her *strengths* and *needs,* and indicating which tools to use to address the learning needs, will empower him or her. Shifting the mindset from "I can't do this work," to "If I think smart, I know I can do better," takes time and requires a concerted effort on the part of all those working with the student. The evaluator should explain to the student that *mindset* is a description of the way a person thinks about his or her abilities, especially when tasks are demanding (Dweck, 2006). Students with a fixed mindset believe they cannot improve with effort, and they give up easily. Those students with a growth mindset believe they *can* achieve, with effort, persistence, and hard work. Helping not only the student, but his or her parents and teachers, adopt a growth mindset is important. When the evaluator is informing parents and teachers about the child's cognitive strengths and weaknesses, it is critical that the conversation encourage a growth mindset perspective. The goal is to ensure that the student and the adults adopt language like this: "I can't do it . . . *yet.* So I am going to keep trying until I succeed." For more information, and for two informal scales for rating mindset, see Naglieri and Otero (2017).

As noted above, the PASS handouts provided by Naglieri and Pickering (2010) can be used to inform a student about a strength or weakness in a PASS area. Each PASS "thinking ability" is described in simple terms, and the student is encouraged to "work smarter" by using a specific PASS way of thinking. For example, the theme of the handout on planning is "You can be smarter if you PLAN before doing things" (Naglieri & Pickering, 2010, p. 63). This handout is very important because it teaches that academic problems can be overcome if strategies are used, the success of strategies is evaluated, and modifications are made as needed. The message in the handout entitled Think Smart and Use a Plan! is that the student can achieve more than in the past by taking a strategic approach. This requires that the student learn to recognize when the demands of a task are particularly hard, and whether the obstacle is related to his or her PASS weakness. This suggestion is well supported by previous PASS research, which shows that encouraging students to use plans when doing math and reading has been very effective (Iseman & Naglieri, 2011)

When students with SLD in reading decoding have a weakness in successive processing (Naglieri & Otero, 2011), they especially need to use planning strategies to succeed. A student who has a weakness in successive processing should be informed that *any* task that demands sequencing will be difficult, but that using a strategy will make the task easier. Examples of such tasks include sequencing letters or sounds to make and spell words, remembering information in order, doing things in a specific order (e.g., tying shoelaces or remembering the combination to a lock), and so forth. One way to meet the demands of any sequencing task that requires reading or spelling is to put sounds and/or letters in groups. This chunking, or grouping, strategy is very helpful. These students should be given the handout Chunking for Reading Decoding (Naglieri & Pickering, 2010, p. 86), which teaches students how to use a chunking strategy for reading decoding instead of trying to sound out and blend sounds to make a word. Using strategies allows the student to arrive at the correct answer by *thinking* about how to solve the problem (using a plan), rather than by trying to decode words sequentially, which demands much successive processing. The change in the thinking reduces the successive processing demands of the task because seeing letters in groups reduces the length of the sequence and involves planning and simultaneous processes. The result is that by shifting the cognitive processing demands of a task, the child can read in a way that does not rely on his or her cognitive weakness (i.e., successive processing), and this shift improves the chances for success. More success means more confidence and the belief that a student can achieve by "thinking smarter."

Informing Teachers and Parents

The ultimate goal of the CAS2, CAS2: Brief, or CAS2 Rating Scale is to provide results that explain how children and adolescents learn and how to maximize their learning. An analysis of strength and/or weakness in any of the PASS neurocognitive abilities will provide information about any challenges to learning and about which instructional strategies or interventions are likely to be the most beneficial. It is important that the selection of teaching methods is based on thoughtful consideration of PASS demands, and that those PASS demands are aligned with the each student's profile. This task means that the teacher must understand the PASS processes required by the instructional lesson plan. For example, a child with a weakness in successive processing is likely to have problems learning from a reading program that demands blending sounds to read or spell words. Knowing this, the teacher can select methods that more efficiently match the learner's characteristics to the method of instruction. A critical part of this process is to examine the academic and PASS demands of any learning environment.

One way for teachers to understand the cognitive demands of any instructional method is to ensure that they understand the four PASS neurocognitive abilities. Naglieri and Pickering (2010) provide teacher handouts that describe the PASS neurocognitive abilities and their relationships to learning. Additionally, a teacher who has completed the CAS2: Rating Scale has already learned something about PASS through the questions included on the scale. When this information is combined with information obtained from the CAS2 or CAS2: Brief, the teacher can gain a greater understanding of the relationships between a student's PASS profile and the PASS demands of the academic tasks. Two important issues should be considered: (1) Most academic tasks involve more than one PASS ability, and (2) the roles of PASS processes may change as the task is learned.

Academic tasks like reading and math clearly require more than one PASS process (Naglieri & Rojahn, 2004), so the identification of a student's neurocognitive weakness helps teachers, parents, and the clinician understand where the learning breaks down. For example, a student with a weakness in planning ability may do poorly in reading because of a failure to consider all the possible meanings of the text. A student with a weakness in successive processing may not remember the order of events described in a paragraph and may arrive at an incorrect understanding of the text. Similarly, a student with a weakness in simultaneous processing may do poorly because of a difficulty in integrating all the relevant information into a cohesive whole to get the overall meaning. Finally, a student with a weakness in attention is likely to miss the details and get distracted by less relevant information, leading to a faulty understanding of the text. If both the teacher and the learner are aware of the student's PASS strengths and weaknesses vis-à-vis the demands of the academic task, then these obstacles can be anticipated and overcome. All this illustrates the importance of encouraging the student, teacher, and parents to work together to help the student succeed.

Intervention Options

There are several resources for using PASS theory to identify interventions that can augment learning for students with academic needs. These include books such as Naglieri and Pickering's (2010) *Helping Children Learn: Intervention Handouts for Use in School and Home*; book chapters by Naglieri and Feifer (2017) and Feifer and Naglieri (2017); and the PASS Reading Enhancement Program (PREP; Das, 1999). Other resources include, for example, *Learning Problems: A Cognitive Approach* (Kirby & Williams, 1991), *Cognitive Strategy Instruction That Really Improves Children's Academic Performance* (2nd ed., Pressley & Woloshyn, 1995), and *Helping Students Become Strategic Learners* (Scheid, 1993). Some of the options provided in these resources are now discussed in more detail.

Planning Strategy Instruction

The connection between planning as described in PASS theory and interventions to improve the use of strategies has been examined in a series of studies. These investigations have involved both math and reading; they have focused on the concept that children can be taught to be more strategic when they complete academic tasks, and that the facilitation of plans has a positive impact on academic performance. While it is true that some students need to be explicitly taught to use strategies, encouraging students to approach their work strategically and devise their own plans has the added advantage of near and far transfer (Iseman & Naglieri, 2010). For this reason, the *planning facilitation* method is designed so that children discover the value of strategy use without being specifically instructed to do so. The students are encouraged to examine the demands of a task in a strategic and organized manner. Research on this intervention method and its relationship to PASS scores on the CAS has been carefully examined in several important research studies.

The first two studies using planning strategy instruction showed that children's performance in math calculation improved substantially (Naglieri & Gottling, 1995, 1997). The children in these two studies attended a special school for those with learning disabilities. Students completed mathematics worksheets in sessions over about a 2-month period. The method designed to teach planning was applied in individual one-on-one tutoring sessions (Naglieri & Gottling, 1995) or in the classroom by the teacher (Naglieri & Gottling, 1997), two to three times per week in 30-minute blocks of time. Students were encouraged to recognize the need to plan and use strategies when completing mathematics problems during the intervention periods. The teachers provided probes that facilitated discussion and encouraged the students to consider various ways to be more successful. More details about the method are provided by Naglieri and Gottling (1995, 1997).

The relationship between planning strategy instruction and the PASS profiles for children with learning disabilities and mild mental impairments was studied by Naglieri and Johnson (2000). The purpose of their study was to determine whether children with cognitive weaknesses in each of the four PASS processes, and children with no cognitive weaknesses, would show different rates of improvement in math when given the same group-based planning strategy instruction. The findings from this study showed that children with a cognitive weakness in planning improved considerably over baseline rates, while those with no cognitive weakness improved only marginally. Similarly, children with cognitive weaknesses in simultaneous, successive, and attention processing showed substantially lower rates of improvement. The importance of this study was that the five groups of children responded very differently to the same intervention (see Table 15.6). Those with a weakness in planning on the CAS benefited the most from the intervention, while those with weaknesses in the other PASS processing domains or no weakness did not benefit as much. Thus the PASS processing scores were predictive of the children's response to this math intervention (Naglieri & Johnson, 2000).

The effects of planning strategy instruction on reading comprehension were reported by Haddad and colleagues (2003). Their study assessed whether an instruction designed to facilitate planning would have differential benefits on reading comprehension, and whether improvement would be related to each child's PASS scores. The researchers used a sample of children in general education, sorted into groups based on their CAS PASS scale profiles. Even though the groups did not differ on CAS Full Scale scores or pretest reading comprehension scores, children with a planning weakness benefited substantially (effect size of 1.4) from the instruction designed to encourage the use of strategies and plans. In contrast, children with no PASS weakness or a successive weakness did not benefit as much (effect sizes of 0.52 and 0.06, respectively). These results further support the research suggesting that the PASS profiles are relevant to instruction.

TABLE 15.6. PASS Standard Scores: Intervention Effect Sizes for Five Groups of Students with Learning Disabilities

Planning	Simultaneous	Attention	Successive	Effect size
69.7	89.0	86.3	91.7	1.4
86.5	92.5	**71.0**	101.5	0.3
88.0	88.0	103.0	**72.0**	0.4
93.0	**70.0**	90.3	89.7	–0.2
83.3	85.0	89.2	83.1	2.0

Note. Cognitive weaknesses are noted in boldface.

Iseman and Naglieri (2011) examined the effectiveness of the strategy instruction for students with learning disabilities and ADHD, who were randomly assigned to an experimental group or a control group that received standard math instruction. They found large pre–post effect sizes for students in the experimental group (0.85), but not those in the control group (0.26), on classroom math worksheets; they also found standardized test score effect sizes on Math Fluency (1.17 and 0.09, respectively) and Numerical Operations (0.40 and –0.14, respectively). One year later, the experimental group continued to outperform the control group. These findings strongly suggested that the students in the experimental group evidenced not only greater improvement than the control students on the math worksheets, but far transfer to standardized tests of math, and that they sustained these improvements at the 1-year follow-up. The findings also illustrate the effectiveness of planning strategy instruction, especially for those with low planning scores on the CAS.

PASS Reading Enhancement Program

PREP was developed as a cognitive remedial program based on the PASS theory. These researchers summarized studies showing that students could be trained to use successive and simultaneous processes more efficiently, with subsequent improvement in reading. PREP aims to improve the use of the PASS cognitive processing strategies that underlie reading. The tasks in the program teach children to focus their attention on the sequential nature of many tasks, including reading, which helps the children better utilize successive processing (a very important cognitive process in reading decoding). PREP is also founded on the premise that the transfer of principles is best facilitated through inductive, rather than deductive, approaches. The program is structured so that tacitly acquired strategies are likely to be used in appropriate ways. For example, the tasks teach children to focus on the sequences of information included in a variety of tasks, including reading.

Support for PREP, which has been summarized elsewhere (Naglieri, 2015), has demonstrated the effectiveness of the instructional method. Children (including children with learning disabilities) who received PREP, in comparison to a regular reading program, improved significantly on measures of nonsense-word decoding and word recognition. When PREP was compared to a meaning-based reading program in a study using two carefully matched groups of first-grade children, the results showed a significant improvement in reading scores for the PREP group over the control group. Specific relevance to the children's CAS profiles was also demonstrated by the fact that those children with a higher level of successive processing at the beginning of the program benefited the most from the PREP instruction, but those with the most improvement in the meaning-based program had higher levels of planning. Taken as a whole, these studies support the effectiveness of PREP in remediating deficient reading skills during the elementary school years. Additionally, they illustrate the connection between the PASS theory and intervention.

The interventions described here and earlier in this chapter (see "Step 1: Interpreting the PASS Profile," above) range from handouts for students, teachers, and parents to guidance in selecting various published reading and math programs. The correspondence of PASS strengths and weaknesses with published reading and math programs is discussed by Naglieri and Feifer (2017). For example, they suggest that programs such as the Wilson Reading System, Read 180, Orton–Gillingham, Ladders to Literacy, and Read to the Code can be used to improve the sequential processing of sounds. Programs such as Academy of Reading, RAVE-O, Reading Recovery, and Great Leaps Reading can be used to improve processing of sounds as groups. Teachers of students who need to make better use of planning and attention processing while reading should also consider approaches such as narrative retelling, active participation, and creating questions. These more formal programs and approaches offer the advantage that teachers may already be familiar with them or have the necessary materials. Even if formal programs are used, the handouts from Naglieri and Pickering (2010) should also be used to inform all parties of the meaning of a student's PASS scores and to build confidence that cognitive processing strengths can be used to maximize learning. For more on interventions in reading and math, see Naglieri and Feifer (2017) and Feifer and Naglieri (2017).

CONCLUDING THOUGHTS

This chapter has described the CAS2, CAS2: Español, CAS2: Brief, and CAS2: Rating Scale, which provide four ways to measure PASS neurocognitive theory (see Chapter 6, this volume). The greatest advantage of the various versions of the CAS2 is that they are grounded in the well-supported PASS theory. This theory helps us understand two key questions: Why does a student fail? And what neurocognitive strengths can be used to help the student succeed? This collection of measures also provides ways to apply PASS theory within a multi-tiered service delivery system—that is, in tier 1 (CAS2: Rating Scale), tier 2 (CAS2: Rating Scale and CAS2: Brief), and tier 3 (CAS2 or CAS2: Español and CAS2: Rating Scale). These four ways to evaluate basic psychological processes have been designed to address the need in the field to assess ability more broadly, more fairly, and more effectively, with a minimum of complexity. Which brings us to one final reminder: The test an examiner select has a profound impact on what the examiner learns about a student and on what can be done to help that student. We suggest that the decision be made with full knowledge of the strengths and weaknesses of all the options.

CHAPTER 16

The Wechsler Adult Intelligence Scale—Fourth Edition and the Wechsler Memory Scale—Fourth Edition

Lisa Whipple Drozdick
Susan Engi Raiford
Dustin Wahlstrom
Lawrence G. Weiss

The Wechsler Adult Intelligence Scale—Fourth Edition (WAIS-IV; Wechsler, 2008) is the most recent edition of the WAIS. It incorporates numerous changes from previous editions to ensure that the instrument continues to reflect advances in modern test theory and research. It is used to assess intellectual ability in adults and adolescents ages 16–90 and provides information about specific cognitive abilities across various domains. It is frequently used with other instruments in comprehensive evaluations.

Memory is frequently evaluated along with intellectual functioning. The WAIS-IV and the Wechsler Memory Scale—Fourth Edition (WMS-IV; Wechsler, 2009) are co-normed to facilitate direct comparison of performance across the two measures. A common referral suggesting the combined use of the WAIS-IV and WMS-IV involves poor or questionable cognitive or memory performance. When the two batteries are used together, the WAIS-IV provides a measure of general cognitive ability that serves as a backdrop for WMS-IV interpretation.

This chapter presents an overview of the WAIS-IV and the WMS-IV, followed by guidelines on the use and interpretation of the instruments separately and in combination. Each overview presents a brief description of the theory and structure of the instrument, descriptions of the subtests and composites, and information on psychometric properties. The section on interpretation provides specific interpretive information for each instrument and on joint use of the two instruments. Finally, a chapter appendix presents a case study to illustrate the combined use of the WAIS-IV and WMS-IV.

WECHSLER ADULT INTELLIGENCE SCALE–FOURTH EDITION

Theoretical Framework

The Wechsler intelligence scales utilize a *theoretical framework of intelligence* to guide development of each edition. Within this framework, multiple lines of inquiry are simultaneously considered to align each new edition of a Wechsler intelligence scale with contemporary thought and knowledge. This framework draws upon current theories of intellect and specific cognitive abilities, and upon active progress in developmental psychology, neuropsychology, cognitive neuroscience, and clinical research and utility. This ensures that the Wechsler scales are highly innovative and modern. Tying an instrument to a single theory limits the ability of the test to evolve dynamically, based on all relevant research and in response to other information from related fields. Moreover, if the theory changes to accommodate new information, the test becomes outdated. The modern Wechsler theoretical framework is described in greater detail elsewhere in this volume (see Wahlstrom, Raiford, Breaux, Zhu, & Weiss, Chapter 9).

David Wechsler, in his time, set the tone of responsiveness to contemporary theory and research as well as clinical utility when developing the Wechsler intelligence scales. He was best known for his clinical acumen and developed his tests to be clinical instruments, although he was trained in statistics by Charles Spearman and Karl Pearson (A. S. Kaufman, Raiford, & Coalson, 2016). Wechsler was influenced by two key theorists of intelligence at the time: the aforementioned Charles Spearman, as well as Edward Thorndike. Spearman's concept of *g* and general intelligence was an obvious influence (A. S. Kaufman et al., 2016; Tulsky, Zhu, & Prifitera, 2000; Weiss, Saklofske, Coalson, & Raiford, 2010), as Wechsler viewed intelligence as a global entity. However, Thorndike's influence was also evident, as Wechsler conceived of this global entity as consisting of qualitatively different elements (A. S. Kaufman et al., 2016; Wechsler, 1939, 1950, 1975). He articulated this view best in the Wechsler–Bellevue Intelligence Scale manual, where he described intelligence as

> the aggregate or global capacity of the individual to act purposefully, to think rationally, and to deal effectively with his [or her] environment. It is global because it characterizes the individual's behavior as a whole; it is aggregate because it is composed of elements or abilities which, though not entirely independent, are qualitatively differentiable. (Wechsler, 1939, p. 3)

Wechsler also postulated that a number of abilities not assessed by intelligence tests affect an individual's ability to navigate his or her environment effectively. These include personality and conative factors, such as drive, persistence, curiosity, and temperament (Wechsler, 1950). Wechsler was unsuccessful in developing a measure of these noncognitive intellective skills, but his practical and clinically based overarching theory of intelligence resulted in a number of strengths that have made the Wechsler intelligence scales the most widely used in the world today (Archer, Buffington-Vollum, Stredny, & Handel, 2006; Rabin, Paolillo, & Barr, 2016). Perhaps most importantly, the Wechsler scales are considered valid and clinically useful instruments, providing a clinician with an accurate snapshot of an individual's functioning that is related to the person's success in real-world settings—including job performance (Hunt & Madhyastha, 2012; Kuncel, Ones, & Sackett, 2010; Schmidt, 2014); mental and physical health and health behaviors (Johnson, Corley, Starr, & Deary, 2011; Rindermann & Meisengerg, 2009); and academic achievement and educational attainment (Deary & Johnson, 2010; S. B. Kaufman, Reynolds, Liu, Kaufman, & McGrew, 2012).

Many of the features discussed later in this chapter were incorporated into the WAIS-IV to address recent advances in the lines of inquiry considered within the Wechsler theoretical framework of intelligence. For example, a growing body of literature emphasizes the importance of fluid reasoning in general cognitive functioning and age-related cognitive decline (e.g., Keage et al., 2015; Pineda-Pardo, Martinez, Román, & Colom, 2016), and fluid reasoning is commonly found to be highly associated with general intelligence (Reynolds, Keith, Flanagan, & Alfonso, 2013). A measure of quantitative fluid reasoning, Figure Weights, was included in the WAIS-IV to expand coverage of this construct. Similarly, working memory has been found to be an important predictor of individual differences in learning and fluid reasoning (Chuderski, 2014; Conway, Cowan, Bunting, Therriault, & Minkoff, 2002; Fry & Hale, 1996; Perlow, Jattuso, & Moore, 1997), and a very close association has also been observed between working memory capacity and *g* (Colom, Rebollo, Palacios, Espinosa, & Kyllonen, 2004; Conway, Kane, & Engle, 2003). In addition, working memory training has been linked to improvements in fluid reasoning ability, suggesting a dynamic interplay between the two in the control of cognitive functioning (Jaeggi, Buschkuehl, Jonides, & Perrig, 2008; Jaeggi, Buschkuehl, Shah, & Jonides, 2014). Furthermore, working memory appears to play a role in age-related cognitive decline (Pineda-Pardo et al., 2016). To address the growing importance of working memory in cognitive ability, the Digit Span Sequencing task was added to Digit Span. This change increases the role of mental manipulation and results in greater demands on working memory, relative to previous versions of Digit Span. Arithmetic was also altered to reduce the role of verbal comprehension skills or mathematical knowledge relative to working memory. For example, difficult items require several simple math computation steps that have to be represented in working memory in favor of the complex calculations included in the prior edition.

Processing speed is another construct important to the expression of intelligence, as research suggests that it interacts with working memory and fluid intelligence; processing speed mediates the relationship between working memory and reasoning (Dang, Braeken, Colom, Ferrer, & Liu, 2015; Fry & Hale, 1996, 2000). Specifically, it has been proposed that rapid information processing may reduce working memory demands, and that this reduction in turn releases cognitive resources for more complex forms of reasoning (Weiss et al., 2010). Furthermore, factor-analytic research has identified processing speed as an important component of the Cattell–Horn–Carroll (CHC) model of intelligence (Schneider & McGrew, 2012 and Chapter 3, this volume), and it has been shown to be sensitive to a number of clinical syndromes, including attention-deficit/hyperactivity disorder (ADHD) (Nielsen & Wiig, 2011), traumatic brain injury (TBI) (Donders & Strong, 2015), epilepsy (Baxendale, McGrath, & Thompson, 2014), and multiple sclerosis (Ryan, Gontkovsky, Kreiner, & Tree, 2012). Processing speed is additionally implicated in cognitive decline related to aging (Manard, Carabin, Jaspar, & Collette, 2014). The WAIS-IV includes both the Coding and Symbol Search subtests in the calculation of the Full Scale IQ (FSIQ). As a result, the contribution of processing speed subtests to the FSIQ increased from 9% in the WAIS-III to 20% in the WAIS-IV, reflecting the growing importance of this construct in intellectual assessment.

Overall, confounding variables within cognitive domains have been reduced in the WAIS-IV, thereby increasing the instrument's ability to tap cognitive functions more purely. For example, to reduce the influence of declining processing speed on the scores of older adults (Lee, Gorsuch, Saklofske, & Patterson, 2008), time-bonus points were removed from Arithmetic and reduced on Block Design. Similarly, Cancellation was added as an alternative processing speed subtest with fewer fine motor demands than Coding, and Visual Puzzles demands less fine motor control than Object Assembly, which it replaces on the Perceptual Reasoning Index (PRI). Despite these changes, care has been taken to ensure that the test retains its validity and clinical utility. A century of cognitive research has demonstrated that human cognitive functions form a dynamically unified entity, as evidenced by the discussion above of fluid reasoning, working memory, and processing speed. Wechsler himself noted the dynamic nature of intellectual abilities, noting that they "appear to behave differently when alone from what they do when operating in concert" (1975, p. 138). Therefore, while the measurement of pure cognitive functions is ideal from theoretical and psychometric standpoints, it does not necessarily result in information that is clinically rich or practically useful in real-world applications (Weiss et al., 2010; Zachary, 1990). Thus the WAIS-IV reflects a balance between theoretically sound cognitive constructs and the need to maintain the predictive value and clinical utility that are central to Wechsler's framework of intelligence.

Criticisms of the WAIS-IV Framework

"It's Atheoretical"

The Wechsler intelligence scales have been criticized for what some perceive as a lack of theoretical orientation (Beres, Kaufman, & Perlman, 2000; A. S. Kaufman & Lichtenberger, 1999; McGrew & Flanagan, 1997). Wechsler selected cognitive tasks for his intelligence battery that were clinically grounded rather than tied to a single theory of intelligence, thus allowing subsequent revisions to incorporate modern advances from a wider array of ongoing clinical and neuropsychological research. As a result, the current editions align and correlate well with tests created more recently and based on specific theories of intelligence, such as the CHC and Luria models. For instance, after analyzing the factor structure of more than 450 datasets, Carroll (1993) revealed the presence of a general intelligence factor, and several studies have provided evidence suggesting that intelligence is composed of specific narrow abilities that appear to cluster into higher-order ability domains (Carroll, 1993; Cohen, 1952, 1957; Horn, 1994). Numerous independent analyses of the WAIS-IV normative sample suggest that the cognitive domains measured by the test align closely with those specified by recent models of intelligence (Benson, Hulac, & Kranzler, 2010; Keith, as cited in Lichtenberger & Kaufman, 2012; Weiss, Keith, Zhu, & Chen, 2013), which include crystallized ability, visual processing, fluid reasoning, working memory, and processing speed. These results suggest that the cognitive constructs measured by the WAIS-IV are similar to those of other tests that are designed around specific theories. This alignment is also supported by the fact that the Wechsler scales correlate highly with theory-based intelligence measures, such as the Kaufman Adolescent and Adult Intelligence Test

(KAIT; A. S. Kaufman & Kaufman, 1993) and the Differential Ability Scales—Second Edition (Elliott, 2007). The totality of this evidence has caused some to rethink their positions regarding the theoretical nature of the Wechsler scales. For instance, Alan S. Kaufman has stated that "I have since reconsidered my stance on the lack of a theoretical framework for Wechsler's scales" (2010, p. xvi), as "the WAIS-IV also was developed with specific theoretical foundations in mind. In fact, revisions were made purposely to reflect the latest knowledge from literature in the areas of intelligence theory, adult cognitive development, and cognitive neuroscience" (Lichtenberger & Kaufman, 2012, p. 20).

"The Index Scores Don't Matter"

Assumptions make a difference in an investigator's approach to factor-analytic studies and to interpretation of those studies' results. One group of researchers takes an approach that is different from the intended test model, assuming that only general intelligence (*g*) is relevant, and not broad cognitive abilities like crystallized intelligence, fluid reasoning, and working memory. Consistent with their assumption, they statistically remove *g* from the index scores and then examine the index scores' residual validity (the *bifactor* model). They then conclude that variance attributed to the first-order factors (the index scores) is too small to be of importance, and that the FSIQ is the only score worth interpreting.

This approach is problematic for a number of reasons. First, individual routing of *g* resources to specific cognitive domains results in greater development of those abilities over time. Thus removing the influence of *g* from the index scores attenuates their power, and creates a rather artificial situation. As Schneider (2013) observed, "the independent portion is not the 'real Gc'. We care about a sprinter's ability to run quickly, not residual sprinting speed after accounting for general athleticism. So it is with Gc: g is a part of the mix" (p. 188).

Second, as noted by Flanagan and Alfonso (2017), even these researchers have published studies demonstrating that these factors have incremental validity in predicting academic outcomes (e.g., Canivez, 2013; Nelson, Canivez, & Watkins, 2013), with up to 2–30% of additional variance explained. Thus the broad factors are worth interpreting.

Finally, in examinees with neurological disorders or brain injuries, discrepancies often characterize the index scores. For example, while the FSIQ may be 100, the Verbal Comprehension Index (VCI) may be much higher than 100, and the Processing Speed Index (PSI) may be much lower. This situation renders the FSIQ insufficient to describe a person's abilities and provide guidance for treatment planning, and it could do the person the disservice of ignoring a real decline in cognitive functioning that should be acknowledged and accommodated. Thus the approach taken by these researchers excludes important information and is too one-sided. Both *g* and the factor index scores are important, and each construct has a place in the practice of assessment.

Test Model and Scores

All Wechsler intelligence scales provide factor-based index scores that measure major cognitive domains identified in contemporary theories of intelligence. The primary advantage of the index scores is their measurement of relatively discrete cognitive domains, which allows a clinician to evaluate specific aspects of cognitive functioning more clearly. For example, individuals with learning disorders may be expected to perform poorly on working memory tasks (Cohen-Mimran & Sapir, 2007; Proctor, 2012; Wechsler, 2008), and individuals with TBI may exhibit poor processing speed skills (Donders & Strong, 2015; Mathias & Wheaton, 2007). The WAIS-IV provides four index scores: the VCI, the PRI, the PSI, and the Working Memory Index (WMI). In addition to these four index scores, it provides the optional General Ability Index (GAI), which is derived from the six FSIQ subtests that contribute to the VCI and the PRI.

The WAIS-IV consists of 15 subtests (10 core and 5 supplemental), three of which are new: Visual Puzzles, Figure Weights, and Cancellation. Figure 16.1 shows the WAIS-IV subtests, as well as the composite scores to which each contributes. Despite the changes made to the WAIS-IV, the correlations with the WAIS-III are high, suggesting that they measure closely related constructs. For example, the two versions' FSIQs correlate .94, and the index scale correlations range from .84 for the PRI (correlated with the Perceptual Organization Index [POI] on the WAIS-III) to .91 for the VCI (Wechsler, 2008).

The WAIS-IV is normed for individuals between the ages of 16 years, 0 months (16:0) and 90:11. The following sections describe the WAIS-IV scales and each composite score that is derived

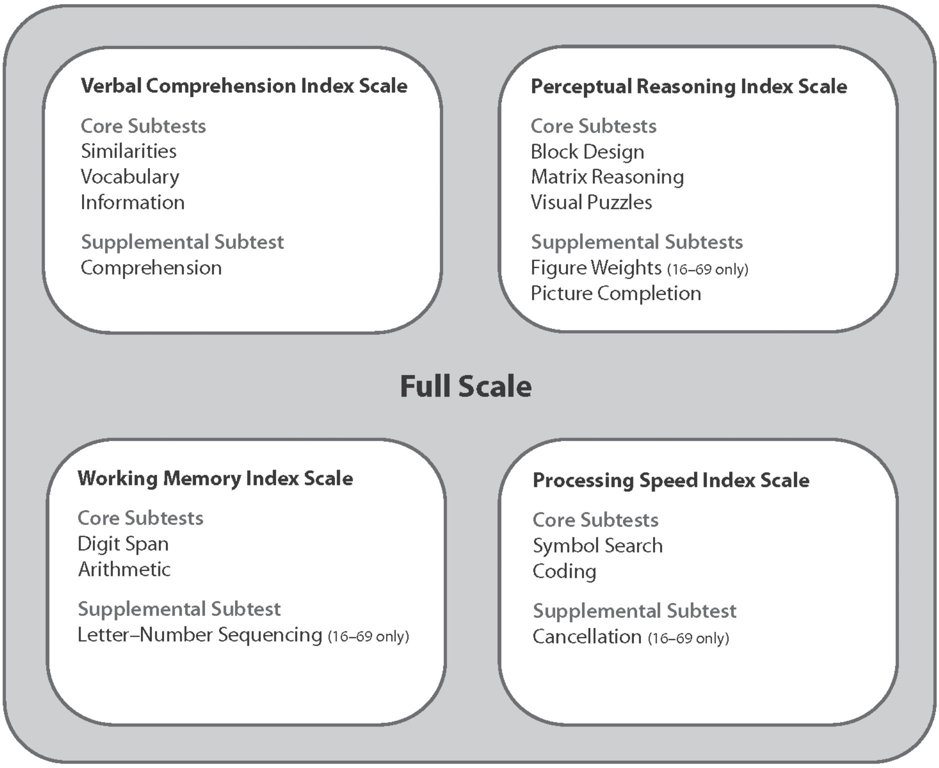

FIGURE 16.1. Test framework of the WAIS-IV. Figures found in the manual for the *Wechsler Adult Intelligence Scale®, Fourth Edition (WAIS®-IV)*. Copyright © 2008 by NCS Pearson, Inc. Reproduced with permission. All rights reserved.

from the core subtests on that scale. General descriptions of the FSIQ, index scores, and subtests are provided elsewhere in this volume (Wahlstrom et al., Chapter 9); thus, rather than focusing on the general nature of the subtests, scales, and index scores that constitute the WAIS-IV, this chapter instead highlights information specific to the WAIS-IV that does not appear in Chapter 9. For example, some subtests that are not described in Chapter 9 are described in the sections that follow.

Full Scale

The Full Scale contains all 15 of the WAIS-IV subtests. The FSIQ is a composite score that estimates an individual's general level of intellectual functioning. It is derived from the sum of 10 core subtest scaled scores. As shown in Figure 16.1, 10 subtests contribute to the WAIS-IV FSIQ: three from the Verbal Comprehension scale, three from the Perceptual Reasoning scale, two from the Working Memory scale, and two from the Processing Speed scale.

As discussed in Chapter 9 (this volume), the FSIQ is considered the score most representative of general intellectual functioning (i.e., *g*), and is a robust predictor of an array of important life outcomes (Deary & Johnson, 2010; Gottfredson, 1997; Gottfredson & Deary, 2004; Hunt & Madhyastha, 2012; Johnson et al., 2011; S. B. Kaufman et al., 2012; Kuncel et al., 2010; Rindermann & Meisengerg, 2009, Schmidt, 2014). Furthermore, *g* consistently emerges in factor-analytic studies—a finding that has been replicated in research using international adaptations of the Wechsler scales (Bowden, Lange, Weiss, & Saklofske, 2008; Georgas, Weiss, van de Vijver, & Saklofske, 2003; Golay & Lecerf, 2011; Weiss et al., 2013).

Verbal Comprehension Scale

There are four subtests on the Verbal Comprehension scale. As shown in Figure 16.1, the VCI is derived from the sum of the three core subtest scaled scores: Similarities, Vocabulary, and Information. If necessary, Comprehension may be used as a substitute for one of the three core Verbal Comprehension subtests in deriving the VCI. Relative to the WISC-V VCI described in Chapter 9, which primarily emphasizes verbal concept formation and verbal reasoning, the WAIS-IV VCI places slightly more emphasis on acquired knowledge.

Perceptual Reasoning Scale

There are five subtests on the Perceptual Reasoning scale: Block Design, Matrix Reasoning, Visual Puzzles, Figure Weights (for ages 16–69 only), and Picture Completion. As depicted in Figure 16.1, the PRI is derived from the sum of the three core Perceptual Reasoning subtest scaled scores: Block Design, Matrix Reasoning, and Visual Puzzles. If necessary, Picture Completion may be used as a substitute for one of the three core subtest scaled scores to derive the PRI. For ages 16–69, Figure Weights may also be used as a substitute.

The PRI is a measure of fluid reasoning, spatial processing, and visual–motor integration. It also reflects working memory and processing speed skills, based on evidence that these abilities are intertwined with fluid reasoning.

Picture Completion

Picture Completion requires the examinee to view a picture and then point to or name the important part missing within a specified time limit. This subtest measures visual perception and organization. It also requires visual discrimination, visual recognition of essential details of objects, crystallized knowledge, reasoning, and visual long-term memory (Lichtenberger & Kaufman, 2012; Sattler & Ryan, 2009).

Working Memory Scale

Three subtests are on the Working Memory scale: Digit Span, Arithmetic, and Letter-Number Sequencing (for ages 16–69 only). As depicted in Figure 16.1, the WMI is derived from the sum of the two core Working Memory subtest scaled scores. If necessary, Letter–Number Sequencing may be used for ages 16–69 as a substitute for one of the core subtest scaled scores to derive the WMI.

In contrast to the WISC-V WMI described in Chapter 9 (this volume), which emphasizes both auditory and visual working memory, the WAIS-IV WMI solely involves auditory working memory. It also draws on quantitative reasoning due to the Arithmetic subtest.

Processing Speed Scale

The Processing Speed scale has three subtests: Symbol Search, Coding, and Cancellation (for ages 16–69 only). As shown in Figure 16.1, the PSI is derived from the sum of the two core subtest scaled scores. If necessary, Cancellation may be used for ages 16–69 as a substitute for one of the core subtest scaled scores to derive the PSI. The PSI is of specific interest on the WAIS-IV, as it is especially sensitive to aging (A. S. Kaufman, 2001; Lichtenberger & Kaufman, 2012), and because processing speed has been hypothesized to underlie age-related declines in other cognitive domains (Salthouse, 2004).

General Ability Index

The GAI is described in Chapter 9 (this volume). It is utilized for all ability–memory comparisons with the WMS-IV to increase the ability to detect discrepancies in individuals with processing speed and working memory deficits, which are commonly observed in individuals with memory deficits (see Glass, Bartels, & Ryan, 2009; Lange & Chelune, 2006; Lange, Chelune, & Tulsky, 2006). However, the GAI should not be used as a substitute for overall ability simply because the WMI and PSI are significantly lower than the VCI and PRI, as working memory and processing speed are important contributors to intelligence (Prifitera, Saklofske, & Weiss, 2005; Weiss et al., 2010). It is best practice to derive and interpret the FSIQ alongside the GAI.

Psychometric Properties

Normative Sample

The WAIS-IV has an excellent normative sample (Sattler & Ryan, 2009). It included 2,200 individuals divided into 13 age bands (see Wechsler, 2008, for detailed descriptions of the age bands). Each age band below 70 years contained 200 examinees, whereas each age band from the ages of 70 to 90 years included 100 examinees. The stratification of the normative sample matched 2005 U.S. census data closely on five key demographic variables: age, gender, race/ethnicity, educational level, and geographic region.

Reliability

The WAIS-IV scores have strong reliability (Wechsler, 2008). First, the overall internal-consistency reliability coefficients for the normative sample are in the .90s for all index scores and .98 for the FSIQ. At the subtest level, the overall internal-consistency reliability coefficients of the normative sample are in the .80s or .90s for all core subtests. In addition, Cancellation is the only supplemental subtest with a reliability below .80, although it is still within the acceptable range (.78). The internal-consistency coefficients of the WAIS-IV subtests calculated from special group samples are very consistent with those obtained from the normative sample, with all subtest coefficients in the .80–.90 range. Second, the test–retest stability coefficients for the WAIS-IV index scores vary from .87 to .96, and the subtest stability coefficients range from .74 to .90. The test–retest stability of the FSIQ is .96. Finally, the interscorer agreement for most WAIS-IV subtests is .98–.99. Even the Verbal Comprehension subtests, which require greater judgment in scoring, have interscorer agreement above .90.

Validity

There is ample evidence to support the validity of the WAIS-IV. The confirmatory factor-analytic studies reported in the test manual provide strong evidence of construct validity and clearly demonstrate that in addition to measuring general intellectual ability, the Wechsler scales measure four cognitive domains: Verbal Comprehension, Perceptual Reasoning, Working Memory, and Processing Speed (Wechsler, 2008). Further evidence of construct validity is provided by independent examinations of the WAIS-IV data. Independent factor-analytic studies verify the factor structure (Bowden, Saklofske, & Weiss, 2011a, 2011b; Ward, Bergman, & Hebert, 2012) and also indicate that the basic factor structure of the WAIS-IV holds for individuals with clinical syndromes such as schizophrenia and TBI (Goldstein & Saklofske, 2010). Similarly, factor analyses in samples of individuals with autism spectrum disorder have revealed factors of verbal comprehension, perceptual reasoning, and freedom from distractibility, as well as a social cognition factor (Goldstein et al., 2008; Goldstein & Saklofske, 2010).

Since the publication of the WAIS-IV, investigators have identified an alternative five-factor structure of the WAIS-IV that also has merit (Benson et al., 2010; Weiss et al., 2013). The factor names proposed by different teams of investigators vary according to the taxonomic systems used, but the names appear to align with Verbal Comprehension, Visual Spatial, Fluid Reasoning, Working Memory, and Processing Speed. In the five-factor model, the multidimensionality inherent in the WAIS-IV PRI is disentangled to reveal unique factors for Visual Spatial (Block Design and Visual Puzzles) and Fluid Reasoning (Matrix Reasoning, Figure Weights, and Arithmetic), similar to the five factor structure of the WISC-V, and consistent with CHC theory (Weiss et al., 2013).

In addition, the WAIS-IV and its predecessors correlate highly with other measures of intelligence. The correlation of the WAIS-IV FSIQ with the WAIS-III FSIQ is .94, and the correlations between index scores are all above .83 (Wechsler, 2008). Moreover, previous versions of the WAIS correlate highly with other measures of intelligence, such as the KAIT and the Stanford–Binet Intelligence Scale: Fourth Edition (Wechsler, 1997). Finally, the WAIS-IV has good concurrent validity, as it correlates highly with composites from the Wechsler Individual Achievement Test—Third Edition (WIAT-III; Pearson, 2009), with correlation coefficients ranging from .42 to .81. In studies with the Delis–Kaplan Executive Function System (D-KEFS; Delis, Kaplan, & Kramer, 2001), the California Verbal Learning Test—Second Edition (CVLT-II; Delis, Kramer, Kaplan, & Ober, 2000), and the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS; Randolph, 1998), high correlations are found between similar constructs, such as the WAIS-IV PRI and RBANS Visuospatial/Constructional scale, and lower correlations between dissimilar constructs, such as WAIS-IV index scores and delayed memory scores on the CVLT-II and RBANS (Wechsler, 2008).

WECHSLER MEMORY SCALE—FOURTH EDITION

Theoretical Underpinnings

The assessment of memory is a key component in many evaluations of cognitive functioning. The measurement of memory ability in evaluations for dementia or mild cognitive impairment is required to make an accurate diagnosis. However, memory is also affected in many other neurocognitive and learning disorders, including TBI, stroke, epilepsy, intellectual disabilities, learning disorders, and autism spectrum disorder (Bauer, 2008; Carlozzi, Grech, & Tulsky, 2014; Eichenbaum, 2008; Squire & Schacter, 2002). Also, many medical and neurological disorders influence memory performance, including multiple sclerosis, HIV/AIDS, lupus, epilepsy, and cancer (Fama, Rosenbloom, Sassoon, Pfefferbaum, & Sullivan, 2012; Lafosse, Mitchell, Corboy, & Filley, 2013; Lindner et al., 2014; Schucard, Lee, Safford, & Schucard, 2011; Soble et al., 2014). Finally, individuals with psychiatric disorders, such as depression, schizophrenia, or bipolar disorder, also exhibit memory difficulties (Grillon, Krebs, Gourevitch, Giersch, & Huron, 2010; Porter, Robinson, Malhi, & Gallagher, 2015; Rock, Roiser, Riedel, & Blackwell, 2014). In addition to memory difficulties known to be associated with specific disorders, knowledge of an examinee's memory ability can be helpful in assessments to help tailor interventions or training programs to a student's learning ability.

The WMS is one of the most popular memory assessment instruments (Rabin et al., 2016). It was first published in 1945 (Wechsler, 1945) and has undergone several revisions since the initial publication (e.g., Russell's WMS [Russell, 1975, 1988]; the WMS-III [Wechsler, 1997]). The changes in the WMS across revisions reflect the growing research on and theories of learning and memory. *Learning* is the process through which new information is acquired, and *memory* is the persistence of learning so it can be recalled at a later time (Squire, 1987). The WMS-IV measures both learning and memory ability. Several key concepts are used across measures of learning and memory and are defined here. For more detailed descriptions of learning and memory processes, theories, and measurement, see Lampinen and Beike (2014), Lezak, Howieson, Bigler, and Tranel (2012), or Squire and Schacter (2002).

While other skills and abilities are involved in memory, the WMS-IV measures the learning and memory constructs of encoding, storage or consolidation, and retrieval of information. *Encoding* is the transformation of external information into mental representations or memories; it reflects the entry of information into the memory system. *Consolidation* is the process through which information in immediate memory is transferred and solidified into or stored in long-term memory stores, and *retrieval* involves retrieving or recalling information from long-term memory stores into active conscious awareness.

Many theories divide memory into short-term memory and long-term memory (e.g., Atkinson & Shiffrin, 1968; Strauss, Sherman, & Spreen, 2006). *Short-term memory* refers to brief, temporary storage of information, lasting from a few seconds to a few minutes. More permanent or long-term memories, lasting from hours to years, are considered *long-term memory*. The WMS-IV measures both short- and long-term memory with the immediate and delayed conditions of Logical Memory, Verbal Paired Associates, Designs, and Visual Reproduction.

Working memory has recently been included as a component of short-term memory. Working memory involves temporary storage and manipulation of information, and the amount of information that can be held in it is very limited. In Baddeley's (2000, 2003) model, the working memory system has multiple components. The *central executive* is a regulatory system that oversees two information activation–storage systems, the *phonological loop* and the *visuospatial sketchpad*. Auditory information is processed and temporarily stored in the phonological loop, and visual information is processed and temporarily stored in the visuospatial sketchpad. In addition to these processes, the *episodic buffer*, regulated by the central executive, transfers information into long-term memory and holds interrelated information in working memory. The central executive controls the flow of information and the attention system, and engages long-term memory as needed. This coordination of cognitive processes by the central executive facilitates learning and other complex cognitive tasks.

Long-term memory is often described as *implicit* (procedural) or *explicit* (declarative) memory. *Implicit* or procedural memory involves learning from experiences without being consciously aware of learning, such as learning to ride a bike or drive a car. *Explicit* or declarative memory involves the conscious storage and retrieval of information, such as personal or factual knowledge. Explicit memory consists of *semantic* and *episodic* memory. *Semantic memory* is the memory for facts and concepts, whereas *episodic memory* is the recollection of personal events and the contexts in which they occur. None of the information required for performance on the WMS-IV is learned prior to the testing session. Therefore, the WMS-IV is primarily a measure of explicit episodic memory, as the "information presented is novel and contextually bound by the testing situation and requires the examinee to learn and retrieve information" (Wechsler, 2009, p. 2).

Test Framework and Scores

Two batteries were developed for the WMS-IV: the Adult and Older Adult batteries. The Older Adult battery contains fewer subtests than the Adult battery and provides a shorter administration time. In addition, the content of the auditory memory subtests differs across the two batteries, with fewer stimuli in the Older Adult battery subtests. These changes have reduced the testing time and improved the subtest floors for older adults. The Adult battery can be used for ages 16–69, and the Older Adult battery is used for individuals ages 65–90. For examinees in the overlapping ages of 65–69, the examiner may select the battery that is more appropriate for the individual being tested.

The WMS-IV Adult battery contains seven subtests, including six primary subtests and one optional subtest. Four of the primary subtests have immediate-recall (I), delayed-recall (II), and delayed-recognition conditions. Scores from the primary subtests combine to create five index scores: the Auditory Memory Index (AMI), the Visual Memory Index (VMI), the Visual Working Memory Index (VWMI), the Immediate Memory Index (IMI), and the Delayed Memory Index (DMI). The WMS-IV Older Adult battery contains five subtests, including four primary subtests and one optional subtest. Three of the primary subtests have both immediate- and delayed-recall conditions and a delayed-recognition condition, which are combined to form four index scores. The VWMI is not available in the Older Adult battery. Unlike the overall FSIQ in the WAIS-IV, there is not an overall memory ability score; index scores are related to specific domains of memory.

Table 16.1 lists the WMS-IV subtests, the conditions within each subtest, and (where applicable) the index scores to which each subtest contributes. For subtests that have both immediate and delayed conditions, the separate conditions are listed in this table. Note that a single subtest may contribute to more than one index. Some subtest conditions produce scores that are not used to derive index scores, but are considered process scores. These are also optional and denoted with parentheses in Table 16.1. Process scores assist

Optional subtests or conditions are in parentheses.

in the interpretation of performance by describing specific skills or abilities required to perform the tasks on the WMS-IV. For example, the Visual Reproduction subtest requires the examinee to draw responses. In order to assess the impact of poor motor ability, a copy condition provides a measure of motor skills. The WMS-IV test models for the Adult battery and Older Adult battery are depicted in Figures 16.2 and 16.3, respectively.

Subtest Descriptions

It is important to note that the factor analyses conducted with the WMS-IV standardization do not include the Brief Cognitive Status Exam (BCSE). In addition, they do not separate the immediate and delayed memory factors, due to the high correlations between these factors (Hoelzle, Nelson, & Smith, 2011; Wechsler, 2009). Although the immediate and delayed factors cannot be separated in factor analyses, they are clinically meaningful and useful (Millis, Malina, Bowers, & Ricker, 1999; Tulsky, Ivnik, Price, & Wilkins, 2003).

Brief Cognitive Status Exam

The BCSE consists of multiple types of items designed to quickly assess various areas of cognitive functioning. The items included in the BCSE were derived from subtests included in the WMS-III (e.g., mental control) or from common mental status and neuropsychological measures (e.g., inhibition). Items include orientation, mental control, incidental memory, clock drawing, inhibition control, and verbal production. Each section of items is used to create a weighted score representing that cognitive ability. The weighted scores are summed to provide an overall BCSE Total Raw Score, which is converted into a classification level indicating the examinee's general cognitive ability.

The BCSE is designed to measure an individual's basic cognitive ability across a variety of tasks. Unlike the comprehensive assessment of cognitive ability provided by the WAIS-IV, the BCSE is intended to provide a quick snapshot of an individual's cognitive status. When the WAIS-IV and WMS-IV are used together, it may not be necessary to administer the BCSE. However, the BCSE provides an opportunity for success early in an assessment session, as most examinees can answer some of the items on the BCSE. Individual items measure orientation to time, mental manipulation of information, incidental memory, planning and organization, the ability to inhibit an overlearned response, and verbal fluency. Other abilities that may be used during this task include confrontation naming, visual perception and attention, processing speed, working memory, planning, cognitive flexibility, auditory comprehension, and verbal expression (Drozdick, Holdnack, & Hilsabeck, 2011; Wechsler, 2009).

Logical Memory

In the Logical Memory subtest, the examinee is read two stories and asked to recall them immediately after presentation and after a 20- to 30-minute delay. Different stories are presented in the Adult and Older Adult batteries. One story in the Older Adult battery is presented twice, creating a multitrial learning task in this age range. Neither story is repeated in the Adult battery. In the delayed recognition task, the examinee answers a series of yes–no questions about details from the stories. Logical Memory measures memory for structured information presented orally. It measures encoding, immediate and long-term retrieval, and recognition of organized, sequentially related auditory information. It also involves auditory comprehension, receptive and auditory language, auditory working memory, auditory attention and concentration, and hearing acuity (Drozdick et al., 2011; Groth-Marnat & Wright, 2016; Lichtenberger, Kaufman, & Lai, 2002). There is a long history of clinical and concurrent validity for Logical Memory (see Lezak et al., 2012, for a review). This subtest contributes to the AMI, IMI, and DMI.

Verbal Paired Associates

In Verbal Paired Associates, the examinee is read a series of paired words. The pairs are either related (e.g., *cat–dog*) or unrelated (*rain–pencil*). After being presented the list, the examinee is read the first word of each pair and asked to recall the second word. If the examinee misses an item, the correct word is given. Four learning trials are given during the immediate condition. Following a 20- to 30-minute delay, the examinee completes three delayed-memory tasks: delayed recall, word recall, and recognition. In the delayed-recall condition, the examinee recalls the second word in each pair again. In the recognition condition, the examinee recalls the second word pair and asked to indicate whether it is a pair from the list. In the word recall condition, the examinee is asked to recall the individual words from the word pairs; no cues are provided, and the examinee does not have to recall the words in pairs.

Verbal Paired Associates measures the ability to learn and retrieve semantically associated and unassociated words presented orally. It involves short-term auditory learning, long-term cued and recognition auditory memory, and associative memory. Other skills include auditory perception and comprehension, auditory working memory or rehearsal, expressive and receptive language, and hearing acuity (Groth-Marnat & Wright, 2016; Holdnack & Drozdick, 2010; Lichtenberger et al., 2002). Like Logical Memory, Verbal Paired Associates has a long history of clinical and concurrent validity studies (see Lezak et al., 2012, for a review). This subtest contributes to the AMI, IMI, and DMI.

Designs

Designs requires the examinee to view a 4 × 4 grid with designs in some of the cells in the stimulus book. Following exposure, the grid is removed from view, and the examinee uses a blank grid and design cards to reproduce the image from memory. Four grids are shown and recalled both immediately and following a 20- to 30-minute delay. A delayed-recognition condition is included in which the examinee selects the two cards displayed in a pictured grid that match the correct design and location as shown in the immediate condition. This subtest measures the ability to recall visual details and spatial information for abstract designs. It involves memory for visual detail and spatial memory; encoding and immediate and long-term retrieval of visual and spatial information; visual perception and organization; self-monitoring; and auditory comprehension. It also involves visual acuity, visual working memory, and gross motor ability (Drozdick et al., 2011; Groth-Marnat & Wright, 2016; Holdnack & Drozdick, 2010). This subtest contributes to the VMI, IMI, and DMI in the Adult battery. It is not included in the Older Adult battery.

Visual Reproduction

For each Visual Reproduction item, the examinee is shown a design for 10 seconds and then asked to draw the design from memory. A total of five designs are shown sequentially, with recall both immediately after presentation and following a 20- to 30-minute delay. Performance on Visual Reproduction is affected by motor constructional abilities (Gfeller, Meldrum, & Jacobi, 1995; Larrabee & Curtiss, 1995). An optional copy condition is available to assess the influence of motor difficulties. The scoring reflects the memory aspects of recall instead of motor accuracy. Visual Reproduction is designed to assess immediate and long-term visual memory for abstract designs. It also involves visual–motor coordination, visual–spatial construction, visual perception and organization, processing speed, planning, self-monitoring, and language ability (Drozdick et al., 2011; Groth-Marnat & Wright, 2016; Lezak et al., 2012). This subtest contributes to the VMI, IMI, and DMI.

Spatial Addition

Spatial Addition requires the examinee to look at two grids, shown sequentially, which contain blue and/or red circles. The examinee is instructed to remember the locations of the blue circles and to ignore the red circles. After being shown both grids, the examinee creates a new grid by placing cards in a blank grid based on a set of rules. This subtest measures visual–spatial working memory. It also involves visual perception and organization, executive functions, and gross motor ability (Drozdick et al., 2011; Groth-Marnat & Wright, 2016). This subtest contributes to the VWMI in the Adult battery. It is not included in the Older Adult battery.

Symbol Span

For each Symbol Span item, the examinee is shown an array of abstract symbols. The array is then removed, and the examinee is shown a second array of symbols containing both the symbols the examinee was shown previously and distractor symbols. The examinee must select the correct symbols in the order presented in the original array. Partial credit is awarded for selecting the correct symbols in an incorrect order. The task involves visual-sequencing working memory. It also involves mental manipulation of visual material, attention, mental flexibility, visual–spatial imaging, and visual perception and attention (Drozdick et al., 2011; Groth-Marnat & Wright, 2016). This subtest is included in both the Older Adult and Adult batteries, but only contributes to the VWMI in the Adult battery.

Index Descriptions

The WMS-IV index scores measure major domains of memory, whereas the subtest scores measure specific aspects of memory. For example, the AMI score summarizes an individual's performance across subtests designed to measure auditory memory, while Logical Memory and Verbal Paired Associates measure more specific aspects of auditory memory. An individual can obtain an average AMI with multiple ranges of subtest scores—for example, average scores on all contributing subtests, or above-average scores on Logical Memory and below-average scores on Verbal Paired Associates. Therefore, it is important to evaluate performance on index scores in the context of the performance on the contributing subtests.

Auditory Memory Index

The AMI is a measure of memory for orally presented information, both immediately and following a delay. It requires auditory attention, comprehension, and retrieval, and receptive and expressive language ability (Groth-Marnat & Wright, 2016; Wechsler, 2009). It consists of the Logical Memory and Verbal Paired Associates immediate- and delayed-recall conditions. It is composed of the same subtests across both batteries.

Visual Memory Index

The VMI is a measure of memory for information presented visually—specifically, abstract visual designs and spatial information. It measures visual perception and organization, as well as immediate and delayed recall and recognition of visual and spatial details (Groth-Marnat & Wright, 2016; Wechsler, 2009). It consists of the Designs and Visual Reproduction immediate and delayed conditions in the Adult battery. For the Older Adult battery, it consists of the Visual Reproduction immediate and delayed conditions.

Visual Working Memory Index

The VWMI is a visual analogue to the WAIS-IV WMI, which measures auditory working memory. It involves attending to, encoding, mentally manipulating, organizing, and recalling visual and spatial information (Groth-Marnat & Wright, 2016; Wechsler, 2009). It consists of the Spatial Addition and Symbol Span subtests and is only available in the Adult battery. The WAIS-IV WMI contains auditory working memory tasks, whereas the WMS-IV VWMI contains visual and spatial working memory tasks. The primary benefit of this structure is interpretive clarity, as some theories of working memory posit distinct systems underlying visual and auditory information processing (Baddeley, 2003).

Immediate Memory Index

Performance on the IMI is an indication of an examinee's ability to recall presented information immediately. It is a good indication of the examinee's ability to encode auditory and visual information. It consists of the immediate-recall conditions of Logical Memory, Verbal Paired Associates, Designs, and Visual Reproduction in the Adult battery, and the immediate-recall conditions of Logical Memory, Verbal Paired Associates, and Visual Reproduction in the Older Adult battery. Since it includes measures of auditory and visual memory, discrepancies between performances on these modalities will affect performance on this index.

Delayed Memory Index

Performance on the DMI is an indication of the examinee's ability to recall presented information following a delay in which other tasks are being completed. It is a good indication of an examinee's ability to consolidate and retrieve auditory and visual information. Although the Designs subtest includes aspects of recognition memory, recognition tasks are not included in the DMI. The DMI consists of the delayed-recall conditions of Logical Memory, Verbal Paired Associates, Designs, and Visual Reproduction in the Adult battery, and the delayed-recall conditions of Logical Memory, Verbal Paired Associates, and Visual Reproduction in the Older Adult battery. Since it includes measures of auditory and visual memory, discrepancies between performances on these modalities will affect performance on this index.

Psychometric Properties

Normative Sample

The WMS-IV has excellent normative samples, with 900 individuals included in the Adult battery sample and 500 included in the Older Adult battery sample. The samples were divided into 14 age bands (9 in the Adult battery and 5 in the Older Adult battery), with 100 individuals in each age band (see Wechsler, 2009, for detailed descriptions of the age bands). The stratification of the normative sample matched 2005 U.S. census data closely on five key demographic variables: age, gender, race/ethnicity, educational level, and geographic region.

The co-collection of the WAIS-IV and WMS-IV normative samples provided the opportunity for the mean ability level for each WMS-IV age band to be set at a GAI of 100, without requiring weighting of the normative sample. This ensured that the norms for the WMS-IV were not biased due to a high- or low-ability sample. In addition, the normative sample was screened for cognitive impairment and suboptimal effort.

Reliability

The reliabilities for the WMS-IV are good to excellent (Groth-Marnat & Wright, 2016; Wechsler, 2009) as indicated by internal-consistency and test–retest reliability estimates and interscorer agreement rates. The overall internal-consistency reliability coefficients for the normative samples are in the .90s for all index scores. At the subtest level, the overall internal-consistency reliability coefficients of the normative samples are in the .80s or .90s for all of the primary subtest scores, with the exception of Verbal Paired Associates II in the Older Adult battery. The lower reliability (.74) in this subtest is due to the small range of scores available in this measure. The internal-reliability coefficients for the process scores are lower, ranging from .74 to .77. The internal-consistency coefficients calculated using clinical samples are generally higher but fairly consistent with those obtained from the normative group, with all subtest coefficients in the .86–.97 range. The test–retest stability coefficients for the WMS-IV tend to be lower than those observed in the WAIS-IV, due to ceiling effects, fluctuations in motivation, and practice effects, which are observed in most memory measures (Strauss et al., 2006). Stability coefficients for the index scores range from .80 to .87, and the subtest stability coefficients range from .64 to .79. The test–retest stability of the process scores ranges from .59 to .76. All WMS-IV subtests have interscorer agreement above .90, with most WMS-IV subtests at .98–.99.

Validity

There is strong evidence to support the validity of the WMS-IV (Drozdick et al., 2011; Groth-Marnat & Wright, 2016; Wechsler, 2009). The confirmatory factor-analytic studies reported in the WMS-IV technical and interpretive manual provide strong evidence of construct validity for the AMI, VMI, and VWMI. As described earlier, the IMI and DMI are not supported by factor-analytic studies, due to the high correlation of these indexes. Further evidence of construct validity has also been provided by independent examinations of the Adult battery normative sample. A series of exploratory principal-component analyses conducted by Hoelzle and colleagues (2011) on each of the Adult battery normative age bands supported a two-factor structure for the WMS-IV, differentiating auditory and visual factors. This study failed to differentiate the VMI and VWMI, but confirmed the visual factor. Factor analyses examining the WAIS-IV and WMS-IV together also support the construct validity of the instruments (Drozdick, Holdnack, Weiss, & Zhou, 2013; Miller, Davidson, Schindler, & Messier, 2013).

In addition to factor-analytic support, the WMS-IV correlates highly with its predecessor and with other memory measures. The WMS-IV technical and interpretive manual (Wechsler, 2009) reports the correlations of the WMS-IV with the WMS-III, WMS-III Abbreviated, CVLT-II, and Children's Memory Scale (CMS; Cohen, 1997). In general, the correlations with the WMS-III are high, although they are lower in the visual memory domain because of the significant changes to visual memory measures in the WMS-IV. With regard to the other memory measures, the correlations are low to moderate, with higher correlations in measures assessing similar constructs (e.g., the AMI with Verbal Immediate Memory in the CMS). Finally, the WMS-IV has good predictive validity, as it correlates highly with related composites from the WIAT-II (Harcourt Assessment, 2005), with correlation coefficients ranging from .29 to .77. Correlations with the D-KEFS, RBANS, Texas Functional Living Scales (Cullum, Saines, & Weiner, 2009), and Independent Living Scales (Loeb, 1996) are also reported; these support the concurrent validity and structure of the WMS-IV (Cullum et al., 2009; Wechsler, 2009).

ADMINISTRATION OPTIONS

The WAIS-IV and WMS-IV can be administered digitally via the Q-interactive™ system. Briefly, the Q-interactive system allows an examiner to administer tests by using two tablets connected via Bluetooth. The examiner uses one to read instructions, record and score examinee responses, and send visual stimuli to the examinee's tablet. The examinee uses the other to view and respond to visual stimuli. Q-interactive is described in more detail elsewhere in this volume (Wahlstrom et al., Chapter 9). Furthermore, an in-depth review of the WAIS-IV on Q-interactive can be found in Cayton, Wahlstrom, and Daniel (2013).

The WAIS-IV and WMS-IV in digital format are scored by using the same normative data as those for the original paper-based tests. As a result, the approach to "digitizing" the tests has been conservative, in order to ensure construct and total raw score equivalence across the two formats (e.g., whether in paper or in digital format, WAIS-IV Block Design requires the examinee to use the traditional blocks; WAIS-IV processing speed tasks and WMS-IV Visual Reproduction require paper response booklets; and WMS-IV Designs requires the physical grid and cards). The conservative design approach and continued use of manipulatives ensure that the response processes used to complete the tasks are identical regardless of whether the tests are given in digital or paper format, and it allows for similar interpretation of test results in both modalities.

Although the design approach to the WAIS-IV and WMS-IV was guided by the requirement of construct equivalence, it is possible that scores could differ between the digital and paper formats for reasons the development team did not anticipate, which could negate the use of the paper norms to score the tests administered in digital format. In order to test this assumption of equivalence, studies were conducted that compared the raw scores obtained between paper and digital administrations of the WAIS-IV and WMS-IV (Daniel, 2012, 2013). Different research designs were utilized across the studies, but for each it was determined a priori that equivalence would be defined by an effect size of less than or equal to 0.20 (i.e., slightly over 0.5 scaled score points).

In the WAIS-IV study, each examiner administered half of the subtests in paper format and the other half of the subtests in digital format, with the order counterbalanced so that every subtest was administered in both paper and digital format. For each subtest, the format effect was calculated by comparing the score from the digital format to a predicted score obtained from the other subtests administered in paper format, scores from the WAIS-IV normative sample, and demographic variables. Scores obtained from the digital format that were significantly higher or lower than the predicted score would indicate a significant format effect. The results of this initial study suggested that 12 of 15 subtests were equivalent, with Coding, Information, and Picture Completion all yielding effect sizes greater than 0.20. Picture Completion was found to be more difficult in the digital format. This was determined to be due to subtle differences in the clarity of the stimuli. When the clarity of the art for the digital format was adjusted to match more closely what was seen on paper, a follow-up study confirmed that there was not a significant format effect. Coding was easier in the initial study—which is a curious finding, considering that the examinee completes the task in a response booklet in both the paper and digital formats, and that the only digital adaptation of this task involved replacing a hand-held stopwatch with a timer on the Practitioner Device. Investigation revealed that an issue with the timer calibration was allowing additional time in the digital format. When this issue was corrected, the format effect dropped below 0.20. Finally, Information was determined to be more difficult in the digital format, with no apparent explanation of the reason why, since the questions are asked and answered verbally in the same manner as in the paper format. Follow-up analysis of the paper Information cases found that when the same prediction analysis was applied to them, scores were also lower than what the predicted score suggested. The reason for this sample effect is unknown, but when accounted for the digital format effect was within a priori standards.

The WMS-IV study utilized three different study designs: (1) an equivalent-groups method, in which individuals were randomly assigned to take the tests in either paper or digital format; (2) a test–retest design, in which examinees took the subtests in both paper and digital format in a counterbalanced order; and (3) a dual-capture method, in which video-recorded administrations of tests were scored by examiners using either the paper or digital format. More detail about why these study designs were selected can be found in Daniel (2013), but note that that the dual-capture design was deemed appropriate only for subtests where the stimulus presentation and the examinee's response do not require a tablet (e.g., Logical Memory). In these subtests, the only threat to equivalence is the examiner's interaction with the tablet. Overall, the studies indicate no format effects between paper and digital administrations of WMS-IV subtests.

One question of particular interest is whether older individuals, who have less digital experience than their younger counterparts (Hart, Chaparro, & Halcomb, 2008), might struggle with the digital format of the WAIS-IV and WMS-IV. The WAIS-IV equivalence study found no correlation between format effect and age, which suggests that this is not the case. Perhaps this result is not surprising. Because of the conservative design approach mentioned above, there are few requirements for the examinee to interact with the tablet. Many subtests do not require a tablet at all, and even those that use the tablet to log an examinee's responses (e.g., Matrix Reasoning) require only a simple tap. In addition, the responses are numbered so that if need be, the examinee can provide the response verbally.

These findings, in conjunction with the overall lack of format effects, suggest that the WAIS-IV and WMS-IV can be administered in either format, and that the reliability and validity information that has been established with the original normative samples can be applied to both. Furthermore, interpretation of the subtests is unchanged by format.

CLINICAL APPLICATIONS

Because the Wechsler intelligence scales are reliable and valid instruments for comprehensive assessment of general cognitive functioning, clinicians have found many clinical applications of these instruments. The WAIS-IV is one of several key instruments for the assessment or diagnosis of (1) psychoeducational and developmental disorders, such as developmental delay, developmental risk, intellectual disabilities, learning disabilities, ADHD, language disorders, motor impairment, and autism; (2) intellectual giftedness; (3) neuropsychological disorders, such as TBI, Alzheimer disease, Huntington disease, Parkinson disease, multiple sclerosis, and temporal lobe epilepsy; and (4) alcohol-related disorders, such as chronic alcohol abuse and Korsakoff syndrome. In addition to the many clinical validation studies reported in the WAIS-IV technical and interpretive manual (Wechsler, 2008), please refer to Lichtenberger and Kaufman (2012), Sattler and Ryan (2009), and Weiss and colleagues (2010) for more detailed discussion of the clinical utility of the WAIS-IV.

The various editions of the WMS are among the mostly widely used assessments of memory functioning (Rabin et al., 2016). The WMS-IV can be an instrumental component of any evaluation involving memory functioning, including evaluations of (1) memory complaints, such as those seen with dementia, depression, and mild cognitive impairment; (2) neuropsychological disorders, such as brain injury or insult, temporal lobe epilepsy, or multiple sclerosis; (3) medical disorders involving memory difficulties, such as lupus, systemic illnesses, or central nervous system infections; (4) psychiatric disorders that influence memory functioning, such as depression, anxiety, or schizophrenia; (5) learning disorders; and (6) substance use disorders or exposure to toxic substances, such as Korsakoff syndrome or heavy-metal exposure. See the WMS-IV technical and interpretive manual (Wechsler, 2009) for the clinical validation studies of the WMS-IV. In addition, see Drozdick and colleagues (2011), Groth-Marnat and Wright (2016), Lichtenberger and colleagues (2002), and Strauss and colleagues (2006) for more information on clinical utility of the WMS-IV and WMS-III.

A number of issues need to be considered when clinicians are administering the WAIS-IV and WMS-IV in conjunction with each other. First, the WMS-IV should be administered prior to the WAIS-IV if they are given during the same testing session. Zhu and Tulsky (2000) found small order effects on the WMS-III when it was administered following the WAIS-III, but not vice versa. Second, as described previously, the GAI is used instead of the FSIQ for ability–memory comparisons. Finally, the WAIS-IV and WMS-IV both assess working memory. Although they measure different modalities, only one of the index scores needs to be obtained if modality-specific weaknesses are not observed.

INTERPRETATION

In addition to the basic interpretation steps and procedures suggested in the technical and interpretive manuals of the WAIS-IV and the WMS-IV (Wechsler, 2008, 2009), many interpretation strategies, methods, and procedures developed by experienced clinicians and researchers for the previous and current versions of the Wechsler intelligence scales are valid and useful (Lichtenberger & Kaufman, 2012; Sattler & Ryan, 2009; Weiss et al., 2010). Although a detailed discussion of interpretation strategies, methods, and procedures is beyond the scope of this chapter, the following interpretive considerations may help readers understand the nature of clinical interpretation. However, these suggestions should not be used as a "cookbook" or comprehensive guideline for interpretation. Clinical interpretation is a very complicated hypothesis-testing process that varies across evaluations. Therefore, no single approach will work for all scenarios, and WAIS-IV and WMS-IV data should always be interpreted within the context of such information as medical and psychosocial history, behavioral observations, and referral questions.

Basic Interpretation of Wechsler Scores

Scores

The Wechsler scales utilize two types of standard scores: scaled scores and composite scores (i.e., FSIQ and index scores). Converting raw scores into standard scores allows clinicians to interpret scores within the Wechsler scales and between the Wechsler scales and other related measures. The scaled scores and composite scores are age-corrected standard scores that allow comparison of each individual's cognitive functioning with other individuals in the same age group.

Scaled scores are derived from the total raw scores on each subtest. They are scaled to a metric with a mean of 10 and a standard deviation (*SD*) of 3. A subtest scaled score of 10 reflects the average performance of a given age group. Scores of 7 and 13 correspond to 1 *SD* below and above the mean, respectively, and scaled scores of 4 and 16 deviate 2 *SD*s from the mean.

Composite scores (e.g., the FSIQ, PRI, and AMI) are standard scores derived from various combinations of subtest scaled scores. They are scaled to a metric with a mean of 100 and an *SD* of 15. A score of 100 on any composite defines an average performance. Scores of 85 and 115 correspond to 1 *SD* below and above the mean, respectively, and scores of 70 and 130 deviate 2 *SD*s from the mean.

In general, standard scores provide the most accurate descriptions of test data. However, for individuals unfamiliar with test interpretation, standard scores are often difficult to understand. Other methods, such as percentile ranks and verbal descriptive classifications, are often used in conjunction with standard scores to describe an examinee's performance. Composite scores should be reported with confidence intervals, so that each score is evaluated in light of the score's reliability. Confidence intervals delineate a range of scores in which the examinee's true score is most likely to fall and remind the examiner that the observed score contains measurement error.

For several process scores on the WMS-IV, the majority of individuals in the normative sample obtained perfect or near-perfect scores, resulting in a skewed distribution of raw scores. Cumulative percentage ranges are used to describe performance for these scores (i.e., >2%, 3–9%, 10–16%, 17–25%, 26–50%, 51–75%, and >75%). Cumulative percentages describe the percentage of individuals who obtained the same or lower score on a task as the examinee. For example, a cumulative percentage range of 51–75 means that the examinee scored as well as 51–75% of the normative sample.

Level of Performance

The composite scores can be characterized as falling within a certain level of performance (e.g., superior, high average, average, low average). The *level of performance* refers to the rank obtained by an individual on a given test, compared to the performance of an appropriate normative group. The descriptive classifications corresponding to the WAIS-IV and WMS-IV composite scores are presented in Table 16.2.

TABLE 16.2. Descriptive Classifications of WAIS-IV and WMS-IV Composite and Index Scores

Score	Classification	Percent included in theoretical normal curve
130 and above	Very superior	2.2
120–129	Superior	6.7
110–119	High average	16.1
90–109	Average	50.0
80–89	Low average	16.1
70–79	Borderline	6.7
69 and below	Extremely low	2.2

Descriptive classifications allow communication of results in terms most individuals can comprehend. Test results can be described in a manner similar to the following example: "Compared to individuals of similar age, the examinee performed in the low average [descriptive classification] range on a measure of general intelligence [domain content]."

For clinical evaluations, the level of performance provides an estimate of the presence and severity of relative strengths or weaknesses in an individual's performance. This can help with clinical decisions for individuals whose level of performance is significantly lower than that of the normative group, either overall or within specific cognitive or memory domains. Alternatively, clinical decisions can be based on relative strengths and weaknesses within an individual's scores (e.g., a specific score is significantly lower than the individual's other scores, representing an intraindividual weakness).

Description of Composite Scores

For both the WAIS-IV and the WMS-IV, the composite scores are more reliable than the subtest scaled scores, and in general they are the first scores examined by the practitioner. On the WAIS-IV, the FSIQ is typically the first score reported and described, as it is the most reliable score and describes the examinee's general intellectual functioning. The standard score is typically provided, as well as the percentile rank and the confidence interval surrounding the score.

Although it is the best single-point predictor of cognitive ability, there are many cases in which additional scores are required to portray a person's cognitive ability accurately, especially cases characterized by extreme discrepancies between index scores. See other recently released volumes for guidance on interpreting the FSIQ in cases with extreme index score variability (Lichtenberger & Kaufman, 2012; Weiss et al., 2010). However, note that extreme index score discrepancies do not invalidate the FSIQ; rather, interpretation of the FSIQ should account for the index discrepancies. Regardless of the presence of index discrepancies, the four index scores should always be included with the FSIQ in the first level of interpretation, as differences in index score profiles may yield important clinical information. For example, research using previous editions of the WAIS has demonstrated that several clinical syndromes are characterized by unique index score profiles, including schizophrenia, autism, and TBI (Goldstein & Saklofske, 2010). It is important to note, however, that index score patterns are not diagnostic of such clinical disorders because the index scores tap broad cognitive abilities that may be impaired in several different clinical conditions. For example, working memory is typically impaired in patients with TBI as well as individuals with specific learning disabilities. Thus index score patterns are best thought of as indicating deficits in specific cognitive abilities, but not diagnostic of a specific clinical disorder. Patterns of index scores may be consistent or inconsistent with specific clinical disorders, but they cannot be diagnostic of them because such patterns overlap substantially across different disorders.

Analysis of Discrepancies among Composite Scores

Given the clinical significance of index score differences on the WAIS and WMS (Dori & Chelune, 2004; Goldstein & Saklofske, 2010; Lange & Chelune, 2006; Lange et al., 2006; Wilde et al., 2001) and the impact of extreme index score discrepancies on the interpretation of the FSIQ, composite score discrepancy analyses are an important aspect of WAIS-IV and WMS-IV interpretation. The statistical significance of the discrepancy between a pair of composite scores can be examined within and between the WAIS-IV and WMS-IV.

Three different methods can be used for score comparisons: simple difference, predicted difference, and contrast scaled scores. The simple-difference method can be used to compare scores within the WAIS-IV or WMS-IV, and the contrast scaled score approach can be used for comparing scores within the WMS-IV. In addition, all three methods can be used to evaluate ability–memory discrepancies between the WAIS-IV and WMS-IV.

For the simple-difference and predicted-difference methods, statistical significance and clinical significance of score differences are important concepts to understand. A *statistically significant difference* between scores (e.g., between the VCI and the PRI scores) means that the likelihood of obtaining a similar difference by chance is very low (e.g., $p < .05$) if the true difference between the scores is zero. The level of significance reflects the level of confidence a clinician can have that the difference between the scores, called the *difference score,* is a true difference. Along with statistical significance, it is important to consider the base rate of various difference scores in the general population. Even a statistically significant difference may occur frequently in normally developing and aging individuals. Often the difference between an individual's composite scores is significant in the statistical sense, but occurs frequently among individuals in the general population.

The statistical significance of discrepancies between scores, and the frequency of the difference in the normative population, are two separate issues and have different implications for test interpretation (Holdnack, Drozdick, Weiss, & Iverson, 2013; Sattler & Ryan, 2009). In order for a score difference to be considered clinically meaningful, it should be relatively rare. There are no strict guidelines to determine whether a significant difference is rare, and clinicians are advised to take into account medical history, cultural context, and other factors when making that decision. That being said, Sattler and Ryan (2009) advise that score differences occurring in fewer than 15% of the normative sample should be considered unusual. However, such discrepancies do not necessarily suggest a clinical condition, as at least one index score discrepancy of 23 points is observed in approximately 50% of examinees from both nonclinical and clinical populations (Kaufman, Raiford, & Coalson, 2016; Raiford & Coalson, 2014).

Simple- and Predicted-Difference Methods

The simple-difference method involves the subtraction of an obtained score from a second obtained score. In the predicted-difference method, the ability score is used in a regression equation to calculate a predicted score. The examinee's actual performance is then compared to the predicted score. These methods are easy to compute and to interpret. The score difference is identified as either a relative strength or a relative weakness, or no difference is observed between the variables. To determine whether the scores are statistically different, the difference score for each comparison is compared to the established cutoff required for statistical significance. The WAIS-IV and WMS-IV administration and scoring manuals provide clinicians with the minimum differences between index scores required for statistical significance at the .15 and .05 levels by age group. The manuals also provide base rates of the various index score discrepancies in the normative sample. The WMS-IV technical and interpretive manual also provides this information for the ability-memory discrepancies.

Contrast Scaled Score Method

The contrast scaled score methodology applies standard norming procedures to adjust a dependent measure by a control variable. These scores answer specific clinical questions, such as "Is the DMI above or below average, given the examinee's IMI score?" Tables for deriving the contrast scaled scores for the WMS-IV indexes are found in the WMS-IV administration and scoring manual. The tables for deriving the ability–memory contrast scaled scores are found in the WMS-IV technical and interpretive manual. A contrast scaled score is interpreted in the same manner as all scaled scores. For example, a 53-year-old examinee with a GAI of 120 and a DMI of 95 would obtain a contrast scaled score of 6, indicating borderline delayed-memory ability given the examinee's general ability.

Evaluation of Subtest Strengths and Weaknesses

Cognitive profiles describe an examinee's relative strengths and weaknesses. It is very common for examinees to perform better on some subtests than on others, and for practitioners to want to interpret these differences as meaningful. Given the frequency of subtest variation, the risk of overinterpretation is high. Practitioners can minimize this risk by assessing subtest strengths and weaknesses in the context of referral questions, as well as all sources of corroborating and contradicting evidence.

However, there are many situations in which subtest-level differences are important (e.g., neuropsychological evaluation of individuals with focal brain damage, interpretation of composite scores with only two subtests contributing), and the Wechsler scales provide three types of subtest score comparisons for these situations: comparison to the mean subtest score, difference scores, and contrast scaled scores.

First, in order to identify subtest strengths or weaknesses, the WAIS-IV provides the minimum difference between a single subtest and the mean of all 10 core subtests required for statistical significance at the .15 and .05 levels, as well as the base rates of these differences. Second, for cases in which it is more appropriate to compare two subtest scores directly (e.g., Digit Span and Arithmetic within the context of interpreting the WMI), the WAIS-IV provides the difference between all possible pairs of subtests required for statistical significance at the .15 and .05 levels, as well as the base rate information for the differences. The WMS-IV provides the same information for specified subtest comparisons. Finally, contrast scaled scores are provided for several WMS-IV subtest comparisons. For more advanced approaches to clinical interpretation of the WAIS-IV and WMS-IV, see Holdnack and colleagues (2013).

Appendix 16.1 provides a case study that demonstrates how the WAIS-IV and WMS-IV can be integrated into a comprehensive evaluation. All personally identifiable information has been altered in the case study report to preserve the confidentiality of the examinee.

APPENDIX 16.1

Brief Case Study

Examinee: Elizabeth H.
Report date: 6/13/2020
Age: 72 years
Date of birth: 2/18/1948
Gender: Female
Years of education: 14
Tests administered: Wechsler Adult Intelligence Scale—Fourth Edition (WAIS-IV), Wechsler Memory Scale—Fourth Edition (WMS-IV)

REASON FOR REFERRAL

Mrs. H. was referred for an evaluation by her primary care physician, Dr. Jordan Lane, due to concerns about her memory and ability to manage her medications.

HISTORY

Mrs. H. is a 72-year-old widowed female who was born in the United States to parents who were first-generation immigrants from Mexico. She speaks English as her primary language and has 14 years of education in the United States. She attended college for 2 years before marrying and raising five children. She has good relationships with her children and grandchildren, and is active in several church and charity groups. She currently lives alone with some assistance from her children. Recently her children have noticed that she frequently misplaces items, repeats stories, and has trouble organizing her bills and calendar. Mrs. H. denies significant problems, but reports feeling more tired and admits forgetting where she places things. She also reports that it is harder for her to learn new things, and that she is sometimes overwhelmed by preparing for meetings and appointments.

BEHAVIORAL OBSERVATIONS

Mrs. H. was well groomed and polite. She exhibited appropriate behavior throughout the assessment. She was alert and oriented to time and place. She appeared to give forth good effort and did not require redirection to the testing. She appeared to fatigue easily, however, and several breaks were given to allow her to rest and refocus on testing.

TEST RESULTS

Mrs. H. completed the 10 core subtests of the WAIS-IV (see Tables 16.A.1 and 16.A.2 for her composite and subtest scores, respectively). She obtained a Full Scale IQ (FSIQ) of 88 (84–92 at the 95% confidence interval), indicating low average overall intellectual functioning in comparison to her same-age peers in the normative sample. Her performance across the index scores shows variability among the skills measured by the FSIQ. Specifically, she demonstrated average verbal comprehension (Verbal Comprehension Index [VCI] = 91 [85–98]) and perceptual reasoning (Perceptual Reasoning Index [PRI] = 100 [94–106]) abilities. However, her auditory working memory (Working Memory Index [WMI] = 80 [74–88]) and processing speed (Processing Speed Index [PSI] = 84 [77–94]) are in the low average range. The General Ability Index (GAI) was also computed in order to examine ability-memory discrepancies. Her GAI of 96 (91–101) indicates that her general verbal and nonverbal problem-solving ability is in the average range.

The WAIS-IV index comparisons for Mrs. H. show that verbal and perceptual reasoning abilities are significantly better than working memory. Similarly, processing speed is significantly lower than perceptual reasoning abilities. FSIQ is significantly lower than GAI. The score profile indicates relative weaknesses in both working memory and processing speed. Subsequently, FSIQ is lower

TABLE 16.A.2. Mrs. H.'s WAIS-IV Subtest Scores

Subtests	Scaled score	Percentile rank
Similarities	8	25
Vocabulary	8	25
Information	10	50
Block Design	8	25
Matrix Reasoning	14	91
Visual Puzzles	8	25
Digit Span	6	9
Arithmetic	7	16
Coding	8	25
Symbol Search	6	9

TABLE 16.A.1. Mrs. H.'s WAIS-IV Composite Scores

Scale	Composite score	Percentile rank	Confidence interval (95%)	Qualitative description
Verbal Comprehension Index (VCI)	93	32	88–99	Average
Perceptual Reasoning Index (PRI)	100	50	94–106	Average
Working Memory Index (WMI)	80	9	74–88	Low average
Processing Speed Index (PSI)	84	14	77–94	Low average
General Ability Index (GAI)	96	39	91–101	Average
Full Scale IQ (FSIQ)	88	21	84–92	Low average

than GAI, due to the impact of significantly lower processing speed and working memory. Although significant index-level variability in performance was observed, significant variability in subtest performance was only observed in the perceptual reasoning domain.

Mrs. H.'s performance on the measures within the PRI was variable. On a task of nonverbal visual–spatial reasoning, she performed above average (Matrix Reasoning = 14); however, scores on measures of nonverbal concept formation and nonverbal reasoning were in the average range (Block Design = 8, Visual Puzzles = 8). It is interesting to note that there were no time constraints on the subtest on which Mrs. H. performed in the above-average range. Her lower performance on the other tests may have been influenced by time constraints. Outside of this relative strength, Mrs. H.'s performance was relatively consistent across subtests and domains.

Mrs. H. also completed the WMS-IV (see Tables 16.A.3 and 16.A.4 for her index and subtest scores, respectively) to examine her memory abilities. Her low average score on the Brief Cognitive Status Exam (BCSE) is consistent with her performance on the WAIS-IV. Her performance across the WMS-IV index scores shows variability. Specifically, she has borderline auditory memory ability (Auditory Memory Index [AMI] = 72 [67–80]) and low average visual and immediate memory abilities (Visual Memory Index [VMI] = 82 [78–87]; Immediate Memory Index [IMI] = 80 [75–87], respectively). However, her delayed memory is extremely low (Delayed Memory Index [DMI] = 67 [62–77]). Mrs. H. appears to be having fairly significant problems with her memory—in particular, her ability to recall information following a delay. On a measure of visual working memory, her performance was in the average range, suggesting relatively intact ability to encode and mentally manipulate visual information.

Mrs. H.'s DMI is significantly lower than her IMI (note that neither the IMI nor the DMI is compared to the AMI or VMI, because they share common subtests). Contrast scores also indicate that delayed memory is extremely low, given her immediate recall ability. The AMI and VMI are not significantly different, suggesting that the memory problems Mrs. H. is experiencing are not specific to either auditory or visual memory.

TABLE 16.A.4. Mrs. H.'s WMS-IV Subtest Scores

Subtests	Scaled score	Percentile rank
Logical Memory I	6	9
Logical Memory II	3	1
Verbal Paired Associates I	6	9
Verbal Paired Associates II	6	9
Visual Reproduction I	8	25
Visual Reproduction II	5	5
Symbol Span	8	25
BCSE	—	Low average

Within the AMI, IMI, and DMI, none of Mrs. H.'s subtest scores were significantly different from the mean of the subtest scaled scores within the domain. However, a significant pairwise difference between Visual Reproduction I and II is evident. This suggests relatively stable performance within domains. The contrast scores for the primary subtest scores revealed relatively consistent performance on Verbal Paired Associates delayed recall when immediate-recall abilities were considered. However, delayed-recall scores on both Logical Memory and Visual Reproduction were unexpectedly low, given her immediate recall ability. Overall, Mrs. H. appears to be having difficulties with long-term memory. In addition, delayed memory appears to be a significant weakness compared to immediate memory.

In addition to the recall conditions, Mrs. H. also completed optional WMS-IV conditions, including the recognition trials for all three delayed-memory conditions—those in Logical Memory, Verbal Paired Associates, and Visual Reproduction; the Word Recall condition of Verbal Paired Associates; and the Copy condition of Visual Re-

TABLE 16.A.3. Mrs. H.'s WMS-IV Index Scores

Scale	Composite score	Percentile rank	Confidence interval (95%)	Qualitative description
Auditory Memory Index (AMI)	72	3	67–80	Borderline
Visual Memory Index (VMI)	82	12	78–87	Low average
Immediate Memory Index (IMI)	80	9	75–87	Low average
Delayed Memory Index (DMI)	67	1	62–77	Extremely low

production. The optional conditions provide additional information about Mrs. H.'s performance on specific subtests. For both verbal memory subtests, recall memory was slightly lower than expected, given the examinee's ability to recognize information. Her performance on Logical Memory II Recognition was extremely low, suggesting that her memory does not improve with cueing and that her problems with delayed memory are due to an inability to encode and retain verbal information. On Verbal Paired Associates Recognition, she performed in the low average range (17–25%) for delayed recognition and word recall (scaled score = 6). The Visual Reproduction optional conditions indicate that Mrs. H. had average recognition (26–50%) for the visual designs. Her ability to copy the designs was also in the average range (26–50%). The recognition and immediate-recall versus delayed-recall contrast scaled scores indicate that delayed free recall is unexpectedly low compared to both recognition and immediate encoding ability, indicating difficulties with encoding and retrieval of visual details and spatial relations among the details. The Visual Reproduction Copy versus Immediate Recall scores show that her immediate-memory performance was lower than expected, given her ability to directly copy the design. Thus the low scores on this subtest are not likely to be attributable to poor motor control.

The WAIS-IV and WMS-IV index comparisons were completed to determine whether Mrs. H.'s memory functioning is consistent with her general cognitive functioning. Table 16.A.5 displays Mrs. H.'s WAIS-IV versus WMS-IV index comparisons, using the predicted-difference method and contrast scores. When the predicted-difference discrepancy model was applied with GAI as the predictor, significant differences were observed between GAI and AMI (base rate = 2–3%), VMI (base rate = 10%), IMI (base rate = 5–10%), and DMI (base rate >1%). These results indicate that memory functioning is significantly lower than expected, considering Mrs. H.'s general problem-solving ability. Her low memory scores are not likely to be attributable to low general ability. The contrast scaled scores also suggest memory problems that are not consistent with her general cognitive abilities. When the GAI was controlled for, her AMI, VMI, IMI, and DMI were all lower than expected.

Mrs. H. was referred for this evaluation due to reports of memory difficulties. Her profile supports the presence of significant memory problems, in addition to problems with processing speed and verbal working memory. Although her performance in most domains was relatively stable, a strength was noted on an untimed measure of nonverbal fluid reasoning.

SUMMARY

Mrs. H. is a 72-year-old widowed female with a history of memory problems. She was administered the WAIS-IV and WMS-IV to determine her general cognitive and memory abilities. Her general intellectual ability is in the low average range, with weaknesses observed in verbal working memory and processing speed. Her memory performance was lower than expected given her general problem-solving ability, with particular problems with delayed memory. Differences were not observed between auditory and verbal memory. It is very likely that Mrs. H. is experiencing mild cognitive impairment.

TABLE 16.A.5. Mrs. H.'s Ability–Memory Discrepancy Analyses and Contrast Scores

	Predicted-difference method				
	Predicted WMS-IV index score	Actual WMS-IV index score	Difference	Critical value	Base rate
AMI	98	72	26	10.41	2–3
VMI	98	82	16	7.89	10
IMI	97	80	17	9.97	5–10
DMI	98	67	31	12.33	<1
Contrast scaled score method					
	WAIS-IV composite	WMS-IV index score	Contrast score		
GAI vs. AMI	96	72	4		
GAI vs. VMI	96	82	6		
GAI vs. IMI	96	80	5		
GAI vs. DMI	96	67	3		
VCI vs. AMI	93	72	4		
PRI vs. VMI	100	82	5		
WMI vs. AMI	80	72	6

CHAPTER 17

The Wechsler Nonverbal Scale of Ability

Assessment of Culturally and Linguistically Diverse Populations

Jack A. Naglieri
Tulio M. Otero

MEASUREMENT OF GENERAL ABILITY

As our environment becomes increasingly diverse in terms of ethnicities, languages, and disabilities/medical fragilities, nonverbal tests of general ability now meet the growing need for cognitive assessment, particularly in North America. Nonverbal tests help address the increased diversity and complexity of a society in which the evaluation of intellectual ability has rapidly become a common practice. Some examinees simply cannot demonstrate their ability through verbal means, and for these persons, nonverbal assessment offers a more effective alternative for obtaining estimates of ability. Researchers have found that nonverbal tests can be used for detecting strengths and weaknesses in children with disabilities (Mayes & Calhoun, 2003), for screening (Webster, Plante, & Couvillion, 1997), for predicting recovery and treatment outcomes (Matson, 2007), and for defining high- versus low-functioning subcategories within disability groups (Bishop, Richler, & Lord, 2006). Nonverbal tests are useful for persons with autism; deafness; speech impairment; traumatic brain injury; limited English proficiency; Intellectual disability; neurocognitive disorders such as dementia and stroke; selective mutism; and other disorders affecting communication (McCallum, 2017).

The assessment of intellectual ability extends as far back as the 1800s. Edouard Séguin, a French psychiatrist developed a test that became known as the *Séguin form board,* which measures a child's ability nonverbally (Pichot, 1948). The test requires placement of various geometric shapes to inserts of the same shape. The form board has since been modified and adapted for use in several other tests and cultures (see Venkatesan & Basavarajappa, 2007, for examples).

The use of nonverbal test questions to assess ability was part of the approach used by the U.S. Army in 1917. Robert Yerkes, then the president of the American Psychological Association, assembled a team of psychologists to design tests that would be used to determine whether Army recruits were fit for military service and advanced training (see Wasserman, Chapter 1, this volume, for a full account). The Army intelligence tests were called the Alpha and Beta, and were designed to be administered to groups of recruits by trained psychological examiners. The Army Alpha was designed to evaluate the general ability of literate English speakers, and the Army Beta was intended for recruits who were illiterate or nonproficient in English. These tests evolved into the Wechsler scales (Naglieri, 2015).

The concept of *general ability,* as measured by traditional IQ tests such as the Wechsler scales, has had a long and successful history in psychology and education—so much so that the tests have been used to define intelligence. There is strong support for a view of the Wechsler scales as good measures of general ability, using both verbal and nonverbal (i.e., visual–spatial) test questions. However, the visual–spatial tests (e.g., Block Design and Visual Puzzles) are often described as measures of *nonverbal ability,* and the verbal tests (e.g., Vocabulary and Similarities) as measures of *verbal ability,* even though Wechsler did not have any intention to measure verbal and nonverbal abilities. In fact, Wechsler did not view verbal and nonverbal tests as measures of two types of intelligence, even though his tests yielded Verbal and nonverbal (Performance) IQs. Wechsler stated that "the subtests are different measures of intelligence, not measures of different kinds of intelligence" (1958, p. 64), and he viewed verbal and performance tests as "equally valid measures of intelligence" (Wechsler & Naglieri, 2006a, p. 1). Furthermore, Bracken and Naglieri (2003) and Naglieri (2003a, 2003b, 2008a, 2008b) have clarified that the term *nonverbal* refers to the *content* of the test, not a type of ability, and that the goal of this type of test is to measure general ability.

Wechsler believed that nonverbal tests would help to "minimize the over-diagnosing of feeblemindedness that was, he believed, caused by intelligence tests that were verbal in content . . . and he viewed verbal and performance tests as equally valid measures of intelligence and criticized the labeling of performance [nonverbal] tests as measures of special abilities" (Boake, 2002, p. 396). Those individuals who have not had the chance to develop proficiency in English do poorly on verbal tests. As a result, their scores on such tests are not good reflections of their general ability to learn, despite their having been exposed to seemingly appropriate instruction. This problem is complicated by the fact that the content of traditional IQ test questions is often similar to that of questions found on tests of achievement.

Traditional IQ tests often include tests of word knowledge—for example, tests that ask the examinee to define vocabulary words or determine how two words are alike. We have described some examples of the similarity of test questions across ability and achievement tests in Chapter 6 of this volume, and similar examples can still be found in the Woodcock–Johnson IV Tests of Cognitive Abilities (WJ IV COG; Schrank, McGrew, & Mather, 2014) and the Woodcock–Johnson IV Tests of Achievement (WJ IV ACH; Schrank, Mather, & McGrew, 2014). For example, the WJ IV COG (like its predecessor in the WJ III) contains a Verbal Comprehension subtest item comparable to "Tell me another word for *small,*" and the WJ IV ACH contains a Reading Vocabulary question similar to "Tell me another word for *little.*" This type of overlap in content artificially increases the correlations between these tests of ability and achievement (thereby distorting the validity of the tests) and raises important questions about the utility of measuring intellectual ability with questions that are clearly achievement-laden. More importantly, however, these test questions pose particular problems for individuals with limited English-language proficiency.

One way to assess ability without the confounding variables of language and knowledge is to use a nonverbal test of ability. This type of test provides a way to assess individuals from diverse linguistic groups, especially those who have limited language skills, as well as children with language impairments. In addition, children who cannot tolerate a lengthy test battery—such as those with autism, those who are inattentive and/or hyperactive, or those who fatigue easily because of traumatic brain injury—are evaluated more easily with nonverbal tests, especially brief ones, than with verbal tests (see Stepler & Brown, 2016).

MEASUREMENT OF GENERAL ABILITY WITH NONVERBAL TESTS

The greatest advantage of a nonverbal test of general ability is that it measures intelligence without using test questions that are unduly reliant on verbal skills. The test questions evaluate *general* ability *nonverbally*—not *nonverbal ability*—via subtests with strong spatial requirements (e.g., blocks to make a design or progressive matrices). The specific administration format and subtests may vary, but the basic concept remains the same. For example, Bracken and McCallum (1998) suggest that an entire ability test must be administered nonverbally and that pantomimed instructions must be used. Others suggest that test directions for administration may be spoken, but that the content of the test questions should not require knowledge of a specific culture (Naglieri, 1997). Another method is to use pictorial directions, as found in the Wechsler Nonverbal Scale of Ability (WNV; Wechsler & Naglieri, 2006a) and the Naglieri Nonverbal Ability Test—Second and Third Editions (NNAT-2 and NNAT3; Naglieri, 2008a, 2016). Nonverbal tests of general ability also differ in the diversity of their subtests. For example, some nonverbal tests consist of one type of item such as the progressive matrix (e.g., the NNAT3), given in either a group or an individual format (e.g., the Naglieri Nonverbal Ability Test—Individual Form [NNAT-I]; Naglieri, 2003b). Another method is to use several different types of nonverbal subtests, as found in the WNV as well as the Universal Nonverbal Intelligence Test—Second Edition (UNIT2; Bracken & McCallum, 2016). Despite their differences in administration methods and subtest content, these nonverbal tests of general ability provide ways to assess a wide variety of individuals fairly, regardless of their educational or linguistic backgrounds and/or disabilities. The goal of fair and equitable assessment is as critical today as it was when the concepts of verbal and nonverbal assessment were introduced in the early 1900s.

Assessment of ability for populations of individuals who vary in educational and linguistic skills has been and continues to be important in the fields of both psychology and education. The initial conceptualization of verbal and nonverbal assessment was stated clearly by Yoakum and Yerkes (1920) when they wrote that the Army Beta (nonverbal) test was used during World War I instead of the Army Alpha (verbal) test to assess soldiers with limited skills in English, to avoid "injustice by reason of relative unfamiliarity with English" (p. 19). Today, as indicated above, there are several different types of nonverbal tests of general ability (for reviews, see Naglieri & Goldstein, 2009; McCallum, 2017). In the remainder of this chapter, we describe an individually administered measure of general ability, the WNV (Wechsler & Naglieri, 2006a).

STRUCTURE AND ADMINISTRATION OF THE WNV

The WNV consists of six subtests that are organized into two forms (one for ages 4–7 years and the other for ages 8–21 years) and two versions (a two-subtest and a four-subtest version). The subtests measure general ability with tasks that vary in specific requirements. Some of the subtests have a strong visual–spatial requirement; others demand recall of spatial information or recall of the sequence of information; and still others involve paper-and-pencil skills. The multidimensionality of these tasks distinguishes the WNV from tests such as the NNAT3 (Naglieri, 2016), which exclusively uses progressive matrices.

Subtests

Most of the WNV subtests have appeared in previous editions of the Wechsler scales and have an established record of reliability and validity for the nonverbal measurement of general ability. The origins and descriptions of the WNV subtests are provided in Table 17.1. Adaptation of the subtests was necessary to accommodate the new pictorial-directions format, identify items that were most appropriate for specific ages, and provide directions in several languages. WNV subtest norms (mean of 50 and standard deviation [*SD*] of 10) and Full Scale score norms (mean of 100 and *SD* of 15) are based on standardization samples collected in the United States and Canada. The subtests are briefly described below.

- *Matrices.* The Matrices subtest requires the examinee to discover how different geometric shapes are spatially or logically interrelated. The multiple-choice items are constructed of geometric figures such as squares, circles, and triangles, in some combination of the colors black, white, yellow, blue, and green. Matrices is always administered (i.e., it is given to examinees in both age bands and is included in both the four- and two-subtest batteries).

- *Coding.* The Coding subtest requires the examinee to copy symbols (e.g., two vertical lines, a dash) that are paired with simple geometric shapes or numbers according to a key provided at the top of the page. Form A is used in the four-subtest battery for ages 4 years, 0 months to 7 years, 11 months (4:0–7:11), and Form B is used in the four-subtest battery for ages 8:0–21:11.

- *Object Assembly.* The Object Assembly subtest consists of items that require the examinee to complete pieces of a puzzle to form a recognizable object, such as a ball or a car. Object Assembly is included in the four-subtest battery of the WNV for examinees ages 4:0–7:11.

- *Recognition.* The Recognition subtest was created for use in the WNV and is included in both the four- and two-subtest batteries for examinees ages 4:0–7:11. It requires the examinee to look at a stimulus (e.g., a square with a small circle in the center) for 3 seconds, and then to choose which option is identical to the stimulus that was just seen. The figures are colored black, white, yel-

TABLE 17.1. Origins and Description of WNV Subtests

Subtest	Origin and description
Matrices	This subtest was adapted from the Naglieri Nonverbal Ability Test—Individual Form (NNAT-I; Naglieri, 2003b). The examinee chooses an option that solves a progressive matrix.
Coding	This subtest was adapted from the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV; Wechsler, 2003). The examinee copies symbols that are paired with simple geometric shapes or numbers using a key that appears at the top of the page.
Object Assembly	This subtest was adapted from the Wechsler Preschool and Primary Scale of Intelligence—Third Edition (WPPSI-III; Wechsler, 2002) and the Wechsler Intelligence Scale for Children—Third Edition (WISC-III; Wechsler, 1991). The child assembles puzzle pieces that make an object (e.g., a car).
Recognition	This is a new match-to-stimulus subtest. The child looks at a page with a design containing geometric patterns for 3 seconds. Then the child chooses which of several options matches the previously viewed stimulus.
Spatial Span	This subtest was adapted from the Wechsler Memory Scale—Third Edition (WMS-III; Wechsler, 1997a). The examinee repeats the examiner's touching of a series of blocks, either in the same order as the examiner or in the reverse order.
Picture Arrangement	This subtest is adapted from the Wechsler Adult Intelligence Scale—Third Edition (WAIS-III; Wechsler, 1997b) and a research version of the Wechsler Intelligence Scale for Children—Fourth Edition—Integrated (WISC-IV Integrated; Wechsler et al., 2004). The examinee puts picture cards in the correct order to tell a logical story within a specified time limit.

low, blue, and/or green, to maintain interest and minimize the likelihood that impaired color vision will influence the scores.

- *Spatial Span.* The Spatial Span subtest requires the examinee to touch a group of blocks arranged in an irregular pattern on an 8½-inch by 11-inch board in the same and reverse order demonstrated by the examiner. Spatial Span is included in both the four- and two-subtest batteries for ages 8:0–21:11.
- *Picture Arrangement.* The Picture Arrangement subtest involves cartoon-like illustrations, which must be put into a sequence that is logical and makes sense. Picture Arrangement is included in the four-subtest battery for examinees ages 8:0–21:11.

Administration

Administration of the WNV starts with short standardized introductions that tell examinees (1) to look at the pictorial directions to understand what to do, and (2) to ask the examiner questions if necessary. These introductions can be provided in English, French, Spanish, Chinese, German, or Dutch. The three steps below provide guidance on administration of the WNV.

1. The first step is to administer the test following standardized directions. These directions include gestures that correspond to the pictorial directions. Pictorial directions are used at step 1 to provide a standardized method of communicating the demands of each task. The pictorial directions show a scene like the one the examinee is in currently. The pictures show an examinee being presented with the question, then thinking about the item, and finally choosing the correct solution. These instructions include actions by the examiner that must be followed carefully, to ensure that the examinee understands the correspondence between the materials and the task. Gestures are used to direct the examinee's attention to specific portions of the pictorial directions and to the stimulus materials, and sometimes to demonstrate the task itself. Sometimes simple statements are also included to convey the importance of both time and accuracy to the examinee.

2. The second step involves using additional directions *as needed* after the standard directions are used. These instructions must be followed exactly and are only given when an examinee is unclear about what he or she is being asked to do. These directions include simple sentences and gestures for further communicating the requirements of

the task. The verbal instructions provide another way to ensure that the examinee understands the demands of the tasks; again, they can be given in English, Spanish, German, French, Chinese, or Dutch. These instructions are only used when two conditions are met: (a) The WNV is administered to an examinee who speaks one of the languages just mentioned; and (b) the examiner or a professional interpreter speaks the same language as the examinee.

3. The third step gives an examiner flexibility to communicate the demands of the task in any form. In general, examiners are given the opportunity to communicate in whatever manner they think will best clarify the demands of the subtest, based on their judgment of an examinee's needs. This may include providing further explanation or demonstration of the task, restating or revising the verbal directions, or using additional words (in a combination of languages, including sign language) to describe the requirements of the task. At no time, however, should an examiner teach an examinee how to solve the items. Instead, the goal is to provide additional help to ensure that the examinee understands the demands of the task. The amount of help provided and the determination about when to stop should both be based on professional judgment.

Using an Interpreter

When an interpreter is used to facilitate communication prior to and during administration, it is important for the interpreter to understand what is and what is not permitted. The interpreter should translate a general explanation of the testing situation for the examinee. It is especially important to translate the introductory paragraph at the beginning of Chapter 3 in the WNV administration and scoring manual (Wechsler & Naglieri, 2006b) before the administration begins. The interpreter must also recognize the boundaries of his or her role in administration. For example, although it is appropriate for the interpreter to translate the examiner's responses to an examinee's response to a sample item, it is not acceptable for the interpreter to make additional statements unless instructed to do so. Importantly, at no time should the interpreter communicate any information that could influence the examinee's scores. See Brunnert, Naglieri, and Hardy-Braz (2009) for more information about working with translators, especially in testing examinees who are deaf or hard of hearing.

SUBTEST ADMINISTRATION TIPS

Administration of the WNV subtests was designed to be straightforward. The WNV administration and scoring manual describes each subtest; the materials needed; start, stop, and reverse rules; scoring; and issues to consider that are unique to each subtest. Below, we highlight the most salient points about individual subtest administration.

- *Matrices.* On this subtest, examiners should be aware of possible responses that may suggest concern. For example, some students who are impulsive may select the option that is mostly but not completely correct. Because the response options were written with varying degrees of accuracy, an examinee who is impulsive may not carefully consider all options. If an examinee is not looking at the options closely, an option that is *almost* correct may be selected. Also important to note is that if an examinee takes a long time to respond (i.e., more than 30 seconds), the examiner may prompt a response.
- *Coding.* On this subtest, the examiner should ensure that the examinee works from left to right and from top to bottom without skipping any items or rows, by providing the appropriate instruction when needed. The examinee can correct mistakes by crossing out the incorrect symbol and writing the new response next to it. The examiner also briefly instructs the examinee to work as quickly as possible. For this reason, examinees should not be allowed to spend too much time making corrections.
- *Object Assembly.* On this subtest, it is important to remember that the examiner should set up the puzzle pieces on the same side of the stimulus book as the examinee's dominant hand, and the stimulus book should be removed before administering the sample item. The examiner should also ensure that the examinee works as quickly as possible. If the examinee is still completing a puzzle when the time limit expires, the examiner should place his or her hand over the puzzle to stop the examinee's progress and then record the examinee's answer. If the examinee seems upset at that point, the examiner should allow the examinee to finish, but should not consider any additional work for scoring purposes. It is also important to remember to begin timing after the last word of the instruction is provided. Note that the puzzle pieces for each item on this subtest are put before the examinee in a specific format *face down*. Once

all the pieces are in front of the examinee, they are turned over in the order indicated by the number on the back of each piece.

- *Recognition.* This subtest requires that the examinee expose each stimulus page for 3 seconds. Examinees are not permitted to turn the pages.
- *Spatial Span.* On this subtest, it is important to arrange the Spatial Span board so that an examinee can reach all cubes on the board easily. Also, the arrangement of the board should allow only the examiner to see the numbers on the back of each blue block. The Spatial Span board should always be placed on the same side of the stimulus book as the examinee's dominant hand. The blocks must be tapped at a rate of one per second, and the examiner should raise his or her hand approximately 1 foot above the Spatial Span board between each tap. If the examinee does not respond after the examiner taps a sequence, the examiner can say, "It's your turn." The examiner should always administer Spatial Span Backward, regardless of the examinee's performance on the initial Spatial Span Forward test.
- *Picture Arrangement.* On this subtest, the examiner should always place the Picture Arrangement cards on the same side of the stimulus book as the examinee's dominant hand. To facilitate administration, the cards for each item of this subtest should be arranged in the order in which they are to be exposed to the examinee. When the examinee completes the item, the examiner should record the sequence and then re-sequence the cards in the presentation order for the next administration. If the examinee is working too slowly, it is permissible to inform the examinee that he or she should work as quickly as possible. If the examinee orders the cards from right to left instead of left to right, the examiner should ask, "Where does it start?" If the examinee is still working when the time limit expires, the examiner should place his or her hand over the story to stop the examinee's progress, and record the examinee's answer. If the examinee seems upset at being stopped while completing the story, the examiner should allow the examinee to finish. No credit can be given for any work completed after the time has expired.

SCORING

Five of the six WNV subtests (i.e., Matrices, Coding, Recognition, Spatial Span, and Picture Arrangement) are scored by summing the number of points earned during administration. The sixth subtest (i.e., Object Assembly) has time bonuses for some items that may be part of the raw score. The raw scores are converted to *T* scores. The sum of *T* scores is converted to a Full Scale score. Percentile ranks and confidence intervals are included in the conversion table. The WNV Scoring Assistant is a computer scoring program that provides scores based on U.S. and Canadian samples. The report-writing feature of the scoring program provides reports for clinicians and parents. The parent report is available in English, French, and Spanish. The scoring program is also linked to the Wechsler Individual Achievement Test—Second Edition (Wechsler, 2001), which allows for comparisons between ability and achievement.

PSYCHOMETRIC PROPERTIES

Standardization

The WNV was standardized in the United States and Canada. The U.S. sample consisted of 1,323 children and adolescents stratified across five demographic variables: age (4:0–21:11); sex; race/ethnicity (described as black, white, Hispanic, Asian, and other); education level (8 years or less of school, 9–11 years of school, 12 years of school [high school diploma or equivalent], 13–15 years of school [some college or associate's degree], and 16 or more years of school [college or graduate degree]); and geographic region (Northeast, North Central, South, and West). Educational level was determined by parental education for examinees ages 4:0–17:11 and by the examinees' own education for ages 18:0–21:11. Approximately 4% of the U.S. normative sample consisted of individuals with limited English skills.

The Canadian sample consisted of 875 examinees stratified across five demographic variables: age (4:0–21:11); sex; race/ethnicity (described as Caucasian, Asian, First Nations, and other); education level (less than a high school diploma; high school diploma or equivalent; college/vocational diploma or some university, but no degree obtained; and a university degree); and geographic region (West, Central, and East). In addition, the Canadian sample consisted of 70% English speakers, 18% French speakers, and 12% speakers of other languages. See the WNV technical and interpretive manual (Wechsler & Naglieri, 2006c) for more details.

Reliability

WNV reliability coefficients are provided for subtest and Full Scale scores by age for the U.S. and Canadian normative samples and for the special groups described in the WNV technical and interpretive manual (Wechsler & Naglieri, 2006b). The reliability coefficients for the U.S. normative sample were .91 for both the two-subtest and four-subtest versions' Full Scale scores across ages, and .74–.91 for the subtests. The reliability estimates for the Canadian normative sample were .73–.90 for the subtests, .90 for the Full Scale score (four-subtest version), and .91 for the Full Scale score (two-subtest version). The reliability estimates for special-group studies (i.e., individuals with giftedness, mild and moderate intellectual disabilities, reading and written expression disorders, or language disorders; English-language learners; and individuals who were deaf or hard of hearing) are provided in the manual. Other information, such as the standard error of measurements (*SEM*), confidence intervals, and test–retest stability estimates for the U.S. and the Canadian normative samples, is also provided in the WNV technical and interpretive manual (Wechsler & Naglieri, 2006c) and administration and scoring manual (Wechsler & Naglieri, 2006b).

Validity

English as a Second Language

As the United States continues to become more diverse, the number of individuals whose primary language is not English has also increased substantially. The largest of these groups is the Hispanic population. Pew research studies indicate this population was dominated by individuals of Mexican origin (66.9%), who resided in the Western (44.2%) and Southern (34.8%) regions of the United States (Motel & Patten, 2015). A report on educational attainment from the U.S. Census in 2015 (Ryan & Bauman, 2016) showed that although dropout rates are lower than in previous years, Hispanics are less likely to have a high school diploma than white non-Hispanics (66.7% and 88.7%, respectively), and less likely to attain a college degree (Krogstad, 2016). These facts make clear the need for psychological tests that are appropriate for examinees from working-class homes with parents who have limited academic and English-language skills. The WNV is useful for assessment of minority children because it yields smaller race and ethnic differences than do intelligence tests with substantially more verbal content, while retaining good correlations with achievement.

Wechsler and Naglieri (2006a) studied the utility of the WNV for a sample of individuals speaking English as a second language (ESL), in comparison to a matched group from the WNV standardization sample. The ESL sample included 55 examinees ages 8–21 years whose native language was not English, who spoke a language other than English at home, and whose parents had resided in the United States for less than 6 years. There were 27 Hispanics and 28 examinees whose primary language was either Cantonese, Chinese, Korean, Russian, or Urdu. This sample earned scores very similar to those of their matched counterparts from the normative sample, with negligible effect sizes for the Full Scale scores from both WNV test batteries, as shown in Table 17.2. Additional information about this sample is available in the WNV technical and interpretive manual (Wechsler & Naglieri, 2006c).

Giftedness

The fact that minority children are underrepresented in classes for the gifted has been and con-

TABLE 17.2. WNV Means, *SD*s, and Effect Sizes for Diverse Populations and Matched Control Groups

	Diverse sample			Control group			
	Mean	*SD*	*n*	Mean	*SD*	*n*	Effect size
Gifted students	123.7	13.4	41	104.2	12.3	41	1.5
English-language learners	101.7	13.4	55	102.1	13.4	55	0.0
Hard-of-hearing students	96.7	15.9	48	100.5	14.2	48	0.3
Profoundly deaf students	102.5	9.0	37	100.8	14.3	37	0.1

Note. Effect size = (X1 – X2)/SQRT [(n1 * SD12 + n2 * SD22)/(n1 + n2)] tinues to be an important educational problem (Ford, 1998; Naglieri & Ford, 2003, 2005). Discussions of this issue have often focused on the types of tests used to evaluate children who may be eligible for gifted programming. Some researchers have argued that the verbal and quantitative contents of some of the ability tests used and procedures followed for identifying students for gifted programming are inconsistent with the characteristics of culturally, ethnically, and linguistically diverse populations (Naglieri & Ford, 2005). Additionally, since IQ has traditionally been measured with verbal, quantitative, and nonverbal questions, students with limited English proficiency and math skills earn lower scores on the verbal and quantitative scales of these tests because they do not have sufficient knowledge of the language or training in math, not necessarily because they are of low ability (Bracken & Naglieri, 2003; Naglieri, 2008a).

The use of measures of ability that demand knowledge of English and math skills was the focus of *McFadden v. Board of Education for Illinois School District U-46* (2013). As we describe in more detail in Chapter 15, this litigation was brought by Hispanic parents who were concerned that their students were significantly underrepresented in gifted education classes. About 40% of the students in the Elgin School District (U-46) were Hispanic, but only 2% of the students in the district's school gifted program were Hispanic. The Court ruled that the use of tests demanding knowledge of English (e.g., the Cognitive Abilities Test, Form 6 [CogAT6]; Lohman & Hagen, 2001), rather than a nonverbal measure of ability (e.g., the NNAT-2), contributed to the underrepresentation of Hispanic students in gifted education. This case illustrates that placing emphasis on a nonverbal test could help to circumvent the problem of underrepresentation of Hispanic students in gifted programs (see Card & Giuliano, 2017; Ford, 2013). To test this hypothesis, a large-scale study using the NNAT-2 was conducted.

Card and Giuliano (2017) conducted an 8-year longitudinal study of rates of gifted identification in a district of approximately 40,000 students. Low-income and minority students were substantially underrepresented in gifted education programs in years 1 and 2, when identification was based on referrals by parents and teachers. During years 3 and 4, the district used the NNAT-2. Without any changes in the standards for gifted eligibility, use of the NNAT-2 led to large increases in the numbers of economically disadvantaged and minority students placed in gifted programs. The newly identified gifted students included blacks, Hispanics, those receiving free/reduced-price lunch, and English-language learners (ELLs)—all members of groups identified at much lower rates during the previous 2 years, when the parent–teacher referral system was used. Importantly, these findings suggest that parents and teachers often fail to recognize the potential of poor and minority students and those with limited English skills. During the following 4 years, when the NNAT-2 was no longer used due to budgetary restraints, the numbers of students in these groups who were found to qualify for gifted programming declined and reverted to numbers consistent with those in years 1 and 2.

The WNV manual reports a study involving gifted children who were matched to control subjects from the standardization sample on the basis of age, race/ethnicity, and education level. The differences between the means were calculated by using Cohen's (1988) formula (i.e., the difference between the means of the two groups divided by the square root of the pooled variance). The study included 41 examinees, all of whom had already been identified as gifted via a standardized ability measure on which they performed at 2 *SD* above the mean or more. The students in the gifted programs performed significantly better than their matched counterparts from the normative sample, with large effect sizes for the Full Scale score on both the two- and four-subtest WNV batteries. See Table 17.2 for more details.

Deafness/Hearing Impairments

The issues of limited spoken language and educational attainment are also relevant to those with deafness or hearing impairments. Because the directions are given pictorially and can be augmented with additional statements and/or communication in sign language, the WNV offers considerable advantages for appropriate evaluation of individuals who are deaf or hard of hearing, as the research studies described below illustrate (see also Brunnert et al., 2009).

Wechsler and Naglieri (2006c) reported two studies involving individuals who were deaf or hard of hearing. The first study involved a sample of profoundly deaf examinees who were compared with a group from the standardization sample of the WNV matched on many important demographic variables. The deaf sample consisted of 37 examinees who "must not have been able to hear tones to interpret spoken language after the age of 18 months, must not lip read, must not be trained in the oral or auditory–verbal approach, and must not use cued speech (i.e., they must have routine discourse by some means of communicating other than spoken language). They must have had severe to profound deafness (hearing loss measured with dB, Pure Tone Average greater than or equal to 55)" (Wechsler & Naglieri, 2006c, p. 65). These examinees performed very similarly to their matched counterparts from the normative sample, with negligible effect sizes (Cohen's *d*) for the Full Scale score for both the two- and four-subtest batteries, as shown in Table 17.2.

Wechsler and Naglieri (2006c) also described a study of individuals who were hard of hearing and compared them to a demographically matched group from the standardization sample. This study included 48 examinees who "could have a unilateral or bilateral hearing loss or deafness, and the age of onset of their inability to hear could be any age and [they] could have cochlear implants" (pp. 65–66). This group also performed similarly to the matched counterparts from the normative sample, again with negligible effect sizes (Cohen's *d*) for both batteries, as shown in Table 17.2.

INTERPRETATION

Like all test results, the WNV scores should be interpreted within the full context of the examinee and the administration setting. Issues such as the behaviors observed during testing, relevant educational and environmental backgrounds, physical and emotional status, and reason for referral must be considered when the results are examined. To obtain the greatest amount of information from the WNV, some interpretive methods are the same for the four- and two-subtest batteries, whereas others are unique to each version. These are discussed next.

Interpretation of Both Versions

The WNV subtests are set at a mean of 50 and *SD* of 10. These scores are combined to yield the Full Scale score. The WNV is the first of the Wechsler tests to express the subtest scores on the *T*-score metric (as opposed to a traditional scaled score with a mean of 10 and *SD* of 3). This format was selected because the individual subtests had a sufficient range of raw scores to allow for the use of *T* scores, which have a greater range and precision than scaled scores. The use of *T* scores also provides greater precision on each subtest, allowing for higher reliability coefficients of the Full Scale score.

The WNV Full Scale is set to have a mean of 100 and *SD* of 15, regardless of whether the four- or two-subtest battery is used. This score provides a nonverbal estimate of general ability that has excellent reliability and validity. It is important to recognize that even though the WNV subtests have different demands—that is, some are spatial (e.g., Matrices or Object Assembly), whereas others involve sequencing (Picture Arrangement and Spatial Span), require memory (e.g., Recognition and Spatial Span), or use symbol associations (Coding)—they all measure general ability. General ability, as represented by the Full Scale standard score, provides an estimate for predicting how well a person, for example, will be able to understand spatial as well as verbal and mathematical concepts, remember visual relationships as well as quantitative or verbal facts, and work with sequences of information of all kinds (Naglieri, Brulles, & Lansdowne, 2009). The content of the questions may be visual or verbal, and may require memory or recognition, but general ability (sometimes referred to as *g*) underlies performance on all these kinds of tasks.

WNV Interpretation—Level 1

In the first interpretive step, the Full Scale score should be reported with its associated percentile score, categorical description (average, above average, etc.), and confidence interval. The following illustrates how this information could be included in a written document:

> Annie obtained a WNV Full Scale score of 91, which is ranked at the 27th percentile and falls within the average classification. This means that she performed as well as or better than 27% of examinees her age in the normative sample. There is a 90% chance that her true Full Scale score falls within the range of 85–99.

The second step in interpretation of the four-subtest version of the WNV is to examine the *T* scores the examinee earned on the subtests, taking into consideration the lower reliability of these scores. Examination of the four WNV subtests should also take into consideration that even though the subtests are all nonverbal measures of general ability, they do have unique attributes, as noted above. In addition, statistical guidelines should be followed to ensure that any differences interpreted are beyond those that could be expected by chance. The values needed for significance when comparing a WNV subtest for an examinee to that examinee's mean *T* score are provided in the WNV administration and scoring manual (Wechsler & Naglieri, 2006b, Table B.1) and in more detail by Brunnert and colleagues (2009), and should be used in examining subtest variability. The following steps should be used to compare each of the four WNV subtest *T* scores to the examinee's mean subtest *T* score:

1. Calculate the mean of the four subtest *T* scores.
2. Calculate the difference between each subtest *T* score and the mean.
3. Subtract the mean from each of the subtest *T* scores (retain the sign).
4. Find the value needed for significance, using the examinee's age group and the desired significance level in Table 12.3 of the WNV manual (Wechsler & Naglieri, 2006b).
5. If the absolute value of the difference is equal to or greater than the value in the table, the result is statistically significant.
6. If the subtest difference from the mean is lower than the mean, then the difference is a weakness; if the subtest difference from the mean is greater than the mean, then the difference is a strength.

When there is significant variability in the WNV subtests, it is also important to determine whether a weakness relative to the examinee's overall mean is also sufficiently below the average range. Determining whether an examinee has significant variability relative to his or her own average score is a valuable way to determine strengths and weaknesses, but Naglieri (1999) has cautioned that a relative weakness could also be significantly below the normative mean. He recommends that any subtest score that is low relative to the examinee's mean score should also fall below the average range to be considered a noteworthy weakness (i.e., at least 1 *SD* below the normative mean).

WNV Interpretation—Level 2

Spatial Span Forward and Backward

The WNV Spatial Span Forward and Backward scores can be interpreted separately. The sizes of the differences required for statistical significance by age and for the U.S. and Canadian standardization samples are 11 and 13 for the .10 and .05 levels for the U.S. sample, and 10 and 13 for these levels for the Canadian sample, respectively, for the combined ages of 8:0–21:11. Table C.1 of the WNV administration and scoring manual (Wechsler & Naglieri, 2006b) provides the information necessary to allow for the comparison between Spatial Span Forward and Backward. A difference of 9 *T*-score points is needed at the .15 level (13 at the .05 level) for significance. (Note that base rate data by the direction of the difference are provided in the WNV manual.)

Information about Spatial Span Forward and Backward *T* scores may be useful, but it should be integrated within the greater context of a comprehensive assessment. For example, if a difference between Spatial Span Forward and Backward is found, it may be expected that similar results will be found on similar tests (e.g., Digit Span Forward vs. Digit Span Backward on the Wechsler Intelligence Scale for Children—Fifth Edition [WISC-V; Wechsler, 2014]). The Backward scores may also be related to the Planning scale of the Cognitive Assessment System (CAS; see Naglieri, 1999) and the CAS2 (see our discussion of the CAS2 in Chapter 15, this volume), and may suggest that the examinee has difficulty with development and utilization of strategies for reversing the order of serial information. In addition, Digit Span and Spatial Span Forward may be considered measures of sequencing, whereas Digit Span and Spatial Span Backward may be considered measures of sustained concentration and visual–spatial working memory, respectively (Miller, 2007, 2010).

Spatial Span can be considered a nonverbal version of the Digit Span subtest of the WISC-V, even though the task has a distinct spatial component. For Spatial Span Forward, the examinee touches a sequence of blocks randomly arranged on an 8½- by 11-inch board in the same order as demonstrated by the examiner. For Spatial Span Backward, the examinee repeats a sequence in the reverse order of that demonstrated by the examiner. Again, then, Spatial Span Backward can be viewed as a task that requires visual–spatial working memory. Goldberg (2009) defines *working memory* as "the selection of task-relevant information" (p. 94), and it is the selection process incorporated into the task that demands strategy use. Observing the examinee's performance on Spatial Span Forward can reveal information about how well he or she initially commits sequenced visual–spatial information to memory. Spatial Span Backward allows the examiner to observe visual working memory capacity and efficiency in the selection of the sequence executed. Normative information for comparisons of Spatial Span Forward and Backward, as well as normative sample base rates found in the WNV manual (Wechsler & Naglieri, 2006b), should be used to understand the reliability of any differences found.

Coding

The WNV Coding subtest also provides the opportunity for finer clinical interpretation. For example, Koziol and Budding (2009) hypothesized that a task such as Coding places demands on working memory because there are numbers and symbols, and that quick performance may be facilitated by "holding this information online in working memory in the course of performing the task" (p. 261). The associations between symbols and numbers are maintained within working memory, and a short-term plan of action is activated. If the number–symbol associations are made quickly, it is assumed that less conscious effort is required for the task. This observation is consistent with Gabrieli, Stebbins, Singh, Willingham, and Goetz's (1997) formulation that working memory capacity facilitates fast performance and the attainment of procedural learning.

An examinee who completes the Coding subtest accurately but very slowly is approaching the task differently than an examinee who completes the task quickly but with many errors (making the wrong number–symbol association, skipping), who in turn is different from an examinee who completes the task quickly and accurately. Useful ways to interpret this kind of performance may be in terms of attention to the instructions (e.g., whether the instruction to "do the task as fast as you can" is ignored) or of conscious effort or concentration. The examinee who works faster for the 120 seconds and gives more responses has approached the task differently than the examinee who works more slowly and gives fewer responses. These examinees have completed the tasks at different rates over the same time interval. From this information, it can be hypothesized that the examinee who works more slowly has to put forth greater conscious control and effort, which may be related to recruitment of more brain areas (Saling & Philips, 2007). The examinee who works more slowly has to concentrate harder, and the examinee who works quickly has probably expended less effort. In this way, the subtest score for Coding may be viewed as a measure of efficiency of concentration.

Matrices

The WNV Matrices subtest is like others that have a long history of being good measures of general ability, as demonstrated by high *g* loadings (Jensen, 1998). Tests like Matrices can be viewed as measures of visual-perceptual reasoning. Matrices can also be considered a test of simultaneous processing, a mental activity by which a person integrates stimuli into interrelated groups or a whole (Naglieri, 1999). Simultaneous processing tests typically have strong visual–spatial aspects. The cognitive demands of the task require the integration of information (Naglieri & Otero, 2011).

SUMMARY AND CONCLUSIONS

The assessment of diverse populations of children and adults with verbal ability tests is particularly problematic for those with limited language skills and/or educational opportunities. The WNV was designed to provide a nonverbal measure of general ability that would be appropriate for a wide variety of culturally and linguistically diverse populations. This assessment should be useful in many settings, including the identification of gifted minority students. This chapter has summarized some of the validity evidence provided in the WNV technical and interpretive manual (Wechsler & Naglieri, 2006c), which supports the utility of the WNV for fair assessment of cognitive ability in several groups (students from culturally diverse backgrounds and/or with language differences, gifted students, and students who are deaf or hard of hearing). Within the context of a comprehensive evaluation, the WNV can provide important information about an examinee's level of general ability. It is important, however, to recognize that traditional tests based on the general ability model can be substantially augmented by measures of neurocognitive processes, which can detect underlying strengths and weaknesses that further explain academic performance.

Appendix 17.1 provides essential aspects of a case study that illustrates the use of the WNV in in the context of a multicomponent evaluation. All personally identifiable information has been altered in order to preserve the anonymity of the examinee.

APPENDIX 17.1

Case Study

REASON FOR REFERRAL

Lucia was seen by a multidisciplinary team to assess her educational needs. The author of this report (Tulio M. Otero, Ph.D.) was requested to evaluate Lucia in the areas of cognitive and academic functioning. Lucia is a third grader who is currently in a regular education class with English-language learner (ELL) services. A review of her files indicated that she suffered a closed head injury at age 3 in a motor vehicle accident. There was brief loss of consciousness (approximately 10 minutes). At the time of this evaluation, no further medical history was available. Despite interventions that included 8 weeks of Lexia Reading and Symphony Math, Lucia has been making only limited progress in both reading and math.

OBSERVATIONS

Lucia is a 9-year-old Hispanic female who speaks both English and Spanish. At home, Lucia speaks only Spanish, since neither of her parents speaks English; at school, she is in a regular classroom setting with ELL services. At school, she speaks mostly English with peers and teachers. Although she has conversational English skills, she is still developing cognitive academic language skills. Lucia preferred to converse with the examiner in English, but during the evaluation both languages were used in order allow maximum opportunities to comprehend and respond to the tests. Although both languages were used, her performance did not improve on verbal portions of the tests. She was alert, oriented, friendly, and cooperative. Her range of emotion was good, and she did not report any significant worries or concerns. Lucia reported that she had gone to bed late the night before because the family had gone to a party. She further indicated that she sometimes naps in the afternoon and then stays awake watching TV until very late in the evening. Although she put forth good effort on all tasks, it was obvious that she struggled from time to time because of fatigue, and therefore was provided with brief breaks and snacks as necessary. She did not have any negative reaction to failure and became quite animated when she did well on tasks.

Lucia struggled on academic achievement tests. During word-reading tasks, she read slowly. Her reading errors can be described as approximations to words based on what they looked like. For example, she read “ground” instead of *around*, “worm” for *wrong*, and “throw” for *threw*. Reading comprehension was deficient and very slow. She did not seem to benefit from the visual stimuli accompanying the passage she needed to read. On math reasoning tasks, Lucia took a long time to initiate a response, needed prompting to use paper and pencil to assist her in deriving the answer, and often used ineffective strategies. Relatively simple items took her several minutes to work through. On calculation tasks, she also did poorly because of either treating subtraction as addition or providing a result that did not make sense. During testing of the limits, Lucia was encouraged to notice her errors and the operation sign. She correctly reworked five items, although she could not receive credit for the reworkings. Her spelling skills seem typical of ELL students who use sounds in Spanish to spell English words. Yet she also missed sounds or sound clusters. Examples of some of her errors were “joump” for *jump*, “forrise” for *forest*, “unfar” for *unfair*, and “meniger” for *manager*.

TESTS ADMINISTERED

- Reynolds Intellectual Assessment Scales (RIAS; Reynolds & Kamphaus, 2003)
- Escalas de Inteligencia de Reynolds (RIAS-Spanish; Reynolds & Kamphaus, 2009)
- Wechsler Nonverbal Test of Ability (WNV; Wechsler & Naglieri, 2006b)
- Cognitive Assessment System—Second Edition: Spanish Edition (CAS2: Español; Naglieri, Moreno, & Otero, 2017)
- WJ IV Tests of Achievement (WJ IV ACH; Schrank, Mather, & McGrew, 2014)
- Batería III Pruebas de Aprovechamiento (Batería III; Muñoz-Sandoval, Woodcock, McGrew, & Mather, 2005)

NONVERBAL TEST RESULTS

Lucia’s overall cognitive ability was assessed by eliminating or minimizing the impact of limited language proficiency through the use of the WNV. This test is used to assess the general cognitive ability of individuals ages 4–21 years. Lucia’s WNV Full Scale score was 95; she scored higher than approximately 37 out of 100 individuals her age. Her general cognitive ability, as assessed by the WNV, is in the average range. These results suggest that her general cognitive ability is somewhat higher than that measured by tests requiring a student to process language both receptively and expressively. This is an example of how nonverbal tests can be particularly important when Hispanic children are assessed, as these students are more likely to have varying histories of educational opportunity and levels of academic English-language proficiency. Lucia's WNV performance is presented in Table 17.A.1.

Lucia was administered the RIAS in English with Spanish support, using select items from the Spanish version of the RIAS. The RIAS is an individually administered measure of intellectual functioning normed for individuals between the ages of 3 and 94 years. It contains several individual tests of intellectual problem solving and reasoning ability, which are combined to form a Verbal Intelligence Index and a Nonverbal Intelligence Index. These two indexes of intellectual functioning are then combined to form an overall Composite Intelligence Index. Each of these indexes is expressed as an age-corrected standard score, scaled to a mean of 100 and an *SD* of 15. The RIAS also contains Verbal Memory and Nonverbal Memory subtests, which are combined to form a Composite Memory Index.

Lucia earned a Composite Intelligence Index score of 81 on the RIAS. This level of performance falls within the range of scores designated as below average and exceeds the performance of 10% of individuals Lucia's age. Lucia earned a Verbal Intelligence Index score of 79, which falls within the moderately below-average range of verbal intelligence skills and exceeds the performance of 8% of individuals Lucia's age. Lucia earned a Nonverbal Intelligence Index score of 88, which falls within the low average range of nonverbal intelligence skills and exceeds the performance of 21% of individuals Lucia's age. Lucia's Verbal and Nonverbal Intelligence Index scores were not significantly different; however, there was a significant difference between scores obtained on nonverbal versus verbal subtests comprising the Composite Memory Index score (86, low average range). This score exceeds the performance of 18% of individuals Lucia's age. Lucia's performance in the Nonverbal Memory domain significantly exceeded her performance within the Verbal Memory domain. The difference between Nonverbal Memory and Verbal Memory is reliable and indicates that Lucia functions at a significantly higher level when asked to perform visual memory tasks (*T* score = 51) as opposed to verbal memory tasks (*T* score = 33). Lucia's RIAS performance is presented in Table 17.A.2.

General Ability Summary

The results of the WNV and RIAS suggest that when general ability is measured by using questions that demand the use of verbal stimuli, the scores are lower than when general ability is measured via tests that are commonly described as nonverbal. These nonverbal test items typically involve spatial and visual stimuli. Given that Lucia is limited in her English-language skills, these results lead to two important conclusions: first, that the verbal measures underestimate her general ability; and second, that the nonverbal scores are likely to give a better indication of her general ability.

TABLE 17.A.1. Wechsler Nonverbal Scale of Ability (WNV) Results for Lucia

	Standard score	Percentile rank	90% confidence interval
Full Scale	95	37	89–102

Subtest	Subtest *T* score	Difference from mean	Critical value	Variability	Base rate
Matrices	51	3	8	NS	32.8
Coding	47	–1	10	NS	47.2
Spatial Span	42	–6	8	NS	18.6
Picture Arrangement	52	4	10	NS	27.7
Within-subtest analysis					
Spatial Span Forward–Backward	39	–8	13	NS	21.6

Note. NS, nonsignificant. The mean WNV subtest score is 48.0.

TABLE 17.A.2. Reynolds Intellectual Assessment Scales (RIAS) Results for Lucia

Subtest	*T* score
Guess What	34
Odd-Item Out	40
Verbal Reasoning	35
What's Missing	43
Verbal Memory	33
Nonverbal Memory	51

Scale	Standard score	90% confidence interval	Percentile rank
Verbal Intelligence Index	79	75–86	8
Nonverbal Intelligence Index	88	83–94	21
Composite Intelligence Index	81	77–87	10
Composite Memory Index	86	81–92	18

Note. Lucia's Verbal Memory score is significantly lower than her Nonverbal Memory score.

ACADEMIC SKILLS RESULTS

Lucia was administered select subtests from the WJ IV ACH and Batería III to evaluate her academic achievement. Relative strengths and weaknesses among her academic skills are described below.

Academic Assessment in English

The WJ IV ACH Broad Reading cluster includes tests of reading decoding, reading speed, and the ability to comprehend connected discourse while reading. Lucia's standard score on this cluster was 61, which falls within the very low range (percentile rank range of <1–1; standard score range of 58–63) for her age. This score suggests that Lucia's overall reading ability in English is very limited; reading tasks above the age 7:5 level will be quite difficult for her. Lucia is likely to require intensive instructional support and targeted interventions in reading. The Letter–Word Identification subtest measured Lucia's ability to identify words. Lucia seemed unable to apply phoneme–grapheme relationships. Passage Comprehension measured Lucia's ability to understand what she had read. The items required Lucia to read a short passage and identify a missing word that made sense in the context of the passage. Lucia appeared to read each passage very slowly and had difficulty identifying the missing word. Reading Fluency measured Lucia's ability to read simple sentences quickly. Lucia appeared to read and respond to the sentences slowly.

The WJ IV ACH Broad Math cluster includes tests of mathematics reasoning and problem solving, number facility, and automaticity. Although her standard score on this cluster was within the very low range (58), her performance varied on different types of math tasks. Lucia's performance was very limited on tasks requiring the ability to analyze and solve applied mathematics problems (the Applied Problems subtest; standard score = 80). Her performance was limited on tasks requiring knowledge of how to perform mathematical computations, either with or without time limits (the Math Calculation Skills cluster, including the Calculation and Math Fluency subtests; standard score = 39). These results indicate that intensive instructional support in math, including targeted interventions, is likely to be needed for Lucia. Calculation measured Lucia's ability to perform mathematical computations; she worked very slowly and relied on the use of strategies that appeared to be inefficient for her age level. To solve each item in Applied Problems, Lucia was required to listen to the problem, recognize the procedure to be followed, and then perform relatively simple calculations. Because many of the problems included extraneous information, Lucia needed to decide not only the appropriate mathematical operations to use, but also what information to include in the calculation. Lucia appeared to have limited understanding of age-appropriate math application tasks. Finally, Math Fluency measured Lucia's ability to solve a series of simple addition, subtraction, and multiplication problems quickly in a 3-minute time limit. Lucia appeared to take longer to work on such problems than is typical for her same-age peers.

In the area of Writing, Lucia attained a standard score within the low range (79), suggesting underdeveloped writing skills. Her Spelling score was significantly lower than her Writing Samples score. Spelling measured Lucia's ability to write orally presented words correctly; Lucia spelled words in a laborious manner. Writing Samples measured Lucia's skill in writing responses to meet a variety of demands. She was asked to produce written sentences that were evaluated with respect to the quality of expression. Lucia was not penalized for any errors in basic writing skills, such as spelling or punctuation. Many of her sentences were inadequate to meet the task demands. Yet she managed to score within the average range on this particular subtest.

Overall, Lucia's academic skills in English, including spelling, sight reading, and math calculation, appear very limited (see Table 17.A.3 for a summary). Lucia's overall ability to apply her academic skills via tests of writing ability, reading comprehension, and math problem solving also seems limited.

Academic Assessment in Spanish

On the Batería III, Breve Lectura includes tests of reading decoding and the ability to comprehend connected discourse while reading. Lucia's standard score of 66 is within the very low range (percentile rank range of 1–2; standard score range of

TABLE 17.A.3. Woodcock–Johnson IV Tests of Achievement (WJ IV ACH) Results for Lucia

CLUSTER/test	AE	Easy to difficult	SS (90% confidence interval)	GE
ACHIEVEMENT	7:4	7:0 to 7:8	67 (65–70)	2:0
BROAD READING	7:1	6:9 to 7:5	61 (58–63)	1:7

	SS			Variation		
Variations	Actual	Predicted	Difference	Discrepancy PR	Discrepancy *SD*	Significant at ±1.50 *SD* (*SEE*)
Intra-Achievement (Brief)						
BROAD MATH	58	79	–20	5	–1.63	Yes

Note. Norms based on ages 9–10. AE, age equivalent; SS, standard score; GE, grade equivalent; PR, percentile rank; *SD*, standard deviation; *SEE*, standard error of estimate. For information on how to interpret the discrepancy percentile rank and discrepancy standard deviation, see Jaffe (2009).\

64–69) when compared to those of others her age. This suggests that reading tasks above the age 7:6 level will be quite difficult for her. Similarly, Ortografía evaluates Lucia's ability to write orally presented words correctly in Spanish. Her standard score is within the low range (74; percentile rank range of 3–7; standard score range of 71–78) for her age. This indicates that Lucia's spelling ability is very limited; spelling above the age 7:9 level will be quite difficult for her. Lucia's Batería III performance is presented in Table 17.A.4.

Academic Assessment Summary

The academic test results suggest that Lucia has weaknesses in academic skills in both English and Spanish. Lucia's performance on nonverbal tests suggests that her performance on academic tasks could be expected to be higher. That is, there is a substantial difference between Lucia's nonverbal scores and her level of achievement in both English and Spanish. To clarify why her levels of academic skills seem low, a measure of neurocognitive processing was administered.

NEUROCOGNITIVE TEST RESULTS

The CAS2: Español was administered to Lucia, in an effort to understand the difference between her nonverbal general ability scores (which were in the average range; WNV Full Scale = 95) and her poor academic achievement scores in both English and Spanish. The CAS2: Español is an individually administered test designed to measure intelligence as a group of neurocognitive processes. It is based on the *planning, attention, simultaneous, and successive* (PASS) theory of intelligence.

The Planning scale of the CAS2: Español measures cognitive control, use of strategies, knowledge and skills, intentionality, and self-regulation. This scale measures a child's ability to determine how to solve a problem, execute that solution, monitor its effectiveness, and modify the approach as needed to achieve the goal. Tasks administered as part of this scale require impulse control, as well as generation, evaluation, and execution of a plan. The Planning scale measures how well the child can solve problems of varying complexity that may involve control of attention, simultaneous, and successive processes, as well as acquisition of knowledge and skill. This ability is associated with the brain area known as the prefrontal cortex. Lucia earned a CAS2: Español Planning standard score of 80, which is within the low average classification and is ranked at the 9th percentile. This percentile rank score means that Lucia did as well as or better than 9% of children her age in the standardization group. There is a 90% probability that Lucia's true Planning score is within the range of 75–88.

The Attention scale of the CAS2: Español measures a child's ability to demonstrate focused, selective cognition over time, with resistance to distraction. Attention can be described as focused, selective, sustained, and effortful activity. *Focused* attention involves concentration directed toward a particular activity, and *selective* attention is important for the inhibition of responses to distracting stimuli. *Sustained* attention refers to the variation of performance over time, which can be influenced by the varying amounts of *effort* required to solve the test. An effective measure of attention presents children with competing demands and requires sustained focus. The components of attention are subserved by neural networks spanning subcortical, dorsal–ventral steams and frontal brain regions in an interactive manner. *Executive attention* is defined as maintaining behavior goals and using these goals as a basis for choosing what aspects of the environment or tasks to attend to and which action to select. Paying attention is

TABLE 17.A.4. Batería III Normative Update Pruebas de Aprovechamiento Results for Lucia

CLUSTER/test	AE	Easy to difficult	SS (90% confidence interval)	GE
LECTURA (READING)	7:2	6:11 to 7:6	66 (64–69)	1:9
Ident. de Letras y Palabras (Letter–Word Identification)	7:3	7:1 to 7:6	70 (68–73)	2:0
Ortografía (Spelling)	7:4	7:0 to 7:9	74 (71–78)	2:0
Comprensión de Textos (Reading Comprehension)	7:1	6:9 to 7:5	71 (68–75)	1:8

Note. AE, age equivalent; GE, grade equivalent; SS, standard score.

the first step in the learning process. Lucia earned a CAS2: Español Attention standard score of 102, which is within the average classification and is ranked at the 55th percentile. This percentile ranking means that Lucia did as well as or better than 55% of children her age in the standardization group. There is a 90% probability that Lucia's true Attention score is within the range of 94–109.

The Simultaneous scale of the CAS2: Español measures a child's ability to integrate separate but interrelated stimuli into groups or into a whole. Simultaneous processing tests have strong visual–spatial aspects for this reason, but this ability is also used to solve tasks with verbal content (e.g., reading comprehension), if the tasks require integration of information into a coherent whole. Simultaneous processing underlies the use and comprehension of grammatical statements because they demand comprehension of word relationships, prepositions, and inflections, so that a person can obtain the meaning of a whole idea. Select aspects of verbal reasoning tasks, such as those in which an examinee is given two to four clues and asked to deduce the object or concept being described, also require simultaneous processing. There was variability in Lucia's scores on the subtests that make up this scale. Lucia had her lowest score on the Verbal–Spatial Relations subtest; however, overall, she earned a CAS2: Español Simultaneous standard score of 95, which is within the average classification and is ranked at the 34th percentile. This means that Lucia did as well as or better than 34% of children her age in the standardization group. There is a 90% probability that Lucia's true Simultaneous score is within the range of 89–101.

The Successive scale of the CAS2: Español evaluates how well a child works with stimuli in a specific serial order, where each element is only related to those that precede it and these stimuli are not interrelated. Successive processing ability involves both the perception of stimuli in sequence and the formation of sounds and movements in order. For example, successive processing is involved in the decoding of unfamiliar words, production of syntactic aspects of language, and speech articulation. This process is measured with tests that demand use, repetition, or comprehension of information based on order. Following a sequence such as the order of operations in a math problem is another example of successive processing. Lucia earned a CAS2: Español Successive standard score of 81, which is within the low average classification and is ranked at the 10th percentile. This means that Lucia did as well as or better than 10% of children her age in the standardization group. There is a 90% probability that Lucia's true Successive score is within the range of 76–89.

Lucia's overall CAS2: Español performance is presented in Table 17.A.5. Note that the Full Scale is omitted from this report and Table 17.A.5 because the significant variability among the four PASS scales renders the overall score misleading. In addition to the PASS scores, the test provides a Nonverbal score; Lucia obtained a Nonverbal score of 97, which is within the average classification and is ranked at the 42nd percentile. This means that Lucia did as well as or better than 42% of children her age in the standardization group. There is a 90% probability that Lucia's true Nonverbal score is within the range of 91–104.

SUMMARY

Lucia's RIAS Composite Intelligence Index (81) indicates mild deficits in general intelligence relative to others of her age when ability is measured with verbal and nonverbal tests. Although students earning a Composite Intelligence Index in the 80s frequently experience at least some difficulty acquiring information through traditional educational methods provided in the classroom setting, Lucia's limited verbal skills depressed her Verbal score on this test. Lucia's score on the RIAS Nonverbal Memory scale is higher than her Verbal Memory score. Importantly, the WNV Full Scale result (95) and the CAS2: Español Nonver-

TABLE 17.A.5. Cognitive Assessment System—Second Edition: Spanish Edition (CAS2: Español) Results for Lucia

Scale	Scaled score	90% confidence interval	Percentile rank
Planning	80	75–88	9
Simultaneous	95	89–101	37
Attention	102	94–109	55
Successive	81	76–89	10
Average PASS score	89.5		

bal score (97) suggest that Lucia's general ability when language-processing requirements are markedly reduced is within the average range.

Lucia's English achievement test scores suggest academic skills within the low range. When compared to those of others at her age level, Lucia's standard score is low in writing, and her standard scores are very low in broad reading, broad mathematics, and math calculation skills. Lucia demonstrated a significant weakness in mathematics, particularly because she confused the operation signs and made calculation errors when borrowing and regrouping. Similarly, the Spanish achievement test results included a very low score in reading. These results strongly suggest that the verbal test scores should be considered underestimates of overall ability, and that the neurocognitive results better explain her levels of intellectual functioning.

Lucia earned scores on the four PASS scales of the CAS2: Español that differed significantly. She earned significantly low scores on measures of planning and successive neurocognitive processes, which help to answer the question "Why is Lucia having academic problems?" These two cognitive weaknesses provide evidence of a disorder in one or more of the basic psychological processes described in the Individuals with Disabilities Education Improvement Act (IDEA) of 2004. When low scores on such measures are accompanied by similarly low achievement scores with adequate opportunity to learn, there is evidence that a child probably meets eligibility criteria for a specific learning disability, according to the discrepancy–consistency method (see Figure 17.A.1) as described by Naglieri and Otero (2017). That is, Lucia appears to have significant variability in basic neurocognitive processes (Planning and Successive weaknesses on the CAS2, with Simultaneous and Attention strengths), a discrepancy between low achievement scores and her CAS2 Simultaneous and Attention scores, and a consistency between low achievement and low CAS2 Planning and Successive scores. For more details on this method, see Naglieri and Otero (2017) and Naglieri and Feifer (2017a, 2017b).

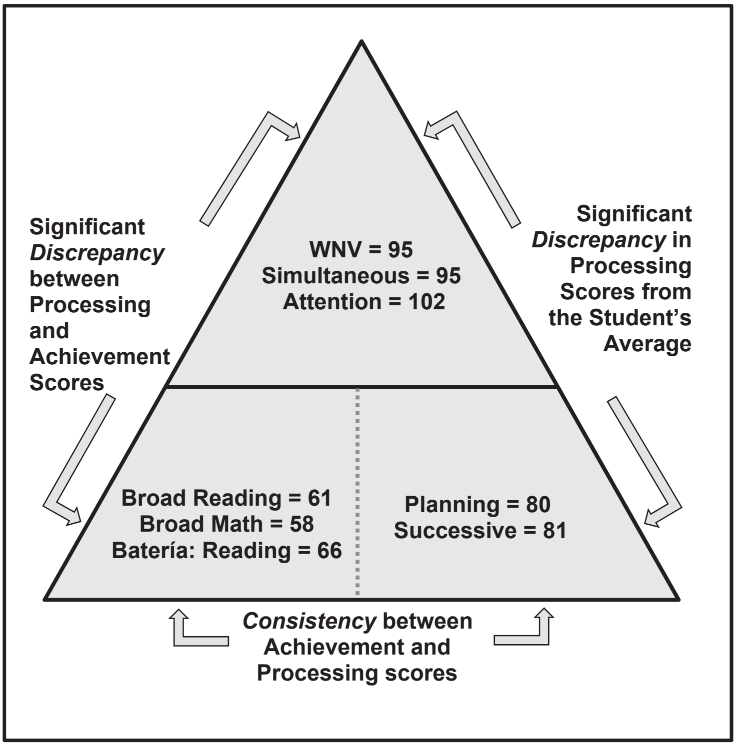

FIGURE 17A.1. Discrepancy–consistency method of SLD eligibility determination for the case of Lucia.

POSSIBLE INSTRUCTIONAL RECOMMENDATIONS AND INTERVENTIONS

- Lucia will probably gain the most from reading instruction presented within the middle- to late-first-grade range. The primary goal is to increase Lucia's exposure to printed words, in hopes of increasing the number of words that she can recognize orthographically.
- Daily reading is recommended for fluency-building intervention. Lucia should read a short passage several times until she can read the passage with ease. The instructor should select material that is at Lucia's instructional reading level. Then the instructor should have her read through the passage aloud; the instructor should record the number of errors, as well as the time it takes Lucia to read the passage. After Lucia completes the passage, the instructor should review the misread words and then have her read it again. This approach should be continued until Lucia has read the passage three to five times or has reached a preestablished goal for accuracy or rate.
- Lucia and her parents should be encouraged to spend time reading every day outside of school.
- To address Lucia's weaknesses in planning and successive neurocognitive processes, reading strategies described in *Helping Children Learn: Intervention Handouts for Use in School and at Home* (Naglieri & Pickering, 2010) should be used. Lucia's teachers and parents can help her follow the instructions in the handouts (e.g., Summarization Strategy for Reading Comprehension, Chunking for Reading/Decoding, Word Families for Reading/Decoding).
- Math instruction presented within the middle-first-grade to early-second-grade range will be likely to produce the greatest gains for Lucia.
- Use of a concrete–representational–abstract sequence will ensure that Lucia understands a computation or math fact: first by using manipulatives, then by drawing representations (pictures or tallies) of the problem, and finally by solving the problem with actual numbers.
- Teachers and parents should consider using math techniques described by Naglieri and Pickering (2010), such as Touch Math, the Part–Whole Strategy, and the Seven-Step Strategy. These methods will help Lucia to solve math problems in a variety of settings.
- The cover–copy–compare intervention requires teacher-made worksheets that provide correctly completed problems on the left side of the paper and the unsolved problems on the right side of the paper. The teacher will instruct Lucia to study each correctly completed problem, then cover it with an index card, complete the matching problem to the right, and check her work by comparing it to the model problem.
- Writing instruction presented within the early- to middle-second-grade level is appropriate for Lucia.
- The Write–Say method may be helpful in addressing Lucia's spelling skills. This intervention will require Lucia to study a spelling list on her own on Monday, and then to participate in an orally administered spelling test on Tuesday. The teacher will provide verbal feedback, and Lucia will then say and write the correct spelling of missed words, letter by letter, five times. The same procedure is to be followed Wednesday and Thursday; however, Lucia will then practice incorrectly spelled words 10 times and 15 times, respectively. Finally, the teacher will administer a summative spelling test on Friday.
- The Add-a-Word spelling program may assist Lucia in developing better spelling skills. To implement this intervention, Lucia's teacher will provide five daily spelling words. Each word must be correctly spelled 5 days in a row before an individual word is replaced with a new spelling word. If on subsequent spelling tests a previously learned word is missed, that word will be placed back onto the current spelling list until it is mastered again.
- Lucia needs to devote more time to writing. Daily writing practice at school and at home facilitates writing for different purposes and for different audiences. Making the connection between writing and real-world applications should be an important motivator in developing Lucia's writing skills.
- Because Lucia earned a low score on the Planning scale of the CAS2, she should be provided with strategies for writing. The following descriptive handouts of specific methods (Naglieri & Pickering, 2010) should be provided to the teachers and parents: Story Plans for Written Composition, Story Grammar for Writing, and Plans for Writing. These will help Lucia acquire strategies for communicating her ideas in writing. These and other handouts are available in Spanish for use by Lucia's parents.
- Lucia will probably gain the most from Spanish reading instruction presented at the late-first-grade to early-second-grade level.

CHAPTER 18

The Reynolds Intellectual Assessment Scales, Second Edition, and the Reynolds Intellectual Screening Test, Second Edition

Tara C. Raines
Cecil R. Reynolds
Randy W. Kamphaus

This chapter provides the reader with an extensive introduction to the Reynolds Intellectual Assessment Scales, Second Edition (RIAS-2; Reynolds & Kamphaus, 2015), and the Reynolds Intellectual Screening Test, Second Edition (RIST-2; Kamphaus & Reynolds, 2015)—recently updated cognitive assessments for children and adults. Brief overviews of the instruments and of noteworthy updates to the second editions are provided. Furthermore, a review of the theory and structure of the RIAS-2 is offered, using a goal-oriented developmental framework. Additionally, more extensive descriptions of the subtests, their administration, and their scoring are provided. Psychometric characteristics of the RIAS-2 as well as guidelines for interpretation are presented. Clinical applications of the RIAS-2 and RIST-2 are briefly discussed. A chapter appendix provides a case study using the RIAS-2 as the featured measure of intelligence.

The RIAS-2 is an individually administered test of intelligence appropriate for ages 3 years through 94 years with co-normed, supplemental measures of processing speed and memory. The RIAS-2 consists of eight subtests. It also includes a two-subtest Verbal Intelligence Index (VIX) and a two-subtest Nonverbal Intelligence Index (NIX). The scaled sums of *T* scores for the four subtests are combined to form the Composite Intelligence Index (CIX), which is the suggested summary estimate of global intelligence. For individuals preferring to include measures of memory and processing speed in the global estimate of intelligence, composite scores that include these subtests are also available. Administration of the four intelligence scale subtests by a trained, experienced examiner requires approximately 20–25 minutes. A Composite Memory Index (CMX) is derived from the two supplementary memory subtests, which requires approximately 10–15 minutes of additional testing time. Additionally, a composite Speeded Processing Index (SPI) consists of two subtests, which take an additional 5–10 minutes to administer. Each index is representative of both verbal and nonverbal subtests. Table 18.1 provides an overview of the RIAS-2 indexes and subtests.

Using a population-proportionate stratified sampling plan, the test developers standardized the RIAS-2 on a sample of 2,154 individuals. The RIAS-2 was designed to eliminate or minimize any cultural biases in the assessment of intelligence for individuals acculturated to and educated in the United States. In essence, this test was designed for individuals with English language proficiency. The RIAS-2 provides standardized *T* scores, which have a mean of 50 and a standard deviation of 10. Each of the indexes is scaled to the common standard score metric used for assessment of intellectual ability, with a mean of 100 and a standard deviation of 15. Via a method known as *continu-*

TABLE 18.1. RIAS-2 Subtests and Indexes

Subtest or index	Description
Composite Intelligence Index (CIX)	CIX provides a summary estimate of global intelligence, designed to estimate *g*, the general intelligence factor.
Verbal Intelligence Index (VIX)	VIX provides a summary estimate of verbal intelligence as assessed by verbal reasoning and reflecting primarily crystallized intellectual functions.
Guess What (GWH)	Examinees are given a set of two to three clues, and are asked to deduce the object or concept being described. This subtest measures verbal reasoning in combination with vocabulary, language development, and overall fund of available information.
Verbal Reasoning (VRZ)	Examinees listen to a propositional statement that essentially forms a verbal analogy, and are asked to respond with one or two words that complete the idea or proposition. This subtest measures verbal-analytical reasoning ability, but with fewer vocabulary and general knowledge demands than Guess What.
Nonverbal Intelligence Index (NIX)	NIX provides a summary estimate of nonverbal intelligence as assessed by nonverbal reasoning and reflecting primarily fluid intellectual functions.
Odd-Item Out (OIO)	Examinees are presented with a picture card containing five to seven pictures or drawings, and are asked to designate which one does not belong or go with the others. This subtest measures nonverbal reasoning skills, but also requires the use of spatial ability, visual imagery, and other nonverbal skills on various items. It is a form of reverse nonverbal analogy.
What's Missing (WHM)	A redesign of a classic task present on various ability measures. Examinees are shown a picture with some key element or logically consistent component missing, and are asked to identify the missing essential element. This subtest assesses nonverbal reasoning: The examinee must conceptualize the picture, analyze its gestalt, and deduce what essential element is missing.
Composite Memory Index (CMX)	CMX provides a summary estimate of verbal and nonverbal memory functions in general, as its component parts correspond to the broad areas of memory skills.
Verbal Memory (VRM)	This scale consists of a single verbal memory subtest. Depending upon the examinee's age, a series of sentences or brief stories are read aloud by the examiner and then recalled by the examinee. This task assesses the ability to encode, store briefly, and recall verbal material in a meaningful context where associations are clear and evident.
Nonverbal Memory (NVM)	This scale consists of a single visual memory subtest. It contains a series of items in which a stimulus picture is presented for 5 seconds, following which an array of pictures is presented. The examinee must identify the target picture from the new array of six pictures. It assesses the ability to encode, store, and recognize pictorial stimuli that are both concrete and abstract or without meaningful referents.
Speeded Processing Index (SPI)	SPI provides a summary estimate of processing speed, primarily involving both decision speed and reaction time while minimizing the efforts of fine motor speed.
Speeded Naming Task (SNT)	Examinees are asked to name pictures of common objects presented in a grid format, and must recognize them quickly, access their names, and speak these aloud to the examiner.
Speeded Picture Search (SPS)	Examinees are asked to find three target pictures within a large array of pictures as quickly as they can.

Note. Index titles appear in boldface. From Reynolds and Kamphaus (2015, p. 10). Copyright © Psychological Assessment Resources (PAR), Inc. Adapted by permission.

ous norming, all indexes yield age-corrected deviation scaled scores (Angoff & Robertson, 1987; Evers, Sijtsma, Lucassen, & Meijer, 2010; Reynolds & Kamphaus, 2015; Zachary & Gorsuch, 1985). Percentile ranks, *T* scores, *z* scores, normal curve equivalents, and stanines are also offered. Age-equivalent subtest scores are only offered for ages 3–14 (Reynolds & Kamphaus, 2015).

The RIST-2 is a general intelligence screening measure derived from subtests of the RIAS-2. This instrument is not designed to provide diagnostic information. Instead, it is designed to provide information on risk for intellectual atypicality. It consists of two subtests of the RIAS-2 (Guess What and Odd-Item Out), and is to be used to determine whether intellectual functioning deviates enough from the mean to warrant additional assessment. This type of screening may be helpful in screening for giftedness and talents or developmental delays, screening for the impact of a stroke or cerebrovascular accident, or screening for the impact of dementia on cognitive functioning.

THEORY AND STRUCTURE

The RIAS-2 has combined practical and theoretical aspects of the assessment of intelligence. This instrument measures five valuable facets of intelligence: general intelligence (including fluid reasoning); verbal intelligence (crystallized abilities); nonverbal intelligence (visual and spatial abilities); memory (short-term memory and learning); and processing speed (decision speed or reaction time). The selection of these aspects was based on their sound history of scientific support (Carroll, 1993; Goldstein & Reynolds, 2011; Horn & Cattell, 1966; Kamphaus, 2001; Reynolds & Kamphaus, 2015). The RIAS-2 is rooted in the Cattell–Horn–Carroll (CHC; Horn & Cattell, 1966) model of intelligence, which is grounded in the assessment of fluid and crystallized intelligence. However, based on more current and practical acknowledgment of the value of both processing speed and memory in the assessment of cognitive ability, subtests measuring these abilities were added to the RIAS-2. It is the test authors' hope that with these additional measures, practitioners can glean comprehensive and useful information about individual cognitive abilities. Additional information about the theoretical underpinnings of the RIAS-2 is available in the RIAS-2 manual (Reynolds & Kamphaus, 2015).

Development Goals

Reynolds and Kamphaus (2015) describe a set of nine primary goals for development of the RIAS-2. These goals are based on their experiences of teaching courses on the assessment of cognitive abilities, and of administering and interpreting many different measures of intelligence; they are also based on the current literature surrounding theoretical models of intelligence and research on intelligence test interpretation. The goals of the instrument build upon the goals established in the development of its predecessor, the RIAS (Reynolds & Kamphaus, 2003). Table 18.2 summarizes these goals, which are reviewed and discussed only briefly below. Additional information on these goals can be found in the RIAS-2 manual (Reynolds & Kamphaus, 2015).

- *Goal 1: Provide a reliable and valid measurement of g and its two primary components, verbal and nonverbal intelligence, with close correspondence to*

TABLE 18.2. Summary of Nine Primary Goals for Development of the RIAS-2

1. Provide a reliable and valid measurement of *g* and its two major practical components, verbal and nonverbal intelligence, with close correspondence to crystallized and fluid intelligence.
2. Provide a practical measurement device in terms of efficacies of time, direct costs, and information needed from a measure of intelligence.
3. Allow continuity of measurement across all developmental levels for ages 3–94 years for both clinical and research purposes.
4. Substantially reduce or eliminate dependence upon motor coordination and visual–motor speed for measurement of intelligence.
5. Eliminate dependence upon reading for measurement of intelligence.
6. Provide accurate predictions of basic academic achievement, at levels at least comparable to those of intelligence tests twice the length of the RIAS-2.
7. Apply familiar, common concepts that are clear and easy to interpret, coupled with simple, easy administration and scoring.
8. Eliminate items that show differential item functioning associated with gender or ethnicity.
9. Provide for the verbal and nonverbal assessment of memory.

crystallized and fluid intelligence. The general intelligence factor, *g*, is the most reliable and enduring aspect of any multifactorial view of intelligence (Deary, 2012; Jensen, 1998). In the Cattell–Horn model (Horn & Cattell, 1966; Kamphaus, 2001) of intelligence, *g* is the dominant factor in the hierarchy of multiple abilities, with the next two dominant facets being crystallized and fluid intelligence. These components bear a close association to the common view of verbal and nonverbal intelligence. The RIAS-2 includes subtests that match both constructs closely to share in the theoretical support of the Cattell–Horn model of crystallized and fluid intelligence, while taking advantage of the very practical division of intelligence into verbal and nonverbal components. Verbal and nonverbal components of intelligence also have strong support from factor-analytic work (e.g., Kaufman, 1994) and the brain sciences (e.g., Riccio & Hynd, 2000).

- *Goal 2: Provide a practical measurement device in terms of efficacies of time, direct costs, and information needed from a measure of intelligence.* Time, cost, and efficiency have always been necessary considerations in the delivery of effective psychological and psychoeducational services. With the growing demand to provide services to children with disabilities in schools, time has become a fundamental consideration for practitioners assessing cognitive abilities. A useful intelligence test needs to provide an objective, reliable, and valid assessment of the major constructs that underlie psychometric intelligence. Intellectual assessment can be conducted efficiently and at a significantly lower cost than it has been in the past. The RIAS-2 was designed to provide an efficient measure of intelligence that is aligned with the guidelines for eligibility, such as those put forth by the special education and Social Security laws in the United States.

- *Goal 3: Allow continuity of measurement across all developmental levels from ages 3 years through 94 years for both clinical and research purposes.* Individuals often require reevaluation of cognitive ability throughout their lives. As they age, different versions of intelligence tests may be required. These various tests have different subtests, measure different aspects of intelligence, were normed in different years, and may have sample stratifications that are not aligned. Thus scores obtained over time may not be comparable because of measurement artifact, and not because of any real changes in an individual's cognitive abilities or structure (Sattler, 2001). Thus there is clinical utility in having a common set of subtests and a common reference group for such comparisons, just as there is utility in longitudinal research that includes intelligence as a variable, whether dependent, independent, or moderator in nature (Andrews, 2007).

- *Goal 4: Substantially reduce or eliminate dependence on motor coordination and visual–motor speed in the measurement of intelligence.* The majority of current individually administered intelligence tests rely heavily on visual–motor coordination and motor speed for accurate assessment of intelligence (Dombrowski & Mrazik, 2008). However, many children referred for special education services struggle with visual–motor tasks or have other neurodevelopmental disorders that produce motor-related problems (Goldstein & Reynolds, 2011). Furthermore, in older populations, the incidence of tremor and related motor problems is quite high. To attempt to measure the intelligence of such individuals with tasks that require rapid manipulation of blocks, small cardboard pieces, or even pencil markings, where speed and accuracy of performance are substantial contributors to the resulting IQ or cognitive index, seems inappropriate. It is our view that intelligence tests should emphasize thinking, reasoning, and problem solving.

- *Goal 5: Eliminate dependence on reading ability in the measurement of intelligence.* Tasks where the ability to read the English language facilitates individual item performance confound the measurement of intelligence with academic ability. Certainly, intelligence cannot be assessed completely independently of prior knowledge, despite many failed attempts to do so (e.g., culture-free tests; see Anastasi & Urbina, 1997; Kamphaus, 2001). However, to confound intellectual assessment with academic skills such as reading and spelling makes such tests inappropriate for nonreaders, individuals with limited English-reading skills, and persons with visual impairments.

- *Goal 6: Provide accurate predictions of basic academic achievement, at levels at least comparable to those of intelligence tests twice the length of the RIAS-2.* Predicting academic achievement and acquired knowledge in such areas as reading, language, and math is an important function for intelligence tests. Predicting achievement should remain a function of any new intelligence test.

- *Goal 7: Apply familiar, common concepts that are clear and easy to interpret, coupled with simple administration and scoring.* Formal intelligence testing via Binet-type tasks is only a century old. During this time, innumerable tasks have been devised to measure intelligence and related abilities. Many of these tasks are quite good at the measurement of cognitive ability and possess long histories in psychology and education. The use of familiar, well-researched tasks has many advantages over the use of novel, less well-established tasks. Many of these tasks are simple and easy to administer, despite the complex mental functions required for deriving a correct solution. Avoiding tasks that require lengthy verbal responses or split-second timing for awarding bonus points can facilitate objective scoring. Tasks that are simple to administer and clearly objective to score reduce or nearly eliminate administration and scoring errors.

- *Goal 8: Eliminate items that show differential item functioning associated with gender or ethnicity.* The problem of bias, whether a function of gender, race, or culture, has long produced debate in psychology, education, and the assessment of intelligence (e.g., Brown, Reynolds, & Whitaker, 1999; Reynolds, Lowe, & Saenz, 1999). Following years of debate, a host of methods for detecting test items that function differentially across nominally defined groups has been devised (Reynolds, 2000). However, in view of the availability of sound statistical approaches for identifying such test items, all intelligence test items should be scrutinized during development and standardization to determine whether the functions are measuring the same constructs and skills across groups.
- *Goal 9: Provide for the verbal and nonverbal assessment of memory.* Brief assessments of memory have been included in intelligence measures since the onset of the practice (Binet & Simon, 1905). The outcomes of this portion of the assessment are typically included in the composite intelligence score or quotient. The RIAS-2 was designed to assess memory, with the understanding that memory is a pivotal part of the diagnostic assessment of many disorders throughout the lifespan. Via conorming, the RIAS-2 allows practitioners to compare IQ directly with key memory functions.

In addition to these nine primary goals, the developers of the RIAS-2 updated the item content from the original RIAS by removing controversial and dated items, adding new content, and extending the basal and ceiling rules. Additionally, all norms were updated with current U.S. census data. These updates were made at the requests of RIAS users to increase the value, acceptance, and applicability of the RIAS-2 as a measure of intellectual functioning. It was with these overarching goals in mind that the RIAS-2 was designed and its structure implemented.

Theory

As noted above, the RIAS-2 was designed to measure five important aspects of intelligence: (1) *general intelligence* (of which the major component is *fluid* or *reasoning abilities*); (2) *verbal intelligence* (sometimes referred to as *crystallized abilities,* which is a closely related though not identical concept); (3) *nonverbal intelligence* (referred to in some theories as *visualization* or *spatial abilities,* and closely allied with fluid intelligence); (4) *memory* (subtests covering this ability have been labeled variously as assessing *working memory, short-term memory,* or *learning*); and (5) *processing speed* (subtests assessing *rapid decision making* and *reaction time*). These five constructs are measured by combinations of the eight RIAS-2 subtests (see Table 18.1).

The RIAS-2 subtests were selected and designed to measure intelligence constructs that have a substantial history of scientific support. In addition, Carroll's (1993) seminal and often-cited three-stratum theory of intelligence informed the creation of the RIAS-2 by demonstrating that many of the latent traits tapped by intelligence tests were test-battery-independent. He clearly demonstrated, for example, that numerous tests measured the same crystallized, visual-perceptual, and memory abilities. However, Kamphaus (2001) concluded that these same test batteries did not measure fluid abilities well.

The RIAS-2 focuses on the assessment of stratum III and stratum II abilities from Carroll's (1993) three-stratum theory. Stratum III is composed of one construct only, *g.* Psychometric *g* accounts for the major portion of variance assessed by intelligence test batteries. More important, however, is the consistent finding that the correlations of intelligence tests with important outcomes, such as academic achievement and occupational attainment, are related to the amount of *g* measured by the test battery. In other words, so-called "*g*-saturated" tests are better predictors of important outcomes than are tests with low *g* saturation. Although the nature of *g* has yet to be fully understood, the scores from *g*-saturated tests have known utility, especially in terms of predictive validity. One theory posits that *g* is actually a measure of working memory capacity (Kyllonen, 1996), whereas another theory posits that it is reasoning ability (Gustafsson, 1999). Regardless of the theory that will eventually be supported, the utility of psychometric *g* remains, much in the same way that the usefulness of certain pharmaceutical drugs will continue before their mechanisms of action are fully understood. For these reasons, the RIAS-2 places great importance on the assessment of psychometric *g* and on the assessment of its theorized main components (i.e., verbal and nonverbal reasoning, working memory and processing speed). With this in mind, the developers of the RIAS-2 settled upon the inclusion of subtests that emphasize reasoning skills and the application of knowledge to problem solving on the intelligence subscales. This also guided the inclusion of two working memory and two processing speed tasks on the separate memory and processing speed subscales.

The second stratum in Carroll's (1993) hierarchy consists of traits that are assessed by combinations of subtests, or stratum I measures. A stratum I measure is typically a single subtest that measures the trait of interest. Combinations of stratum I subtests, such as those used to form the VIX and NIX, are considered stratum II measures and should result in enhanced measurement of complex traits such as verbal and nonverbal intelligence. Combining stratum II index measures into an overarching composite measure, such as the CIX, allows for the measurement of a complex stratum III trait, such as general intelligence.

There are, however, several stratum II traits to choose from. These traits include fluid intelligence, crystallized intelligence, general memory and learning, broad visual perception, broad auditory perception, broad retrieval ability, broad cognitive speed, and processing speed (i.e., reaction time or decision speed). However, it is important to note that myriad investigations suggest that these abilities are ordered by their assessment of *g* (Kamphaus, 2001). Specifically, subtests that tap fluid abilities are excellent measures of *g*, whereas tests of psychomotor speed are weak. If one accepts the aforementioned finding that *g* saturation is related to predictive validity, then the first few stratum II factors become the best candidates for inclusion in an intelligence test battery like the RIAS-2.

Any test of *g* must measure so-called "higher-order" cognitive abilities and those associated with fluid abilities, such as general sequential reasoning, induction, deduction, syllogisms, series tasks, matrix reasoning, analogies, quantitative reasoning, and so on (Carroll, 1993). Kamphaus (2001) advocated the following definition of reasoning: "that which follows as a reasonable inference or natural consequence; deducible or defensible on the grounds of consistency; reasonably believed or done" (*New Shorter Oxford English Dictionary,* 1999). This definition emphasizes a central cognitive requirement to draw inferences from knowledge. This characteristic of general intelligence is measured best by two RIAS-2 subtests, Verbal Reasoning and Odd-Item Out, although all subtests have substantial *g* saturation (see Reynolds & Kamphaus, 2015).

First-order factors of crystallized ability typically have one central characteristic: They involve language abilities (Vernon, 1950). These language abilities range from vocabulary knowledge to spelling to reading comprehension. On the other hand, it is not possible to dismiss this type of intelligence as a general academic achievement factor (Kamphaus, 2001), for several reasons. First, indicators of a latent construct do not necessarily reflect the content of the abilities that they represent. For example, the Snellen chart is the standard measure of visual acuity, but it is essentially a letter recognition test. In other words, the contrived nature of this task is far removed from the typical daily activities involving vision; however, performance on the task is a good indicator of visual acuity in numerous activities. Second, Carroll (1993) identified a separate set of factors associated with school achievement and knowledge that included tests of specific academic subject areas (e.g., English, history), among other tests—a finding suggesting that the "reading" and "writing" tests of the crystallized intelligence factor were measuring an intelligence construct. Otherwise, these same tasks would have loaded on factors that are clearly recognizable as academic attainments.

Kamphaus (2001) has suggested that the term *crystallized* for this second-order factor does not fully capture the centrality of language processes involved in successful performance on subtests typically associated with this ability. He proposed the term *verbal* to describe the latent construct tapped by subtests like those selected for the RIAS-2 to assess this ability. Furthermore, Kamphaus suggested this label would better represent the centrality of language development to successful performance on these subtests, while recognizing the wide variety of tests that measure this latent trait (e.g., word reading and spelling). In addition, the term *verbal* has often been used by the general public when describing types of intelligence—a fact suggesting that this label may be helpful for communicating the results derived from such measures (Weinberg, 1989). Kamphaus proposed that the verbal factor be defined as "oral and written communication skills that follow the system of rules associated with a language" (p. 45), including comprehension skills. The RIAS-2 includes Guess What and Verbal Reasoning as measures of verbal ability. Verbal Memory is also a member of the verbal factor in terms of factor-analytic results.

Nonverbal tests have come to be recognized as important measures of spatial and visual-perceptual abilities—abilities that may need to be assessed for a variety of clients, including those with brain injuries. In the 1963 landmark Educational Testing Service Kit of Factor-Referenced Cognitive Tests, spatial ability was defined as "the ability to manipulate or transform the image of spatial patterns into other visual arrangements" (quoted in Carroll, 1993, p. 316). The RIAS-2 subtests What's Missing and Odd-Item Out follow in this long tradition of tasks designed to measure visual–spatial abilities.

Digit recall, sentence recall, geometric design recall, bead recall, and similar measures loaded consistently on a *general memory and learning* stratum II factor identified by Carroll (1993) in his numerous analyses. The RIAS-2 Verbal Memory and Nonverbal Memory subtests are like these tasks, although more complex than simple confrontational memory tasks such as pure digit recall. Carroll's findings suggest that the RIAS Verbal Memory and Nonverbal Memory subtests should be good measures of the memory construct that has been identified previously in many investigations of a diverse array of tests. Carroll described memory span as "attention to a temporally ordered stimulus, registration of the stimulus in immediate memory, and output of its repetition" (p. 259). This operational definition is an accurate description of the RIAS-2 memory subtests and composite. Memory is typically considered a complex trait with many permutations, including visual, verbal, long-term, and short-term. Carroll's analysis of hundreds of datasets supports the organization of the RIAS-2, in that he found ample evidence of a general memory trait that may be subdivided further for particular clinical purposes.

The rate at which an individual can perform a simple task quickly is typically considered a reflection of cognitive processing speed. This is aligned with Carroll's stratum II construct of *processing speed*. In alignment with the verbal–nonverbal approach of the RIAS-2, subtests that measure processing speed in both modalities are offered. More notably, the developers of this assessment actively sought tasks of processing speed that reduce reliance on motor skills to demonstrate ability in this area. However, performance on this task may still be confounded by other variables such as attention. In a three-factor solution, these processing speed tasks emerge as distinct from other RIAS-2 tasks and are thus valuable as a unique construct to be assessed. The Speeded Naming Task and Speeded Picture Search subtests are used to measure these abilities. Additional information about the theory that drives the RIAS-2 can be found in the test manual.

Description of Subtests

Subtests from the original RIAS were updated and expanded for the RIAS-2. These subtests have a familiar look and feel, with deep histories in the field of intellectual assessment. There are a total of four intelligence subtests, two memory subtests, and two processing speed subtests. The intelligence subtests were chosen due to their complex nature: Each assesses many intellectual functions and requires their integration for successful performance. The memory and processing speed subtests were chosen not only for complexity, but also due to their representation of the primary content domains of the constructs being measured. A brief description of the subtests is provided below.

- *Guess What.* This subtest measures vocabulary knowledge in combination with reasoning skills that are predicated on language development and funds of information. For each item, the examinee is asked to listen to a question that contains clues presented orally by the examiner, and then to give a verbal response (typically one or two words) that is consistent with the clues. The questions pertain to physical objects, abstract concepts, and well-known places and historical figures from a variety of cultures and geographic locations. Many disciplines are represented among the test questions.
- *Verbal Reasoning.* The second verbal subtest measures analytical reasoning abilities. More difficult items, of necessity, also require advanced vocabulary knowledge. For each item, the exam-

inee is asked to listen to an incomplete sentence presented orally by the examiner, and then to give a verbal response (typically one or two words) that completes the sentence—most commonly completing a complex analogy. Completion of the sentences requires the examinee to evaluate the various conceptual relationships that exist between the physical objects or abstract ideas contained in the sentences. Many different types of relationships from a broad content range are represented in these items.

- *Odd-Item Out.* This subtest measures general reasoning skills, emphasizing nonverbal ability. For each item, the examinee is presented with a picture card containing five to seven figures or drawings. One of the figures or drawings on the picture card has a distinguishing characteristic, making it different from the others. For each item, the examinee is given two chances to identify the figure or drawing that is different from the others. Two points are awarded for a correct response given on the first attempt. One point is awarded for a correct response given on the second attempt (i.e., if the first response was incorrect).

- *What's Missing.* This subtest measures nonverbal reasoning skills through the presentation of pictures in which some important component of the pictured object is missing. Examinees must conceptualize the pictured object, assess its gestalt, and distinguish essential from nonessential components. For each item the examinee is shown a picture card, asked to examine the picture, and then to indicate (in words or by pointing) what is missing. Verbally naming the missing part correctly is not required, so long as the examinee can indicate the missing component correctly. For each item, the examinee is given two chances to identify what is missing from the picture. Two points are awarded for a correct response provided on the first attempt. One point is awarded for a correct response provided on the second attempt. Two incorrect responses are awarded a score of 0.

- *Verbal Memory.* This subtest measures the ability to encode, briefly store, and recall verbal material in a meaningful context. Young children (ages 3–4 years) are asked to listen to sentences of progressively greater length as each is read aloud by the examiner; they are then asked to repeat each sentence back to the examiner, word for word, immediately after it is read aloud. Older children and adults are asked to listen to two stories read aloud by the examiner and then to repeat each story back to the examiner, word for word, immediately after it is read aloud. The sentences and stories were written to provide developmentally appropriate content and material of interest to the targeted age group. Specific stories are designated for various age groups.

- *Nonverbal Memory.* This subtest measures the ability to encode, briefly store, and recall visually presented material, whether the stimuli represent concrete objects or abstract concepts. For each item, the examinee is presented with a target picture for 5 seconds, and then with a picture card containing the target picture and an array of similar pictures. The examinee is asked to identify the target picture among the array of pictures presented on the picture card. For each item, the examinee is given two chances to identify the target picture. Two points are awarded for a correct response given on the first attempt. One point is awarded for a correct response given on the second attempt. Two incorrect responses are awarded a score of 0. The pictures are, primarily abstract at the upper age levels, and pictures of common objects at the lower age levels. The use of naming and related language strategies, however, is not helpful, due to the design of the distractors. For example, one early item presents as a target stimulus a picture of a cat. On the recall page, six cats are presented, each characteristically different (except one) from the target stimulus.

- *Speeded Naming Task.* This subtest measures the ability to differentiate stimuli and verbally name them under time constraints. Examinees are presented with pictures of common objects in a grid format. They are then asked to recognize them quickly and speak the name of each object aloud to the examiner. The subtest provides an accurate report of verbal processing speed (aligned with CHC definitions) for individuals with intact attentional, visual-perceptual, and speech abilities.

- *Speeded Picture Search.* This subtest assesses the ability to nonverbally differentiate stimuli under time constraints. Examinees are shown an array of pictures and asked to identify three target pictures as quickly as possible. This, like the other processing speed subtest, is aligned with CHC theory, as the stimuli are simple and could be identified with ease without the time constraints. It is the coupling of the task with the time limits that makes this a measure of processing speed. This measure provides an accurate account of processing speed ability for individuals who do not have reported attentional, visual-perceptual, or speech impairments.

ADMINISTRATION AND SCORING

The RIAS-2 was specifically designed to be easy to administer and objective to score. Examiners giving the RIAS-2 should be experienced with general test administration procedures and properly credentialed in their state or province. They should also review all materials associated with the test, including the manual, stimulus books, and record form, before attempting to administer this test. To promote efficient administration, the RIAS-2 and RIST-2 record forms contain the necessary instructions and examiner guides necessary to administer the tests. Experienced examiners as well as graduate students have consistently reported that these tests are surprisingly easy to administer and score.

Once an examiner has established rapport with an examinee, the protocols outlined in the manual for standardized administration should be followed. Instructions for the examinee are short and simple. Basal and ceiling rules as well as start points are clearly labeled and outlined in both the record form and the test manual, and should be followed to maintain fidelity of administration. For all subtests except Verbal Memory, there are clear, objective lists of correct responses for each test item, and seldom are any judgment calls required. Studies of the interscorer reliability of these five subtests with trained examiners produced reliability coefficients of .99 (Reynolds & Kamphaus, 2015). On Verbal Memory, some judgment is requited when examinees do not give verbatim responses; however, the scoring criteria provide clear examples and guidelines for such circumstances, making the Verbal Memory subtest only slightly more difficult to score than the others. The interscorer reliability study of this subtest produced a coefficient of .95.

The time required to administer the entire RIAS-2 (including the intelligence, memory, and processing speed subtests) averages 40–45 minutes once the examiner has practiced giving the RIAS-2 and has become fluent in its administration. The administration time for the RIST-2 (the screening subtests of the RIAS-2) averages about 12–15 minutes. As with most tests, the first few administrations are likely to take longer. The four intelligence subtests alone (i.e., Guess What, Odd-Item Out, Verbal Reasoning, and What's Missing), can be administered to most examinees in about 20–25 minutes. The two memory and two processing speed subtests can typically be administered in about 10 minutes for each set. However, significant time variations can occur as a function of special circumstances (e.g., very-low-functioning individuals will likely take much less time to complete the battery, and very-high-functioning individuals may take longer). A detailed description of the methods used for setting these administration parameters is given in the test manual.

PSYCHOMETRIC PROPERTIES

The psychometric characteristics of any measurement device and its scores are crucial in determining its utility. In this section, we summarize the reliability of the scores derived from the RIAS-2 and RIST-2, as well as evidence related to the validity of their interpretations. Due to the length restrictions in a single book chapter, a discussion of the developmental process of the tests simply cannot adequately be provided; such a discussion can be found in the test manual. However, the RIAS-2 underwent years of development, including tryout and review of the items on multiple occasions by school psychologists, clinical psychologists, and neuropsychologists. Items were written to conform to clear specifications, consistent with the goals for development of the test as given previously in this chapter. Items were reviewed by panels of expert psychologists for content and construct consistency to ascertain the cultural saliency of the items and to eliminate any potential problems of ambiguity or offensiveness in various settings. The developmental process speaks directly to the psychometric characteristics of the tests and is described in greater detail in Reynolds and Kamphaus (2015). These should be considered carefully in any full evaluation of the instrument.

Standardization

The RIAS-2 was normed on a sample of 2,154 participants residing in 32 states between the years of 2013 and 2014. U.S. Census Bureau projected characteristics of the U.S. population for 2012 were used to select a population-proportionate sample. Age, gender, ethnicity, educational level (parental educational level was used for ages 3 years through 16 years, and the participants' actual educational level was used at all other ages), and region of residence were used as stratification variables. Participants in the norming were screened for many low-incidence disorders that might interfere with their performance on the test, such as color blindness, uncorrected hearing and vision difficulties, or a history of traumatic brain injury (TBI) or attention-deficit/hyperactivity disorder (ADHD). The resulting norms for the RIAS-2 and the RIST-2 were calculated on a weighted sampling that provided a virtually perfect match to the census data. The overall sample was a close match to the population statistics. Tables with specific demographic information are available in the test manual.

Score Reliability

Reliability is a psychometric concept referring to the accuracy and consistency of scores obtained on a measurement device, and not that of the test itself. To the degree to which test scores contain error, the reliability of the score is reduced. Errors in test scores may come from a variety of sources, such as errors associated with content sampling, time sampling, administrative and scoring errors, and the like. Traditionally in psychology, these error sources are evaluated by using specialized correlation procedures. The largest source of error in test scores is typically errors due to content sampling. To assess this source of error, measures of the internal consistency of the items are used, the most widely known and applied being Cronbach's (1951) alpha.

Since the RIAS-2 is a power test (items are presented in order of difficulty, from least to most difficult, and individuals' scores depend entirely on how many items they respond to correctly), the internal-consistency reliability of the items on the RIAS-2 subtests was investigated by using Cronbach's coefficient alpha. Internal-consistency estimates for the RIAS-2 indexes (i.e., the VIX, NIX, CIX, CMX, and SPI) were derived by using a simplification of Guilford's (1954, p. 393) formula. This formula was designed for application to the special case present in the RIAS-2, where both the VIX and the NIX have only two components, each scaled to a common metric, and where the CIX represents a linear, equally weighted composite of the sums of *T* scores for the four subtests (see Nunnally, 1978, p. 249, formula 7-15). Alpha reliability coefficients for the RIAS-2 subtest scores and the Nunnally reliability estimates for the index scores are presented in the test manual. It is noteworthy that 100% of the alpha coefficients for the RIAS subtest scores reach .84, or higher, for every age group. Further, the median alpha reliability estimate for each RIAS-2 subtest across age equals or exceeds .90. This point is important because many measurement experts recommend that reliability estimates above .80 are necessary and those above .90 are highly desirable for tests used to make decisions about individuals. All RIAS-2 subtests meet these recommended levels.

One cannot always assume that because a test is reliable for a general population, it will be equally reliable for every subgroup within that population. Therefore, test developers and researchers should demonstrate, when possible, that the instrument demonstrates measurement equivalence and reliability for subgroups. This is particularly important for groups that, because of gender, racial, cultural or linguistic differences, might experience test bias (Reynolds, 2000). Thus it is instructive to view the various reliability estimates for the RIAS-2 (or any test) for smaller, meaningful subgroups of a population. As noted in the *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA], American Psychological Association, & National Council on Measurement in Education, 1999, 2014), these values may also provide information relevant to the consequences of test use. Reliability estimates reported in the RIAS-2 manual suggest uniform internal consistency across age (3–94 years), as well as across gender and racial groups.

Test score stability (sometimes referred to as *error due to time sampling*) refers to the extent to which an individual's test performance is constant over time and is usually estimated by the test–retest method. In this procedure, the test is given to a group of individuals, a period of time is allowed to pass, and the same individuals are tested again. Then the results of the two administrations are compared. The stability of RIAS-2 scores over time was investigated by using the test–retest method with 97 individuals ages 3 years through 72 years. The intervals between the two test administrations ranged from 7 to 43 days, with a median test–retest interval of 18 days. The correlations for the two administrations, along with mean scores and standard deviations, are reported in detail in the RIAS-2 manual (Reynolds & Kamphaus, 2015).

The obtained coefficients are of sufficient magnitude to allow confidence in the stability of RIAS-2 test scores over time. The values are quite good for all of the subtests, but especially for the index scores. Both the uncorrected coefficients and the corrected, or disattenuated, coefficients are reported (the corrected coefficients have been corrected for the alpha for each subtest). When viewed across age groups, the values are generally consistent with the values obtained for the total test–retest sample. The test–retest stability coefficients for scores on the RIAS-2 subtests and indexes are quite strong and provide evidence of more than sufficient short-term temporal stability of the scores to allow examiners to be confident in the obtained results.

Validity of RIAS-2/RIST-2 Test Scores as Measures of intelligence

According to the 1999 edition of the *Standards, validity,* in this context, refers to "the degree to which evidence and theory support the interpretations of test scores entailed by proposed users of tests" (AERA et al., 1999, p. 9). Reynolds (1998) has defined *validity* similarly, arguing that it refers to the appropriateness and accuracy of the interpretation of performance on a test (see also Montgomery, Torres, & Eiseman, Chapter 30, this volume). Validation of the meaning of test scores is also a process—one that involves an ongoing, dynamic effort to accumulate evidence for a sound scientific basis for proposed test score interpretations (AERA et al., 1999; Reynolds, 1998). Validity will always be a relative concept because the validity of an interpretation will vary according to the purpose for which test scores are being used, the types of individuals or populations being examined, and the specific interpretations being made.

As with any measure of intelligence, many other basic but subsidiary cognitive processes, such as auditory and visual perception, logical reasoning, language processing, spatial skills, visual imagery, attention, and the like, play a role in performance on the RIAS-2. These skills are the building blocks of the primary intellectual functions assessed by the RIAS-2. As previously described, the cognitive abilities measured by the RIAS-2 are grounded in Carroll's (1993) work. Initial validity evidence associated with the RIAS-2 indexes is highly consistent with the long history of intelligence testing research. A comprehensive review of the validity evidence is presented in the test manual.

Correlations with the Wechsler Scales

Measures of intelligence should generally correlate well with one another, if they are measuring *g* and related constructs. Thus, to understand a new measure and its appropriate interpretations, it is instructive to assess the relationship of the new measure to other measures of intelligence. For children (ages 6 years through 16 years), the best-known and most widely researched scale over the years and one that has maintained a reasonably consistent structure is the Wechsler Intelligence Scale for Children, which at the time the RIAS-2 was developed was in its fourth edition (WISC-IV; Wechsler, 2003). Tables available in the test manual demonstrate the correlations between the WISC-IV and the RIAS-2. The RIAS-2 indexes all correlated highly with the WISC-IV Full Scale IQ (FSIQ), with correlations ranging from a low of .58 (SPI to FSIQ) to a high of .77 (CIX to FSIQ). This pattern is predictable, as the highest correlations were between aspects of the tests measuring similar elements of *g*.

A group of 72 adults were administered the RIAS-2 and the Wechsler Adult Intelligence Scale—Fourth Edition (WAIS-IV; Wechsler, 2008) in a counterbalanced design. Most of the RIAS-2 indexes correlated positively with WAIS-IV composites, ranging from a low of .23 (SPI with Perceptual Reasoning) to a high of .77 (VIX with Verbal Comprehension). Again, the strongest relationships were demonstrated between indexes measuring similar constructs (e.g., VIX with Verbal Reasoning).

Correlations with Measures of Academic Achievement

One of the major reasons for the development of the early, individually administered intelligence tests was to predict academic achievement levels. Intelligence tests have done well as predictors of school learning, with typical correlations in the mid-.50s and .60s (for summaries, see Kamphaus, 2001; Sattler, 2001). To evaluate the relationship between the RIAS-2 and academic achievement, 253 individuals across the lifespan (ages 4–85 years) were administered the RIAS-2 and the Academic Achievement Battery (AAB; Messer, 2014). Correlations between the RIAS-2 and the AAB indexes were moderately strong and positive, ranging from .16 (SPI with Expressive Communication and Mathematical Reasoning) to .56 (CIX with Total Achievement). Learning is school is heavily dependent on language, which is confirmed by the positive correlations between the VIX and all AAB indexes. A more in-depth look at these relationships is provided by the relevant tables in the RIAS-2 manual.

Performance of Clinical Groups

Examination of performance on the RIAS-2 by groups of individuals who meet formal criteria for various diagnoses can also be instructive. For example, individuals with intellectual and developmental disabilities (IDD), dementia, and other cognitive problems associated with intellectual impairment should earn lower scores on the RIAS-2 than their typically developing peers in the RIAS-2 standardization sample. In interpreting such scores of preselected samples when those samples are selected on the basis of extreme scores on a cognitive measure, one must always consider the problem of regression to the mean on a second testing. For example, scores obtained from a sample with IDD will typically be higher on a second testing, but the scores should still be well below the population mean.

During the standardization of the RIAS-2, 12 different clinical groups were identified, and their scores on the RIAS-2 were analyzed to supplement the validation of the interpretation of RIAS scores. In each instance, the primary diagnosis given by the agency serving the examinee was accepted, and no independent review or diagnosis was undertaken. The samples included individuals with TBI, dementia, stroke/cerebrovascular accident, IDD, deafness and hearing impairments, specific learning disabilities (SLD), and a variety of others. The various impairments represented many organic deficits within each category, along with diffuse brain lesions. There were samples of children with SLD and ADHD that came from more than one source. In reviewing the outcomes of testing with the RIAS-2 with these 12 clinical samples, Reynolds and Kamphaus (2015) concluded that all of the various clinical groups in these studies demonstrated some levels of deviation from the population mean on the RIAS-2. Although most deviations are small, as is commonly found in the literature, the samples with more severe disorders performed more poorly. Again, however, the purpose for presenting these data is not to make definitive statements about these clinical groups, but to describe how the RIAS-2 scores function for each group. Moreover, these data are preliminary and not definitive as to any score patterns on the RIAS-2 that may emerge for clinical groups. Replication with larger and more carefully defined samples will be necessary before firm conclusions can be drawn. The evidence thus far is quite supportive because the score patterns do conform well.

APPLICATIONS OF THE RIAS-2 AND RIST-2

As a measure of intelligence, the RIAS-2 is appropriate for a wide array of purposes and should be useful when assessment of an examinee's intellectual level is needed. The RIAS-2 can be used across school and clinical settings with preschool and school-age children for purposes of diagnosis and intervention plan development; it is useful for students with disabilities, as well as gifted and talented students. Diagnosis of specific disorders, such as IDD, SLD, and the various dementias, often require the use of an intellectual test as a part of evaluation. The RIAS-2 is appropriate for such applications. Clinicians who perform general clinical and neuropsychological evaluations will find the RIAS-2 very useful when a measure of intelligence is needed. Practitioners will also find the RIAS-2 useful in disability determinations under various state and federal programs, such as the Social Security Administration's disability program and Section 504 regulations. Employers may find the RIAS-2 or RIST-2 helpful as a tool to predict success in job training programs and, in other instances, to predict possible difficulties when lower limits are set on IQ levels for specific jobs. Finally, the RIAS-2 and RIST-2 are strong predictors of academic performance. When intelligence level is a question in such situations, the RIAS and the RIST are appropriate choices.

Appendix 18.1 presents a case report that demonstrates how the RIAS-2 can be integrated into a comprehensive evaluation. It is an amalgamation of several authentic cases, and therefore does not resemble any one individual.

CONCLUSIONS

The RIAS-2 and RIST-2 are standardized assessments of intellectual functioning for individuals ages 3–94 years. The RIAS-2 is a quick and efficient comprehensive measure of cognitive ability. The RIST-2 is a screening instrument designed to guide identification of risk for atypical cognitive functioning. These instruments, standardized on a large and diverse sample, are firmly rooted in widely accepted intelligence test theory. The RIAS-2/RIST-2 indexes capture the most empirically sound aspects of intelligence, supporting their use across populations and affirming the utility of the results. These instruments were developed with special attention to well-reasoned modern standards for psychological and educational assessment (AERA et al., 1999, 2014). Therefore, the RIAS-2 and RIST-2 are optimal for use in making determinations for educational or clinical purposes, as well as for benefits eligibility.

APPENDIX 18.1

Sample Case Report

Child's name: Tamik Parris
Parent's name: Tanya Parris
School: One Great Elementary School
Address: 123 Awesome Street, Excellent City, Fine State
Grade: 1
Test date: November 10, 2016
Examiner: Karen Schuyler
DOB: 10/14/2010 Age: 6:0

CONSULTATIONS

Teacher, Nicole Talapatra; parent, Tanya Parris

INSTRUMENTS ADMINISTERED

Reynolds Intellectual Assessment Scales, Second Edition (RIAS-2)
Kaufman Test of Educational Achievement—Second Edition (KTEA-II)
Behavior Assessment System for Children, Third Edition (BASC-III), Teacher Rating Scale (TRS) and Parent Rating Scale (PRS)
Children's Self-Report and Projective Inventory (CSRPI), selected subtests
Records review
Interviews with parent, teacher, and child

REFERRAL REASON

Tamik was referred for evaluation by the Student Support Team at One Great Elementary School. Teachers report concerns regarding Tamik's social-emotional and academic performance. He is significantly below grade level in all academic areas. In addition, Tamik has had several major disruptive episodes. These episodes have included threatening to harm himself, running from his designated area, appearing disoriented, and requiring administrative time outs. Tamik has a current certification of special education eligibility from another state and requires reevaluation to determine eligibility for special education services in Fine State.

BACKGROUND INFORMATION

Information for this section was gathered from the parent information form and parent interview. Tamik currently lives with his biological mother and his older sister. The family recently relocated from another state following his parents' divorce. Tamik's family is African American. It was reported that he has a good relationship with his family members, despite behavioral difficulties. Tamik's mother disclosed that he did witness domestic violence as a toddler, and that his behavior has escalated since she separated from his father 2 years ago. Ms. Parris reports that Tamik and his father were very close, and adds that he still often screams for his father to come home. Currently, Tamik's father has no custodial rights, and he has not seen Tamik in over 2 years.

It was revealed during the parent interview that Tamik was the product of a typical pregnancy and delivery. Developmental milestones were reported as met within normal limits. No significant medical history was revealed.

School history indicates that Tamik attended school in the previous state of residence before enrolling at One Great. According to Ms. Parris, his previous schools noted behavioral and academic concerns. Tamik was found eligible for special education services under the category of "emotional disturbance" at the beginning of his kindergarten year. This information was also obtained from the interview with Ms. Parris. She reports that Tamik was in a classroom with seven other children, a teacher, and a paraprofessional. At the time of the evaluation, Tamik's records from his previous school were not available. Multiple unsuccessful requests have been made to obtain this information.

Since beginning school at One Great, Tamik has had notable difficulty adhering to classroom rituals and routines. Additionally, he has had several major disruptive episodes that include running from the school building, threatening to kill himself, and being verbally aggressive with staff. Please review the functional behavior assessment data for detailed accounts of Tamik's behaviors.

The observed behaviors have had a negative impact on Tamik's academic functioning. He is on a specific behavior management plan to address problem behaviors.

On November 11, 2016, Tamik passed his hearing and vision screenings.

TEST BEHAVIOR AND OBSERVATIONS

At the time of the evaluation, Tamik separated from his class reluctantly. He appeared well groomed and well nourished. He was dressed in the style of his peers. Upon reaching the assessment area, Tamik appeared to be more comfortable, as demonstrated by his relaxed posture and the ease with which he completed tasks asked by the examiner. Tamik was asked to draw a picture of a person to build rapport. His conversation in response to the drawing was morose. He indicated that he drew a "grim reaper" that "kills real demons." His response to questions about his picture included repeated themes of death. At times, he struggled to answer the questions appropriately, and his conversation appeared disjointed. Despite these observations, it is believed that rapport was adequately established and maintained.

Tamik fidgeted throughout the assessment session and asked numerous questions about various objects in the assessment room. He required frequent redirection to attend to the tasks presented. Despite this, Tamik enthusiastically attempted all items presented. He appeared to enjoy verbal praise as he worked through the tasks.

It is believed that Tamik's distractibility may have had a negative impact on his performance during this assessment. However, this behavior is consistent with teacher reports of his classroom behavior. Therefore, due to optimal participation and test setting results, this evaluation is considered an accurate estimate of Tamik's current functioning.

TEST RESULTS AND INTERPRETATION

Cognitive Processes

Intelligence refers to a person's ability to receive information through various perceptual modalities, to retain information in memory, and to organize it meaningfully through various cognitive processes (i.e., concept formation, comprehension, reasoning, judgment, planning, information processing, working memory, and problem solving).

Reynolds Intellectual Assessment Scales, Second Edition

The Reynolds Intellectual Assessment Scales, Second Edition (RIAS-2), is an individually administered measure of intellectual functioning normed for individuals between the ages of 3 and 94 years. The RIAS-2 contains several individual tests of intellectual problem-solving and reasoning ability that are combined to form a Verbal Intelligence Index (VIX) and a Nonverbal Intelligence Index (NIX). These two indexes of intellectual functioning are then combined to form an overall Composite Intelligence Index (CIX). When the VIX and the NIX are combined into the CIX, a strong, reliable assessment of general intelligence is obtained. Scores for this portion of this instrument are presented in terms of standard scores (SS) with a mean of 100 and a standard deviation of 15. The index scores are categorized within the following descriptive ranges:

69 or below: Significantly below average
70–79: Moderately below average
80–89: Below average
90–109: Average
110–119: Above average
120–129: Moderately above average
130 or above: Significantly above average

Tamik's CIX, VIX, and NIX scores were as follows:

- *Composite Intelligence Index.* Tamik obtained a CIX score of 103. This level of performance is considered within the average range, falls within expected limits, and falls into the 58th percentile. The results obtained with this and the other indexes of the RIAS-2 impress the examiner as being accurate reflections of Tamik's current intellectual functioning.
- *Verbal Intelligence Index.* Skills measured by the VIX include the ability to deduce or infer relationships and the ability to apply knowledge to problem solving that involves using words and language skills. The VIX provides a measure of verbal reasoning ability, with primary emphasis on crystallized intelligence functions. Tamik performed in the average range on this index, with a score of 108, which falls into the 47th percentile. Subtests within this index measure verbal reasoning

in combination with vocabulary, language development, and an overall fund of available information.

- *Nonverbal Intelligence Index.* Skills measured by the NIX include the ability to perceive, manipulate, or transform accurately the image of spatial patterns into other visual arrangements. The NIX provides a measure of nonverbal reasoning ability with primary emphasis on fluid intelligence functions. Tamik performed in the average range on this index as well. His performance yielded a score in the 66th percentile. Subtests within this index measure nonverbal reasoning, spatial ability, visual imagery, visual discrimination and deductive reasoning. It appears that Tamik demonstrated a relative strength in nonverbal tasks.

Table 18.A.1 presents the *T* scores that reflect Tamik's performances on the individual subtests used to derive the CIX, VIX, and NIX. Each *T* score has a mean of 50 and a standard deviation of 10. Approximately two-thirds of the population earns *T* scores between 40 and 60.

In addition to the four subtests that yield the CIX, VIX, and NIX as measures of intellectual functioning, the RIAS-2 offers two further index scores. These are the Composite Memory Index (CMX) and the Speeded Processing Index (SPI). Tamik's performances on these, as well as his performances on the subtests used to derive these scores, are reported below.

- *Composite Memory Index.* The CMX provides a summary estimate of verbal and nonverbal memory functions in general as its component parts correspond to the broad areas of memory skills. Tamik obtained a CMX score of 96, exhibiting memory capacity in the average range. Tamik's performance within this cluster revealed fairly even development across verbal and nonverbal short-term memory. His performance fell into the 39th percentile.
- *Speeded Processing Index.* The SPI provides a summary estimate of processing speed, primarily involving both decision speed and reaction while minimizing the efforts of motor speed. Tamik obtained an SPI score of 82 (12th percentile), which is in the low average range for processing speed. Tamik's performance within this cluster revealed better developed visual short-term memory than verbal short-term memory. It is important to note that Tamik required redirection during these tasks multiple times. This may have affected his score on the verbal speeded processing activity. Therefore, while this may be an accurate portrayal of his current functioning, it is likely to be an underestimate of his ability.

Table 18.A.2 presents the *T* scores that reflect Tamik's performances on the individual subtests used to derive the CMX and SPI. Each *T* score has a mean of 50 and a standard deviation of 10. Approximately two-thirds of the population earns *T* scores between 40 and 60.

Academic Performance

Kaufman Tests of Educational Achievement, Second Edition

Tamik's academic skills were measured with the Kaufman Test of Educational Achievement—Second Edition (KTEA-II). The KTEA-II is an individually administered, standardized test instrument designed to measure skills in reading, mathematics, written language, and oral language. The KTEA-II contains a series of tasks arranged in eight subtests, with six additional reading-related subtests. For purposes of interpretation, Tamik's performance on the questions within each subtest is compared to that of a normative sample of students at the same age, and converted to a standard score. Standard subtest scores are combined to yield scores for Reading, Mathematics, Written

TABLE 18.A.1. Tamik's RIAS-2 Subtest *T* Scores for the CIX, VIX, and NIX

Subtest	Age-adjusted *T* score	Percentile	Description
Guess What (GWH)	48	45	Vocabulary, language development, overall knowledge
Odd-Item Out (OIO)	59	82	Nonverbal reasoning, spatial ability
Verbal Reasoning (VRZ)	51	53	Verbal-analytical reasoning
What's Missing (WHM)	52	55	Nonverbal deduction, attention to visual detail

TABLE 18.A.2. Tamik's RIAS-2 Subtest *T* Scores for the CMX and SPI

Subtest	Age-adjusted *T* score	Percentile	Description
Verbal Memory (VRM)	45	32	Verbal recall in a meaningful context
Nonverbal Memory (NVM)	51	53	Nonverbal recognition without meaningful context
Speeded Naming Task (SNT)	35	7	Verbal differentiation/recognition of simple stimuli under time constraints
Speeded Picture Search (SPS)	46	34	Visual differentiation/recognition of simple stimuli under time constraints

Language, and Oral Language. Each of the standard scores has a mean of 100 and a standard deviation of 15. A selection of Tamik's KTEA-II scores is presented in Table 18.A.3.

These results are inconsistent with classroom reports of Tamik's academic ability. In class, he has demonstrated limited abilities in all academic areas. He appeared to enjoy this portion of the assessment. He was allowed to stand and take frequent breaks when completing tasks. Tamik does not complete assignments in the classroom and requires one-on-one assistance to begin tasks in the classroom.

Social-Emotional Functioning

Social-emotional assessment is the evaluation of an individual's social relations, coping strategies, and self-perceptions. The assessment is based upon information obtained from a variety of sources, which can include evaluations by teachers and parents, as well as individual personality testing. Current reports indicate that Tamik is having difficulty attending to tasks, is demonstrating a great deal of overactivity in the classroom as well as at home, and is having major disruptive episodes in the classroom and other school settings.

TABLE 18.A.3. Selected KTEA-II Scores for Tamik

Subtest or **composite**	SS
Letter and Word Recognition	92
Reading Comprehension	92
Reading Composite	**91**
Math Concepts and Applications	97
Math Computation	104
Math Composite	**101**
Spelling	90
Phonological Awareness	98

Note. Composites are given in boldface.

Children's Self-Report and Projective Inventory

Tamik was administered selected sections of the Children's Self-Report and Projective Inventory (CSRPI). Due to limited attention to tasks and increasing agitation as the assessment progressed, the entire instrument was not attempted. Tamik was asked to draw a picture of his family with everybody doing something. His explanation of the picture was disjointed. However, he supplied a drawing of himself on the right side of the picture, holding a long straight object with a point like an arrow. He stated that in the picture, he was exercising. He drew his mother and sister on the other side, much smaller, and said they were talking. He then stated that his aunt was also exercising until his mother left. In the center of the picture very large, he drew Giovanni (a family friend). He reported that Giovanni "knows how to walk." Tamik was additionally asked to draw a picture of a child in the rain. Tamik growled when the examiner requested this picture. He hastily drew one large black cloud at the top of the page. He then began drawing raindrops very haphazardly all over the paper. He drew himself in a house, then drew more raindrops, using a lot of pressure with the crayon, over himself and in the house. When asked about the drawing, he stated that he was "running without a raincoat" and that he "open[ed] the door to the house and just made it, but RAIN!" He became increasingly agitated and added, "It is inside the house! Rain crashed and came inside the house!" A drawing of this nature may be indicative of anxiety and feelings of limited coping resources. Tamik is in the middle of several familial transitions and may lack the necessary coping mechanisms to deal with these changes.

- Tamik was also administered a sentence completion task as part of the CSPRI. His responses included themes of death, abandonment, and punishment. Some significant responses included the following (Tamik's sentence completions are italicized):

Most kids think I'm *a jerk.*
When my parents fight, I think that *they will kill like hit each other.*
I don't understand why my parents *let me go outside and die.*
I wish I could *spend more time with my friend. I don't have a friend.*
In 10 years, I hope I'll *be a police and kick somebody's butt.*

Additionally, when asked what makes him happy, Tamik stated, "To jump in a pool and die. I would be a little bit happy, but still bored." During this portion of the assessment, Tamik had periods of focused cooperation and periods of anger and resistance. The results of interviews and the projective assessment suggest that Tamik is demonstrating markedly different social and emotional development from that of his peers.

Behavior Assessment System for Children, Third Edition

The Behavior Assessment System for Children, Third Edition (BASC-3), is a multimethod, multidimensional system used to evaluate the behavior and self-perceptions of children and young adults ages 2–25 years. Separate rating scales are available for completion by teachers and by parents. Scores are reported as T scores with a mean of 50 and a standard deviation of 10.

The Parent Rating Scale (PRS) is a comprehensive measure of adaptive and problem behaviors observed by parents at home and in the community. The PRS assesses most of the clinical and adaptive skills domains that the Teacher Rating Scale (TRS) measures. In addition, the PRS includes a scale (Activities of Daily Living) that the TRS does not measure.

Table 18.A.4 is provided as a guide to BASC-3 T-score interpretation. Scores in the clinically significant range indicate a high level of maladaptive behavior or lack of adaptive behavior. Scores in the at-risk range indicate the presence of significant problems that, while requiring intervention, may not be severe enough to warrant a formal diagnosis. A selection of Tamik's BASC-3 scores is reported in Table 18.A.5.

TABLE 18.A.4. Interpretation of BASC-3 *T* Scores

Clinical scales	Adaptive scales
70+: Clinically significant	70+: Very high
60–69: At risk	60–69: High
41–59: Average	41–59: Average
31–40: Low	31–40: At-risk
30 or below: Very low	30 or below: Clinically significant

The BASC-3 PRS was completed by Ms. Parris, Tamik's mother. The TRS was completed by his teacher, Ms. Talapatra. Variance in environmental structure and rater expectations may account for discrepancies in score reports.

An analysis of Tamik's BASC-3 scores indicates that he is exhibiting clinically significant behaviors across areas assessed in the school setting. In contrast, his mother reported no areas of concern. This is inconsistent with the parent interview, where Ms. Parris reported that Tamik exhibits noncompliant and disruptive behavior at home and in the community. Specifically, she reported that she cannot get him to go to bed; that he becomes loud and disruptive in stores, often running from her; and that he is aggressive with her almost daily when she brings him to school.

Ms. Talapatra's scores yielded an F index ("fake bad") score in the "extreme caution" range. High scores on the F index indicate the possibility that a respondent has reported items in an overly negative manner. However, children who present in acute psychological distress may also score highly on this scale. Based on the severity of behaviors observed by Ms. Talapatra in the school and those reported by Ms. Parris in the home and community, the TRS scores may constitute an accurate report of Tamik's current behavioral functioning. Based on observations and related information presented in this report (all of which support the presence of maladaptive behaviors), it is likely that Ms. Talapatra was being forthright and candid in describing Tamik's behavior, and that the ratings represent a valid assessment of Tamik's social-emotional functioning.

TABLE 18.A.5. Selected BASC-3 Rating Scale Scores for Tamik

BASC-3 scales	Description	Teacher	Parent
Behavioral Symptoms Index	Overall rating of the individual's behavior	117	52
Externalizing Problems		104	51
Hyperactivity	Tendency to be overly active, rush through work, and act without thinking	89	51
Aggression	Tendency to act in a hostile manner (either verbal or physical) that is threatening to others	116	52
Conduct Problems	Tendency to engage in antisocial and rule-breaking behavior	95	49
Internalizing Problems		94	46
Anxiety	Tendency to be nervous, fearful, or worried about real/imagined problems	62	47
Depression	Feelings of unhappiness, sadness, or stress that may result in an inability to carry out everyday activities	120	51
Somatization	Tendency to be overly sensitive to and complain about relatively minor physical problems or discomforts	69	42
School Problems (TRS)		74	—
Attention Problems	Tendency to be easily distracted	74	59
Learning Problems (TRS)	Presence of academic difficulties, esp. in understanding or completing work	70	—
Additional clinical scales			
Atypicality	Tendency to behave in ways that are considered strange, such as being disconnected from or unaware of normal surroundings	120	52
Withdrawal	Tendency to evade others to avoid social contact	100	42
Adaptive Skills			
Adaptability	The ability to adapt readily to changes in the environment	24	48
Social Skills	Skills needed to interact successfully with peers/adults in home, school, and community settings	28	48
Leadership	Skills associated with accomplishing academic, social, or community goals, including the ability to work well with others	38	63
Study Skills (TRS)	Skills that are conducive to strong academic performance, including organizational skills and good study habits	31	—
Functional Communication	The ability to express ideas and communicate in ways others can easily understand	24	56
Activities of Daily Living (PRS)	The skills associated with performing basic, everyday tasks in an acceptable and safe manner	—	49

CONCLUSIONS AND RECOMMENDATIONS

Tamik is a 6-year-old boy who currently resides with his biological mother and older sister. His family has recently moved from another state, and his parents have recently divorced. Available history indicates that Tamik was the product of a typical pregnancy and delivery. It was reported that all developmental milestones were met within normal limits.

Current results indicate that Tamik's intellectual functioning is within the average range. Academic assessment revealed that Tamik has age-appropriate academic skills in all areas, despite his inability to demonstrate these in the classroom. Behavior checklists and interviews reveal that Tamik is exhibiting significant social-emotional distress. This could be attributed to the number of adverse childhood experiences he has endured. In addition to witnessing domestic violence in early childhood, Tamik has lost access to a parent as a result of divorce and has now relocated across the country. The information gathered in this evaluation should be reviewed by the eligibility team, in conjunction with progress on his behavior intervention plan and previous school records (when these become available), to determine Tamik's need for special education support. This evaluation has found that Tamik demonstrates an inability to build and maintain interpersonal relationships, a general pervasive mood of unhappiness, and inappropriate behaviors under normal circumstances.

At the current time, available information suggests that Tamik meets diagnostic criteria for other specified trauma- and stressor-related disorder (F43.8) in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5). At the time, not enough information is available to determine whether he meets full DSM-5 criteria for a more specific trauma- and stressor-related disorder. However, the symptoms he is exhibiting are believed to be related to his multiple adverse childhood experiences.

The following remediation strategies may be helpful:

- Individual and conjoint therapy with Tamik's mother, focused on helping him navigate his adverse childhood experiences, is recommended. Tamik may benefit from cognitive restructuring, positive self-talk, and relaxation techniques. Tamik's treatment might also include helping him build insight into his own and others' feelings and address the trauma in his family.
- Tamik would benefit from structured, supportive classroom environments. Rules and expectations should be simply, clearly, and consistently presented and reviewed frequently. Consequences for both appropriate and inappropriate behavior should be enforced on a consistent basis through providing positive reinforcement (rewarding appropriate behavior) and ignoring inappropriate behavior. This could be managed in the form of a token economy, which should be coordinated with a home token economy. This plan should be coordinated with Tamik's mother to ensure consistent application in both home and school settings, including target behaviors and reinforcers.
- Positive feedback should be provided to Tamik when he responds in an appropriate way to new adults, situations, and places. His mother and teacher should talk with him beforehand about new situations and adults, so he knows what may happen or what to expect.
- Adults should use physical proximity to encourage Tamik to pay attention to tasks.
- The teacher can channel Tamik's overactivity by assigning him classroom duties (e.g., sharpening pencils, watering plants, delivering notes, handing out papers) that provide opportunities for seat breaks.
- Instances of appropriate behavior should be acknowledged through recognition and encouragement.
- Tamik should be assisted to develop social skills such as cooperating with others, sharing, giving/receiving compliments, entering a group, and standing up for his own rights without being aggressive. Instructional approaches such as modeling and role playing should also be helpful.
- Close supervision during unstructured periods is recommended.

CHAPTER 19

The NEPSY-II

Robb N. Matthews
John L. Davis

STRUCTURE

The NEPSY-II (Korkman, Kirk, & Kemp, 2007) is an integrated battery of subtests designed to assess a broad range of functioning in children ages 3–16 years (Kemp & Korkman, 2010). Case conceptualization often requires a broad scope of evaluation: Assessment professionals must go beyond traditional measures of general characteristics (e.g., intellectual functioning) and include targeted assessment of specific traits or skills (e.g., divided attention, ideational fluency). In such cases, practitioners must choose assessment techniques that effectively target the various aspects of traits or skills under consideration, in order to gather relevant information and to develop ecologically valid recommendations related to the examinees' needs (Rhodes, D'Amato, & Rothlisberg, 2009). As a stand-alone measure or as a complement to other techniques typically used in assessing the neurological functioning of children, the NEPSY-II provides one of the few avenues for targeted assessment of specific cognitive skills in younger populations (Brooks, Sherman, & Strauss, 2010; Titley & D'Amato, 2008). Based on the general neuropsychological principles put forth by Luria (1980) and operationalized through a flexible multidomain design, the NEPSY-II allows examination of the subcomponents of complex cognitive processes. The structure and development of the NEPSY-II have been informed by current literature surrounding child development, child psychology, and pediatric neuropsychology (Korkman et al., 2007). As such, this battery provides a method for merging quantitative measures and qualitative observations of performance to create a comprehensive clinical perspective on an examinee's functioning.

The NEPSY-II is intended to assist clinicians of varying proficiency levels in better understand complex aspects of examinees' cognitive processing. The flexible structure allows the clinicians to address the specific issues raised in referral questions, to identify basic and interactive cognitive subcomponents of functional skills, and to cultivate informed recommendation based on the examinees' functioning across targeted domains (Kemp & Korkman, 2010; Luria, 1980).

The NEPSY-II structure is based on six theoretically derived domains of cognitive processing (Kemp & Korkman, 2010). These cognitive domains are thought to inform and predict a child's success in meeting the expectations across diverse environments (Brooks, Sherman, & Strauss, 2010; Hooper, 2010). The NEPSY-II has been intentionally constructed to allow for flexible administration of individual subtests. The particular set of subtests administered can be based either on a predetermined battery as specified in the manual, or on a clinician's conceptualization of a referral question and its related primary functional components (e.g., attention) or secondary subcomponents (e.g., memory); however, administration of the entire 36-subtest battery is not required. Suggested referral batteries listed in the scoring assistant and assessment planner are combinations of subtests the test developers believe may be useful for particular "classes" of difficulties and those components most likely to be affected (Korkman et al., 2007). In some populations, a short-battery or a fixed-battery approach can be an efficient way to answer referral questions. The flexible design of the NEPSY-II allows a clinician to use other information and the presenting problem to select which domains or combinations of subtests will be most useful for a specific referral. Although the NEPSY-II is not designed to assess for specific diagnoses (e.g., learning disorders), its flexible structure may contribute to a diagnostic conclusion based on identified patterns (i.e., diagnostic clusters) of cognitive processing consistent with a particular condition (Kemp & Korkman, 2010; Titley & D'Amato, 2008). Most importantly, the structure of the NEPSY-II allows for more in-depth examination of specific cognitive processing areas that may be helpful in selection of well-designed intervention programs (Titley & D'Amato, 2008).

THEORETICAL UNDERPINNINGS

The NEPSY-II, like the original NEPSY (Korkman, Kirk, & Kemp, 1998) and the original NEPS in Finnish, are based on Luria's (1980) model of functional systems and an integrated theory of brain function. As such, the initial 36 subtests and 30 performance areas were intended to correspond to components of complex cognitive functions (Korkman, 1999). A *functional system* is made up of multiple brain regions and their interconnections; all these working together form the basis for a complex psychological function or process (e.g., attention, language). The integration of the individual components (i.e., brain structures and connections) is what allows for complex thought and processes (Luria, 1980). From a clinical perspective, the nature of the individual's impaired performance is determined by the specific location of damage or developmental difference within the affected functional system(s), as well as by the effects of this damage or difference on the rest of the functional systems (Bauer, 2000; Pramuka & McCue, 2000).

Luria (1980) believed that the fundamental purpose of a neuropsychological assessment is to better describe the function of the neuropsychological symptoms (i.e., the presenting problems that result in referral for assessment). In effect, the assessment is designed to present various opportunities, thus identifying those contexts in which an individual's deficits become significant (Bauer, 2000). In this regard, Luria's approach is considered to be client- and problem-centered, with examination of performance across and within the various functional systems. As part of this process, there is a need to examine performance or function at simple, complex, and integrated levels, as well as with varying input and output demands. The interpretation is to some extent qualitative; it is not based on the number of problems solved or on a total score, but rather on which problems were and were not solved. The emphasis on complex patterns of functioning (i.e., strengths or weaknesses) is a key component of the Luria model. It is the examination of the pattern of strengths and weaknesses, believed to represent intact or disrupted systems, on which the interpretation is based (Bauer, 2000).

As noted above, specific combinations of the NEPSY-II subtests are intended to represent the various functional systems in an effort to better understand and quantify which brain functions are intact and which are impaired. Five of the six content domains of the NEPSY-II were also in the original NEPSY and correspond to specific functional systems identified by Luria. Specifically, these domains are Attention and Executive Functioning, Language, Memory and Learning, Visuospatial Processing, and Sensorimotor. For the NEPSY-II, the sixth domain of Social Perception, representing some aspects of social-emotional functioning, was created to address concerns specific to the autism spectrum. For each domain, the NEPSY-II offers subtest-level scores rather than aggregate domain-level scores.

It is important to note that these six domains are theoretically based, rather than statistically based (Korkman et al., 2007); this is one reason why it was determined that the domain scores were not appropriate. In effect, the test authors recognized that no single subtest only measures one of the functional domains, and that because of the differing components measured by each subtest, the correlations within and across domains vary considerably. With subtests measuring some overlapping skills, one strength of the theoretical rather than statistical design is the ability to assess deficits underlying impaired performance both within and across functional domains (Korkman et al., 2007). Consistent with developmental considerations, differing subtests or formats are deemed appropriate for differing age levels within each domain. Given that specific functional systems have been implicated for differing neurodevelopmental disorders, there is also flexibility in the combinations of subtests that can be administered, based on the presenting problem. Although domain scores are no longer calculated, the provision of contrast scores (an indication of whether differences between subtest scores are meaningful) allows for examination of patterns (i.e., the syndrome analysis).

ORGANIZATION AND FORMAT

Within the six domains, the NEPSY–II includes 32 individually administered and autonomous subtests, with an additional 4 delayed-recall subtests. These wide-ranging subtests are designed to assess neuropsychological functioning across the six domains, as presented in Table 19.1. Each subtest is theoretically derived to assess specific skill strengths and weaknesses. Input, output, and processing demands vary across subtests and within domains; the combination of subtest scores and differences in performance is what is important. The manual provides suggested batteries to assist in planning assessments for specific referral questions. These eight tailored batteries are based on information obtained in special-group studies for deficits in reading, math, attention, social/interpersonal skills, behavioral management, school readiness, and perceptual–motor delays. These suggested batteries are empirically based, and are designed to align with profiles of children known to possess deficits in the aforementioned areas. The format of the NEPSY-II is designed to offer flexible administration of subtests to explore specific facets of neurological functioning in children.

In terms of the demands placed on examinees, the subtests range from oral responding to individual paper-and-pencil work. The NEPSY-II is very well designed in terms of providing test material that promotes engagement across the range of ages it is intended to assess. Due to the wide range of potential subtests, users should carefully consider each child's profile and assessment needs prior to administration. Examiners should also pay special attention to the age range of examinees appropriate for each subtest, as the NEPSY-II varies considerably in format in this area. This variation is a strength of the NEPSY-II: Because it offers a wide range of tests that are appropriate across different ages and developmental levels, it affords examiners complete coverage of the intended construct. However, this variation has the potential to create confusion or misadministration of subtests. The NEPSY-II offers 17 subtests for ages 3–4, 22 subtests and 2 delayed tasks for ages 5–6, 23 subtests and 2 delayed tasks for ages 7–12, and 24 subtests and 3 delayed tasks for ages 13–16. For specific information on the age range for each subtest, see Table 19.1.

SCORING

Most subtests of the NEPSY-II provide multiple score options that allow for a variety of applications, including general performance, error rates, or measures of subcomponent skills necessary for task completion. Scores in the NEPSY-II include (but are not limited to) primary scores, process scores, combined scaled scores, and contrast scaled scores. Primary scores describe the overall ability assessed by each subtest. Process scores are intended to provide additional insight into the child's ability or error rates for the subtest. The combined scaled scores were developed to assist the clinician with understanding the unique contributions of specific subcomponents of a process and with determining whether they fall within expected limits. Combined scaled scores are similar to index scores on many other popular instruments, but interpretation is achieved by considering both the domain being measured and the subcomponents being combined in the score (Korkman et al., 2007). Several subtests of the NEPSY-II provide multiple primary scores; therefore, the contrast scaled scores allow comparison of scores within subtests. Contrast scaled scores were designed to hold the impact of one characteristic constant while performance on another is considered. These scores indicate the degree to which examinees' performance is within expectations, given their performance on a related subcomponent or skill (Kemp & Korkman, 2010). This aspect of scoring provides clinicians with additional information to discriminate between higher-level and lower-level skill deficits within a single subtest.

Additional scores available from the NEPSY-II include percentile ranks, cumulative percentages, and behavioral observations. Korkman and colleagues (2007) used percentile ranks in place of standard scores on some subtests, due to the level of skewness present in the distribution. In other

TABLE 19.1. NEPSY-II Subtests and Descriptions

Domain	Subtest	Descriptions
Attention and Executive Functioning	Animal Sorting	Assesses the ability to group pictures based on self-initiated sorting criteria.
	Auditory Attention	Assesses selective auditory attention and the ability to sustain attention.
	Response Set	Assesses the ability to shift and maintain attention.
	Clocks	Assesses the ability to organize, execute, and recreate the expression of time on an analog clock.
	Design Fluency	Assesses the child's ability to generate unique designs presented in structured or random arrays.
	Inhibition	Assesses the ability to inhibit automatic responses in favor of novel responses and the ability to switch between response types.
	Statue	Assesses motor persistence and inhibition.
Language	Body Part Naming and Identification	Assesses expressive and receptive language for identifying body parts with self-prompts and with picture prompts.
	Comprehension of Instructions	Assesses the ability to follow oral instruction with increasing complexity.
	Oromotor Sequences	Assesses oral–motor coordination.
	Phonological Processing	Assesses the child's understanding of phonological processing through repeating or recreating words with substitute words or phonemes.
	Repetition of Nonsense Words	Assesses phonological decoding skills.
	Speeded Naming	Assesses the child's ability to rapidly name common material when presented visually.
	Word Generation	Assesses the child's ability to rapidly generate verbal responses.
Memory and Learning	List Memory	Assesses verbal learning and memory, rate of learning, and the role of interference in recall for words.
	List Memory Delayed	Assesses long-term memory for words.
	Memory for Designs	Assesses spatial memory for novel visual material.
	Memory for Designs Delayed	Assesses long-term visual–spatial memory.
	Memory for Faces	Assesses discrimination and recognition of facial features.
	Memory for Faces Delayed	Assesses long-term memory for faces.
	Memory for Names	Assesses the child's memory for names, with three trials to rehearse.
	Memory for Names Delayed	Assesses long-term memory for names.
	Narrative Memory	Assesses memory for verbally presented material with free-recall and cued conditions.
	Sentence Repetition	Assesses rote memory for sentences that increase in complexity and length.
	Word List Interference	Assesses working memory and recall for verbally presented material.

(continued)

TABLE 19.1. *(continued)*

Domain	Subtest	Descriptions
Sensorimotor	Fingertip Tapping	Assesses the child's finger dexterity and motor speed.
	Imitating Hand Positions	Assesses the ability to imitate hand/finger positions.
	Manual Motor Sequences	Assesses the ability to imitate hand movement sequences.
	Visuomotor Precision	Assesses motor speed and accuracy.
Social Perception	Affect Recognition	Assesses the child's ability to recognize affect from a picture cue.
	Theory of Mind	Assesses ability to understand and properly attribute mental states.
Visuospatial Processing	Arrows	Assesses the ability to identify and infer line directionality.
	Block Construction	Assesses the ability to construct three-dimensional models from a two-dimensional picture prompt.
	Design Copying	Assesses the ability to reproduce images from a two-dimensional picture prompt.
	Geometric Puzzles	Assesses mental rotation and visual–spatial skills.
	Picture Puzzles	Assesses visual discrimination and visual–spatial skills.
	Route Finding	Assesses visual planning and directionality.

words, subtests yielding only percentile ranks tend to assess those skills generally seen early in the typical developmental process and were therefore generally at an advanced level in the standardization sample (Kemp & Korkman, 2010). NEPSY-II percentile ranks are presented in ranges, so that scores falling in the 26th–50th or 51st–75th percentiles should be interpreted as falling in the expected range of performance. Cumulative percentages represent the base rates or probability of occurrence of a particular performance, characteristic, or profile (Sattler, 2008), and should be interpreted with regard to the "rareness" of a particular outcome; this is discussed further in the section on interpretation.

In keeping with the Lurian tradition, the NEPSY-II also allows for structured qualitative observations of an examinee's performance. Some of the coded observations are simply descriptive of performance, while others are formalized observation measures. The set of behavioral observations coded on the NEPSY-II protocol are based on the clinical experience of the test authors and the behavior of typically developing children in the normative sample (Korkman et al., 2007). For example, cumulative percentages permit clinicians to compare instances of "out-of-seat behavior" with those for the normative group by age. Reviewing behavioral observations can give a reference point from which to develop hypotheses about an examinee's performance (Kemp & Korkman, 2010). Those behaviors tallied and summed in the protocol are converted to cumulative percentages (or base rates) and are included in an appendix in the test manual.

PSYCHOMETRIC PROPERTIES

Item Generation

With the revision of the NEPSY-II, several modifications were made to the original NEPSY, including the addition of several subtests and the omission of others. The manual appropriately describes the theoretical basis that necessitated these modifications, as well as the development of new subtests and additional items to existing subtests. The examination of items was conducted in multiple phases. This allowed the test authors to examine the psychometric impact of the changes in items and subtests. Specific item evaluation procedures or item evaluation outputs are not available in the manual.

Ceiling and Floors

One component of item generation involves assurance of appropriate floors and ceilings of each subtest. This is important in order to ensure assessment sensitivity across a broad range of abilities in children (Korkman et al., 2007). To this goal, the NEPSY-II provides additional items to ensure appropriate floors and ceilings in every subtest. For younger ages and lower levels of ability, additional subtests have been specifically included (e.g., Body Part Naming and Identification for 3- to 4-year-olds). Each six primary domains offer developmentally appropriate items for children between 3 and 16 years old.

Standardization

The NEPSY-II normative data were collected from 2005 to 2006. The normative data for the NEPSY-II were derived from a sample that closely matched the U.S. census data of children ages 3–16. An analysis of data gathered in the October 2003 census provided the basis for stratification across the variables of age, race/ethnicity, geographic region, and parent education level. Twelve hundred examinees were assessed for the normative sample, with 100 children from each of the 12 age groups ranging from 3 through 16. Ages 3–12 were divided by 6-month intervals, with 50 cases collected from children in the first 6 months of each year of age, and 50 cases collected from children in the last 6 months of that same year. For each age group in the normative sample, examinees were further separated by race/ethnicity categories. Each child in the normative sample was categorized as belonging to one of the following groups: white (i.e., European American), African American, Hispanic, or other.

The groups were also stratified by gender to include 50% males and 50% females. Children were also stratified by four major geographic regions of the United States: Northeast, Midwest, South, and West. Children were further selected for the normative group to represent the proportions of children living in each region. Finally, the sample was stratified by parental educational level; the children were grouped according to the parents' reported educational attainment. For children in two-parent homes, the average of the parents' educational level was used (Korkman et al., 2007).

In the renorming of the NEPSY-II, several new subtests were added (Animal Sorting, Clocks, Inhibition, Memory for Designs, Word List Interference, Affect Recognition, Theory of Mind, Geometric Puzzles, and Picture Puzzles). For many of the subtests in the NEPSY-II, items were carried over from the original NEPSY and renormed. For several subtests in the NEPSY-II (Design Fluency, Repetition of Nonsense Words, List Memory, List Memory Delayed, and Imitating Hand Positions), the normative data from the original NEPSY continue to be used, with no renorming conducted. The rationale provided was that these subtests were not expected to be subject to the Flynn effect (Flynn, 1984, 1987) or changes in the population demographics; however, no empirical examination is offered to support this decision.

Reliability

Data are available in the manual for interrater reliability in scoring protocols, test–retest stability, decision consistency of classification, and internal consistency. Each of these reliability coefficients are listed for both the primary and process scores for subtests that were evaluated (Korkman et al., 2007). Interrater reliability in scoring the NEPSY-II protocol was assessed through percent agreement. Agreement rates ranged from 93% to 99%, with Word Generation at the lowest level (93%) and Memory for Names at the highest level (99%).

Test–retest stability was calculated on both the primary and process scores. A diverse group of 165 children (52% male, 48% female) took the NEPSY-II on two occasions. The sample was then divided into six age groups: 3–4 years, 5–6 years, 7–8 years, 9–10 years, 11–12 years, and 13–16 years. Test–retest intervals ranged from 12 to 51 days, with a mean of 21 days between administrations. Several indices for evaluating test–retest stability are provided. Test–retest scores showed generally adequate stability across time for all age groups in subtests assessed. Despite a very thorough treatment of subtest stability, the manual does not provide stability data for two of the subtests in the Sensorimotor domain (Manual Motor Sequences and Fingertip Tapping). Stability estimates for several subtests (Design Fluency, Repetition of Nonsense Words, List Memory, List Memory Delayed, and Imitating Hand Positions) are based on data collected for the original NEPSY, as these were not renormed (Korkman et al., 2007).

A decision consistency index was also used to document reliability for several subtests. This alternative to standard test–retest reliability estimates was used because of skewed score distribution or restricted variance within particular subtests that might artificially lower reliability estimates. For these subtests, raw scores were converted to percentile ranks, combined scaled scores, or contrast scaled scores. Decision consistency shows the agreement between converted raw scores by two separate administrators. The test authors set two classification ranges as the criteria for judging decision consistency. For percentile ranks, the authors categorized scores as either above or below the 10th percentile. Combined or contrast scores were categorized as above or below a scaled score of 6. To achieve reliability with this index, a child would be assessed by two separate administrators, and the raw score would be converted to a percentile rank, combined score, or contrast score (where appropriate). If the resulting converted score was in the 6th percentile on the first administration and the 9th on the second, the subtest was said to be reliable. Decision consistency between raters was moderate to high on each subtest across all age groups. For three subtests (Oromotor Sequences, Manual Motor Sequences, and Route Finding), the analysis of decision consistency from the NEPSY is reported; notably, these subtests have the lowest decision consistency (Korkman et al., 2007).

In addition to stability coefficients and decision consistency procedures, split-half (Spearman–Brown) and alpha methods were used to calculate internal consistency when appropriate. The manual reports reliability coefficients for primary and process scores across individual age groups, and provides an average across the six age bands noted earlier (3–4, 5–6, 7–8, 9–10, 11–12, and 13–16). The reliability data indicated adequate to high internal consistency for a majority of subtests (r_{12} range = .21–.91). The highest internal-consistency scores were found on Comprehension of Instructions, Design Copying, and Fingertip Tapping. The lowest internal-consistency scores were found on the Inhibition and Memory for Designs subtests (Korkman et al., 2007).

Validity

Due to the wide array of specific skill areas examined on the NEPSY-II, evidence of concurrent validity is provided through a series of correlation studies on separate instruments designed to measure cognitive ability, academic achievement, neuropsychological functioning, and behavior. For example, concurrent validity of intellectual functioning was assessed with the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV; Wechsler, 2003), the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007), and the Wechsler Nonverbal Scale of Ability (WNV; Wechsler & Naglieri, 2006). Correlations between these instruments suggested that the NEPSY-II scores correlate well with cognitive performance in both verbal and nonverbal applications. Correlations with the Verbal Comprehension Index of the WISC-IV ranged from a low on the Auditory Attention subtest (–.02) to a high on the Narrative Memory subtest (.58). Concurrent validity in academic domains was assessed with the Wechsler Individual Achievement Test—Second Edition (WIAT-II; Psychological Corporation, 2001). Results yielded a low to moderate link between the NEPSY-II Attention and Executive Functioning domain and the WIAT-II tests of Mathematics Reasoning (r = .09–.43), Oral Expression (r = .03–.52), and Written Language (r = .08–.47). Within the NEPSY-II Memory and Learning domain, the Sentence Repetition subtest strongly correlated with the WIAT-II tests of Reading Comprehension (r = .87) and Pseudoword Decoding (r = .87). The Narrative Memory subtest of the NEPSY-II varied in correlation (r = .04–.61) with the Children's Memory Scale (CMS; Cohen, 1997). Moderate correlations were shown between subtest scores of the CMS and the Auditory Attention subtest (r = .03–.42). The variability reflects the range of constructs the NEPSY-II is designed to assess. It would not be expected that all NEPSY-II subtests would correlate with any specific measure; however, the presence of high to moderate correlations for each of the constructs mentioned above provides reasonable evidence of validity.

Additional concurrent and construct validity coefficients were derived from a variety of other measures. Results of the NEPSY-II ranged in correlation (r = –.45–.65) to the content of various measures, including the Delis–Kaplan Executive Function System (D-KEFS; Delis, Kaplan, & Kramer, 2001); the Bracken Basic Concept Scale—Third Edition: Receptive (BBCS-3:R; Bracken, 2006a); the Bracken Basic Concept Scale—Expressive (BBCS:E: Bracken, 2006b); the Devereux Scales of Mental Disorders (DSMD; Naglieri, LeBuffe, & Pfeiffer, 1994); the Children's Communication Checklist—Second Edition (CCC-2; Bishop, 2006); the Brown Attention-Deficit Disorder Scales for Children and Adolescents (Brown ADD Scales; Brown, 2001); and the Adaptive Behavior Assessment System—Second Edition (ABAS-II; Harrison & Oakland, 2003). The highest levels of association were found between the Memory for Designs Delayed subtest of the NEPSY-II and the School Readiness (.61) and Receptive Total (.64) composites of the BBCS-3:R. In addition, the Inhibition–Switching subtest of the NEPSY-II correlated highly (.59) with the Color Word Interference subtest of the D-KEFS. In contrast, correlation coefficients were moderate but negative for the Affect Recognition subtest of the NEPSY-II in relation to the Conduct scale (–.45) and Externalizing composite (–.40) of the DSMD. The Inhibition–Switching combined scaled score also had a moderate negative correlation (–.41) with the Focus cluster of the ABAS-II.

The authors also conducted several studies of "special groups" to test criterion validity, or the scale's clinical utility in yielding information that supports a diagnosis or disability classification. Children with the following diagnoses/educational classifications were included: attention-deficit/hyperactivity disorder (ADHD), reading disorder, language disorder, mathematics disorder, mild intellectual disability, autistic disorder, Asperger syndrome, traumatic brain injury, deafness/hearing impairment, and emotional disturbance. Small-group studies compared each of the score indices for each of the subtests between a group of children with a specific condition and a control group. The control group was matched with the normative sample on demographic categories. By examining differences in mean scale scores between children identified with a particular condition and the matched controls, the test authors identified specific subtests where children within an identified diagnosis/classification group diverged from the norm. These studies helped to form the empirical basis for recommended subtests for each condition. The NEPSY-II does not provide a diagnostic recommendation for any particular condition; rather, the test authors recommend using the information from suggested batteries as a method to conceptualize deficits commonly associated with a particular condition. The authors emphasize that the NEPSY-II should not be used as the sole source to diagnose or classify a child for educational purposes (Korkman et al., 2007).

INTERPRETATION

General Principles

Consistent with common assessment practice, levels of test performance are typically described and categorized statistically, to allow comparison between an individual's performance and levels of performance in the general population (Sattler, 2008). At the same time, the importance of understanding that mild deficits (e.g., low average functioning) may significantly interfere with daily functioning cannot be understated in interpreting performance on measures such as the NEPSY-II (Riccio, Sullivan, & Cohen, 2010; Yeates, Ris, Taylor, & Pennington, 2010). Furthermore, the probability that any given technique or instrument samples (and that scores are therefore affected by) more than one closely related skill set or domain is quite high. Paramount to skilled interpretation of performance is an understanding of the component processes being sampled, their interrelation, and how these processes may be manifest across circumstances or domains. Therefore, familiarity with current cognitive theories as well as with ongoing research is essential to the adequate interpretation and integration of results of the NEPSY-II.

Differentiating specific narrow characteristics or comorbid conditions can be difficult, and may result in several plausible conclusions about an examinee's performance or the relationships between the examinee's skills. Consequently, hypotheses or conclusions regarding particular performances or the interaction of characteristics may also vary among clinicians. As the number of subtests administered, observations recorded, or comparisons made between scores increases, it is also important to remember that the likelihood that spurious results will arise also increases (Crocker & Algina, 2006). To offset the impact of spurious results, consistency among the findings across measures or techniques is the most stable method (i.e., the most resistant to erroneous conclusions) of conceptualizing results in a coherent and practical manner that is useful for describing an examinee's needs, drawing diagnostic conclusions, and developing effective recommendations (Korkman et al., 2007; Riccio et al., 2010; Sattler, 2008; Yeates et al., 2010).

Moreover, the NEPSY-II allows a clinician to make a developmental comparison of the subcomponents of a given characteristic by examining underlying individual processes, although it was not designed to examine all potential characteristics or interactions of characteristics within or across cognitive domains (Kemp & Korkman, 2010; Korkman et al., 2007). Considering the developmental differences between a beginning reader's skills and an established reader's skills elucidates these principles. The beginning reader is deliberate in applying sound–symbol association, directed attention, and working memory, whereas the established reader probably uses only sight recognition of overlearned material (Kemp & Korkman, 2010). Thus the chain of skills used by both these readers may have been similar in the beginning, but has shifted with maturation, so that the readers now differ in their application and level of automaticity of reading skills. Considering only the outcome of a reading measure would be insufficient evidence on which to base a conclusion or develop recommendations. Targeted examination of skills allows a clinician to clarify the nature of an examinee's primary and secondary difficulties (according to Luria's model), and subsequently allows for improved recommendations and intervention development. The ability to differentiate the root cause (primary) of a deficit, such as poor phonological processing, from its impact (secondary), such as slow processing speed, effectively becomes a function of the clinician's knowledge and expertise in the areas under consideration. Thus, although clinicians of varying levels of training and experience can administer and score the NEPSY-II with proficiency (Brooks, Sherman, & Strauss, 2010), both choosing the appropriate subtests and interpreting performance across subtests or domains require a higher degree of expertise in neuropsychological constructs, developmental theory, and the professional literature (Titley & D'Amato, 2008).

Results

With these basic principles in mind, the next consideration for interpretation is at the level of the scores generated. The successful interpretation of NEPSY-II results begins with looking for patterns of scores at the subtest level, then moving to combined scaled scores, percentile ranks, and finally behavioral observation base rates (Kemp & Korkman, 2010). Although each of these scores is standardized along the same metric (mean of 10, standard deviation of 3), and therefore could result in the same descriptions of range (e.g., low average, average, high average), interpretation of the scores varies considerably (Korkman et al., 2007). In keeping with conventional assessment results, scaled scores compare an individual's performance to that of same-age peers (Sattler, 2008). These scores can be used to compare the examinee's skills to the population, identify patterns of strengths and weaknesses, and/or identify a pattern of performance consistent that may suggest potential intervention strategies. The conventional method of score analysis may be the final level of analysis for evaluators with little training in neuropsychology, or the beginning of analysis for evaluators with a greater depth of training (Kemp & Korkman, 2010). Beyond the scale scores, techniques such as consideration of error types (i.e., error analyses) or examination of differences in performance across subtests or domains (i.e., profile analyses) may help to clarify an examinee's needs. This higher level of analysis is supported by examining the examinee's overall profile as it is related to the identified difficulties; the combined and contrast scaled scores are useful in this regard.

The combined scaled scores allow the clinician to consider not only the outcome of performance, but the chain of events leading to that outcome (Korkman et al., 2007). The contrast scaled scores then allow the clinician to understand the examinee's range of functioning and more clearly identify potential contributing factors. Caution is warranted in the interpretation of contrast scores, however, as they only represent *differences* in level of functioning. Thus a performance on one subtest in the superior range (e.g., Memory for Faces) versus a performance on another subtest in the average range (e.g., Memory for Faces Delayed) can result in a similar contrast scaled score to that produced with performance differences of average versus below average. Although the contrast scaled score values will be similar, the implications for functioning in these two scenarios are significantly different.

Another consideration involves the cumulative percentage scores or the base rates, as these provide important information in the interpretation process. Although the observed difference between scores can be statistically significant, the base rate indicates how meaningful that difference is. For a difference to be considered rare (i.e., clinically meaningful), Sattler (2008) has suggested a base rate of no more than 15%, while Kemp and Korkman (2010) have supported using a more stringent rate of 10%. Finally, in addition to interpretation of the various scores provided, the behavioral observations need to be considered to lend additional qualitative insights into an examinee's functioning.

Integration

NEPSY-II results are best used as a supplement to the results of other standardized measures, as well as to historical, observational, and functional information (Titley & D'Amato, 2008). Integrating NEPSY-II results with other psychometric and functional data into a comprehensive discussion of an examinee's strengths and weaknesses can be a difficult task, especially for less experienced clinicians (Hooper, 2010). Selecting a battery of tests/techniques designed to address the referral issue(s) efficiently and effectively is the first step in this process. Appropriate selection allows for comparison across subtests, within and across domains, and with other measures (e.g., intellectual) to identify the patterns of performance. Poor performance in a single area or on a single measure, without corroborating evidence, is insufficient for identifying a developmental deviation or a diagnostic conclusion; typical children show developmental differences over time, without significant impact on their daily life (Meltzer, 2007). Significant findings across measures of similar or related characteristics (e.g., subtests and coded observations) give informational consistency and internal support to hypotheses and conclusions (Kemp & Korkman, 2010). Selection of measures and methods should ensure coverage of all functional domains, with specific subtests of the NEPSY-II providing supplemental coverage.

One approach to integration would follow the model of cross-battery assessment (Flanagan, Ortiz, & Alfonso, 2013), which aligns various subtests across measures based on broad and narrow abilities. The NEPSY-II was co-normed with the WISC-IV, and is currently included as a supplemental assessment in cross-battery assessment paradigms (Flanagan et al., 2013). For clinicians deriving their own combinations of subtests for narrow and broad abilities, the information provided in Table 19.1 can be helpful in placing the NEPSY-II subtests into this type of integrative model. Alternatively, the cognitive hypothesis-testing model (e.g., Flanagan, Fiorello, & Ortiz, 2010; Flanagan, Ortiz, Alfonso, & Mascolo, 2006)—which identifies normative deficits, considers plausible contributing or causal factors (e.g., lack of motivation vs. a cognitive deficit), and links current results to ecological deficits identified in the referral question—is another model that can be used.

Regardless of the model employed, the general idea is that of moving from the simple to the complex, with emphasis on consistencies, to facilitate the identification of patterns of performance and the integration of performance on the NEPSY-II with other information gathered during the evaluation process. To facilitate the integrative process, the clinician will need to be familiar with research on the chosen instruments or techniques (i.e., what is being measured) and how the instruments relate to each other (Hooper, 2010).

Some examples from research on the NEPSY or NEPSY-II reinforce the idea that assessment of higher-level cognitive processes is far more complex than simply administering one or more subtests and generating a score in a particular range. In their review of bilingual children's performance on NEPSY subtests, Garratt and Kelly (2008) found significant performance differences from monolingual children. Bilingual children demonstrated lower visual attention, naming speed, and verbal comprehension; however, their performance on the Imitating Hand Positions and Design Copying subtests was superior to that of their monolingual peers. In addition, Dixon and Kelly (2001) found potential cultural influences on the NEPSY, as British children were noted to demonstrate better phonological processing, visual attention, and verbal comprehension skills than their American counterparts. These differences may be in part due to differences in educational strategies in different cultures, to the use of theoretically versus empirically derived domains, due to homogeneity in the norming samples, or to the interaction of these or other unidentified issues. Regardless of the causes of these differences, these findings underscore the need to consider results of the NEPSY-II in the broader context of all other information.

Gifford, Mahaney, and Gorman (2008) found that children with ADHD performed significantly better than children with autism spectrum disorder (ASD) on NEPSY-II tests of motor speed and dexterity, whereas children with ASD outperformed children with ADHD on tests of visual–spatial analysis and attention to detail. Gifford and colleagues (2008) commented that these findings diverged from their expectations, as no significant differences between these groups were noted on NEPSY-II tests of attention and concentration or of executive skills. In a second study, Gifford, Mahaney, and Gorman (2009) found that children with ADHD performed better on visual memory tasks than children with ASD and children with seizure disorders, while the children with ASD performed better than children with seizure disorders on tests of phonological processing. Among children with ASD, differences were also found for subgroups on the spectrum; the meaning of these differences is the subject of theoretical discussion and additional research.

Finally, Brooks, Sherman, and Iverson's (2010) research supports the notion that typically developing children's performance can fall well below expectations on a given day or subtest. When the seven subtests for 3- to 4-year-olds were considered together, 71.5% of the sample had one or more scores below the 25th percentile, and 40% of the sample had two or more scores below the 10th percentile. The number of low scorers in this group was mediated by parental education level, with lower levels of parental educational attainment being associated with increased rates of NEPSY-II scale scores falling below the expected range. Stamina also appears to play a role in typically developing children's NEPSY-II performance. When a 1-hour battery consisting of eight subtests was used, 70.3% of participants ages 5–6 had one or more scale scores below the 25th percentile, and 37.2% of participants had two or more scale scores below the 10th percentile. When a 2-hour battery consisting of 12 scale scores was used, 82.6% of these participants had one or more scores below the 25th percentile, and 49.3% had two or more scores below the 10th percentile. Once again, the base rates of children with low scores decreased as a function of their parents' educational attainment. The authors found similar relationships between parental education and the lowered score base rate in the 7- to 16-year-old group as well.

BEYOND TRADITIONAL INTELLECTUAL ASSESSMENT

Traditional intellectual assessment is concerned with quantifying general ability (*g*), and is most often used in determining intellectual disability or as one component of identifying learning disability. The NEPSY-II is not a measure of intelligence, but a supplemental measure to increase the extent to which the assessment process examines all functional systems. The majority of intellectual assessment instruments do not effectively measure the full range of cognitive abilities (Flanagan et al., 2006); thus the use of a traditional intelligence test with the NEPSY-II provides the means for obtaining a comprehensive assessment of domains of function (Pramuka & McCue, 2000). It provides additional information on the narrow abilities that may otherwise be ignored and are important for development of appropriate interventions.

The NEPSY-II, in combination with a general measure of ability, is consistent with a focus on the need to integrate cognitive and behavioral data. It thus increases clinicians' ability to deal with the multidimensionality of individuals (Riccio & Reynolds, 2013) and to translate this understanding into educationally relevant information (Goldstein & Naglieri, 2008). As noted earlier, the NEPSY-II permits systematic variation of the inputs, outputs, and levels of complexity, to maximize the likelihood of dissociating the potential underlying problem that is presenting as impaired performance. It is not solely a deficit-based approach; it is consistent with Luria's assertion that neuropsychological assessment is a valuable approach for determining not only deficits, but individual strengths or intact cognitive functions, as they relate to everyday functioning. Focusing on strengths lends itself to compensatory models that focus not on the underlying impairment, but on ways to compensate for the impairment to improve everyday living (Glisky & Glisky, 2002). Compensation approaches identify methods to bypass deficit skills through the use of intact functions or alternative methods of reaching the same goal (Anderson, 2002).

A more unified picture of the individual should increase the predictive value of the assessment as it relates to achievement as well as realistic life planning (Silver et al., 2006; Teeter & Semrud-Clikeman, 1997). By not only emphasizing how well a student does or doesn't do, but gaining an understanding of the types of problems (i.e., inputs, outputs) that are most difficult for the individual, a clinician can identify interventions that focus on circumventing the problems (i.e., accommodations, modifications). The more comprehensive picture typically associated with neuropsychological assessment examines individual performance across a range of functional domains, including linguistic, perceptual, sensory–motor, attention, memory, learning, executive control/planning, speed of processing, and emotional functioning (Riccio & Reynolds, 2013; Silver et al., 2006).

Following in the traditions of Luria, neuropsychological assessment such as that provided by the NEPSY-II looks beyond the failure to attain a specific skill to the underlying brain–behavior relationship that contributes to this difficulty. This is seen as important, in that this same problem within the functional system may indicate increased likelihood of failure in attaining other academic, functional, social, or behavioral skills (Riccio & Reynolds, 1998, 2013). At the same time, Kemp and Korkman (2010) have warned against drawing conclusions about specific brain function based on NEPSY-II results: A child's brain is still developing, and the long-term effects of a congenital or acquired injury on brain development will differ, depending on a number of factors that may vary over the lifespan.

Neuropsychological assessment (e.g., with the NEPSY-II) may be appropriate to establish initial functioning, as well as to track progress; it may serve to clarify intervention needs and result in referrals to other specialists (Berkelhammer, 2008). Intervention planning goes beyond the labeling or eligibility/placement process to include the identification of specific management or rehabilitation techniques, medical management approaches, outcome-related goals, and modifications that need to be addressed (Silver et al., 2006). Changes in functioning on the various subtests of the NEPSY-II, due to their developmental sensitivity, may be more apparent than on the traditional full-scale score of an intelligence test. The flexibility of being able to select specific subtests, rather than having to administer the full battery, also renders the NEPSY-II more suitable for follow-up evaluation.

CONCLUSIONS

The NEPSY-II is one of the few flexible, child-friendly batteries of tests available for the assessment of higher-level cognitive functions (Brooks, Sherman, & Strauss, 2010; Davis & Matthews, 2010). It is best used to supplement rather than to replace traditional standardized intelligence tests, in order to obtain a more comprehensive picture of multilayered abilities. It should be kept in mind that theoretical as well as statistical and psychometric bases need to be considered in using the NEPSY-II. Developmental and cultural contexts must also be considered. Without considering expected developmental or cultural differences, a clinician could easily draw erroneous conclusions and develop baseless recommendations. Similarly, convergent validity (i.e., consistency across subtests and measures) is important in decreasing the likelihood of potentially spurious results.

Although some may rightly argue against various statistical properties of this battery or the norming choices made by the authors (Titley & D'Amato, 2008), the NEPSY-II ultimately demonstrates excellent clinical utility through an integrated battery of subtests and a variety of scores allowing for in-depth assessment of an examinee's skill set (Hooper, 2010). The NEPSY-II represents continuing strides forward in the integration of qualitative and quantitative information in the comprehensive evaluation of children. Building on the foundation of the NEPSY, the NEPSY-II continues to enhance the breadth and depth of available assessment instruments for children and adolescents. However, several areas in need of additional consideration remain.

Defining the NEPSY-II domains via factor analysis would lend significant power to the battery's predictive validity. The problem with such a task is the lack of agreement in the literature regarding the definitions or methods of assessment for particular skills. For instance, although executive functions are frequently discussed in the literature, and are generally agreed to be of great importance, a widely accepted formal definition of these skills has not been established (Jurado & Rosselli, 2007; Kenworthy, Black, Harrison, Rosa, & Wallace, 2009). Furthermore, common differences in the definition of executive skills leads to differences in the validity of particular evaluation methods, as well as the ecological validity of resulting recommendations.

Developing suggested batteries and assessment practices based on research defining expected performance could also enhance the predictive and diagnostic power of the NEPSY-II. Although social perception is a concern in a variety of conditions, how would a child with a given condition perform on the NEPSY-II? Could the degree of impairment related to a given condition be ascertained on the basis of NEPSY-II performance? What impact would the level of chronicity have on a performance profile? Broadening the stratification to factors beyond those typically employed (e.g., race, socioeconomic status) could also lend insight into NEPSY-II performance. As discussed above, different cultural or familial experiences can significantly affect a performance profile. Along this line, the applicability of the NEPSY-II would probably be broadened if it were considered in relation to instruments developed for assessing English-language learners for instance. Moreover, how do the methods of assessment used in NEPSY-II subtests (e.g., Theory of Mind) influence expected performance? How should methods of assessment be expected to vary by language or cultural background? Finally, how do NEPSY-II results translate into ecologically valid recommendations? Would a particular pattern of performance suggest one recommendation or strategy over another? These types of questions (and surely others) require ongoing research related to underlying neuropsychological characteristics of the individuals being evaluated, as well as how the NEPSY-II measures those characteristics and how those measurements translate into improved recommendations.

CHAPTER 20

The Universal Nonverbal Intelligence Test—Second Edition

A Multidimensional Nonverbal Alternative for Cognitive Assessment

R. Steve McCallum
Bruce A. Bracken

The Universal Nonverbal Intelligence Test (UNIT; Bracken & McCallum, 1998) and the revised and newly standardized edition, the Universal Nonverbal Intelligence Test—Second Edition (UNIT2; Bracken & McCallum, 2016b), are language-free tests of cognitive ability that require no receptive or expressive language from the examiner or the examinee for administration. The need for nonverbal assessment in the United States has grown steadily over the past 30 years and continues to expand as the country becomes ever more diverse. According to estimates from the U.S. Census Bureau (2016), minority populations increased steadily in the United States from 2010 to 2015. Specifically, the percentages increased from 12.6 to 13.3%, from 0.9 to 1.2%, from 4.8 to 5.6%, and from 16.3 to 17.6% for blacks/African Americans, American Indians/Alaska Natives, Asians, and Hispanics/Latinos, respectively. The percentage of white non-Hispanics decreased from 63.6 to 61.6%.

Taken together, minority children constitute an ever-increasing percentage of public school children, particularly in many large cities. For example, minorities constitute an overwhelming percentage of the school populations in Miami (approximately 84%), Chicago (89%), and Houston (88%). In addition, the population with limited English proficiency (LEP) is the fastest-growing group in the nation. There are more than 200 languages spoken in the greater Chicago area (Pasko, 1994), and 140 in California (Unz, 1997). A recent report from the U.S. Department of Education (2016) showed 19 prominent languages spoken by students in English-language learner (ELL) programs, with Spanish being the most prominent (71% of ELL students nationally). Other prominent languages included Chinese, Arabic, Vietnamese, Haitian-Creole, Russian, Navajo, and 12 other languages ranked second or third in frequency, depending on the state. Moreover, within the last few years, an increasing number of refugees from the war-ravaged Middle East have come into the United States. Many students from these minority populations may be disenfranchised when assessed on English-language-loaded tests. Moreover, there are many students who cannot be assessed optimally with language-loaded tests (e.g., those who have significant language and communication deficits limiting their ability to respond effectively). In some cases, it is difficult to determine whether such students' limited communication skills are the result of language-related deficits or limited cognitive ability. Such a distinction is useful in determining appropriate diagnoses and interventions, and nonverbal cognitive tests such as the UNIT2 help practitioners make such determinations.

Another population often misdiagnosed when language-loaded tests are used consists of individuals with hearing impairments. According to figures from the National Institutes of Health (2010), 28,600,000 Americans are deaf or have other significant hearing impairments. Still other students have neurological and psychiatric conditions that inhibit effective verbal communications (e.g., autism spectrum disorder, traumatic brain injury, verbal learning disabilities, severe depression, and selective mutism). In a chapter focusing on nonverbal personality assessment, Wasserman (2017a) concluded that nonverbal personality assessment may be indicated for (1) individuals with neurologically based acquired language disorders (e.g., aphasia, language-based learning disabilities); (2) individuals with varied cultural, linguistic, or national backgrounds (e.g., non-English-speaking persons); (3) individuals who are illiterate or poorly educated; (4) individuals who are deaf or hard of hearing; (5) individuals with forms of emotional disturbance that are manifested through an inability or unwillingness to produce an adequate and unconstrained sample of verbal behavior; and (6) individuals who are prone to misrepresent themselves on verbal self-report or interview measures. Individuals from these same populations would likely benefit from nonverbal cognitive assessment as well.

Since its publication, the original UNIT has provided examiners a viable option for assessing the cognitive abilities of examinees who cannot be assessed optimally with a language-loaded instrument. Numerous assessment experts have explored the psychometric properties of the UNIT, and the scrutiny overall has been positive (see Athanasiou, 2000; Bandalos, 2001; Fives & Flanagan, 2002; Maller, 2000). In addition, the UNIT has been used to operationalize general intellectual ability among students with limited language abilities and other who are at risk due to language-related issues, as well as individuals who are not from at-risk populations (e.g., Brinton, Spackman, Fujiki, & Ricks, 2007; Fujiki, Spackman, Brinton, & Illig, 2008; Hughes & Zhang, 2007; Lienemann, Graham, Leader-Janssen, & Reid, 2006; Noland, 2009; Liew, McTigue, Barrois, & Hughes, 2009; Pendarvis & Wood, 2009).

As the authors of the original UNIT, we have retained many of the positive features of the original test in its revision, but added many valuable revision features and updates. As a result of a thoughtful and comprehensive revision, there is every reason to believe that the UNIT2 will be even more positively acclaimed than the original test. In the following sections, we describe the theory and structure of the UNIT2, as well as its administration/scoring directions, interpretive strategies, psychometric properties, and salient strengths and weaknesses.

THEORY AND STRUCTURE

The UNIT2 contains six subtests, as did the UNIT, and retains the focus on the assessment of memory and reasoning and the intent to assess cognition using *two organizational strategies* (symbolic and nonsymbolic processing). However, the UNIT2 provides a broader assessment of cognition than the original test by including two measures of quantitative thinking, one symbolic and one nonsymbolic.

Within each of the two fundamental organizational strategies, the three cognitive abilities of memory, reasoning, and quantitative thinking are assessed in a hierarchical arrangement, such that memory is considered to be a more foundational building block of cognition (see Jensen, 1980). There are two memory subtests, Symbolic Memory and Spatial Memory; two reasoning subtests, Cube Design and Analogic Reasoning; and two quantitative subtests, Nonsymbolic Quantity and Number Series. Three of the subtests require some motoric manipulation (i.e., Symbolic Memory, Spatial Memory, and Cube Design); the remaining subtests (i.e., Analogic Reasoning, Nonsymbolic Quantity, and Number Series) require only a pointing response. With one exception (Cube Design, which requires design constructions), the subtests that require motoric manipulation can be adapted to allow for a pointing response only, if necessary.

As mentioned previously, the original UNIT employed subtests that feature both symbolic and nonsymbolic task demands. *Symbolic* organization strategies require the use of concrete and abstract symbols to conceptualize the environment; these symbols are typically language-related (e.g., words), although the symbols may take on any form (e.g., numbers, statistical equations, rebus characters, flags). Symbols are eventually internalized and come to label, mediate, connote, and (over time) make meaningful our experiences. *Nonsymbolic* strategies require the ability to perceive and make meaningful judgments about the physical relationships within our environment; this ability is symbol-free (or relatively so) and is closer to fluid-like intellectual abilities. The UNIT2 continues that tradition; however, Symbolic and Nonsymbolic Quotients are not provided for the UNIT2, as both processes predict academic performance about equally well when group data are analyzed.

Within each of the two fundamental organizational categories included in the UNIT (i.e., nonsymbolic and symbolic), problem solution requires one of three types of cognitive abilities—*memory, fluid reasoning,* or *quantitative thinking.* That is, some of the items require primarily symbolic organization and rely heavily on memory (e.g., those included on the Symbolic Memory subtest). Other items require considerable symbolic organization and reasoning skills, but less short-term or working memory (e.g., those included on the Analogic Reasoning subtest, which requires long-term memory and reasoning). Some items seem to require nonsymbolic organization strategies and memory primarily (e.g., those on the Spatial Memory subtest). Others require nonsymbolic organization and reasoning, but little memory (Cube Design). Number Series requires symbolic organization and quantitative ability; whereas Nonsymbolic Quantity requires nonsymbolic ability and quantitative skills. The UNIT2 theoretical model is depicted in Figure 20.1.

The rationale for conceptualizing the use of symbolic versus nonsymbolic strategies to operationalize intelligence is supported in the literature. For example, Wechsler (1939) emphasized the importance of distinguishing between highly symbolic (verbal) and nonsymbolic (perceptual or performance) means of expressing intelligence. Jensen (1980) provided a rationale for a two-tiered hierarchical conceptualization of intelligence, consisting of the two subconstructs of memory (level I) and reasoning of a fluid and quantitative nature (level II). However, in contrast to many low-*g*-loaded level I memory tasks designed to require reproduction or recall of simple content, the UNIT2 memory tasks were developed to require more complex memory functioning (e.g., working memory).

The theoretical organization of the UNIT is consistent with portions of several instruments that adopt the Cattell–Horn–Carroll [CHC] model), as described by Cattell (1963), Horn (1968, 1974), Carroll (1993), and others (e.g., Woodcock, 1990; Woodcock, McGrew, & Mather, 2001; Schrank, McGrew, & Mather, 2014; see also Schneider & McGrew, Chapter 3, this volume). Kevin McGrew (personal communication, September 2016) has identified components of strata I and II within the UNIT2 model, including fluid reasoning, visual processing, and quantitative reasoning from stratum II, as well as visual memory, visualization, visual memory, quantitative reasoning, and induction from stratum I.

Intelligence consists primarily of a pervasive and fundamental general cognitive ability, *g,* which provides a base for the development of other unique or specialized skills. Although there are many methods for determining levels of intelligence, it makes little sense to conceptualize intelligence in a dichotomized manner as being either verbal or nonverbal. Rather, there are verbal and nonverbal means available to assess intelligence. Consequently, the UNIT2 should be considered a nonverbal measure of intelligence, not a measure of nonverbal intelligence, as it was designed to be a strong measure of *g,* underpinned by symbolic and nonsymbolic processes.

In addition to retaining the most salient theoretical features of the UNIT, we have addressed limitations of the original test in the revision. For example, the norms were updated and the age range extended to 21 years, 11 months; test floors were extended for younger examinees; the administration format was improved by allowing a one-way easel presentation; and pictured stimuli were colorized. In addition, there are now two Standard Battery administration options available: one that does not include short-term memory, and one with

	Symbolic Content	**Nonsymbolic Content**
Memory	Symbolic Memory	Spatial Memory
Fluid Reasoning	Analogic Reasoning	Cube Design
Quantitative Thinking	Numerical Scales	Nonsymbolic Quantity

FIGURE 20.1. Conceptual model for the UNIT2.

short-term memory. Also, a strong two-subtest Abbreviated Battery may be administered (Analogic Reasoning and Nonsymbolic Quantity).

SUBTESTS AND COMPOSITES

In addition to subtest scores and a Full Scale IQ (FSIQ), three composites can be calculated for the UNIT2 Full Scale Battery: Memory, Reasoning, and Quantitative composites. As mentioned previously, examiners may elect to administer the Standard Battery with the Memory composite (SBIQ-M) or without it (SBIQ). The UNIT2 subtests (Symbolic Memory, Nonsymbolic Quantity, Analogic Reasoning, Spatial Memory, Number Series, and Cube Design) and their administration are described in the section that follows.

ADMINISTRATION AND SCORING

Administration of Subtests

Administration of all six UNIT2 subtests requires approximately 45–50 minutes. Norms allow for two-, four-, and six-subtest batteries. The shorter batteries require approximately one-third to two-thirds less time than the full battery.

Although administration of the UNIT2 subtests is 100% nonverbal, the examiner may communicate with the examinee (if they have a common language) to establish rapport, discuss extra-test issues, and the like, as well as to reduce the awkwardness that may otherwise occur with a nonverbal interaction. The examiner must, however, present the UNIT2 stimuli nonverbally, using eight nonverbal gestures (which were used during standardization and are presented in the manual) to communicate task demands. To aid in teaching task demands, the examiner is instructed to make use of demonstration items, sample items, and "checkpoint" items; checkpoint items allow the examiner to provide feedback only if the item is failed, but unlike demonstration and sample items, checkpoint items are scored. Specific descriptions and subtest directions follow.

Symbolic Memory stimulus pages are located in Stimulus Book 1 and are presented to the examinee for 5 seconds each. Symbolic Memory items depict one or more universal human figures (i.e., baby, girl, boy, woman, and man) in varying combinations; each human figure is produced in both green and black. Examinees younger than 8 years must identify and select the matching image from options presented below the stimulus picture. For examinees older than 8 years, the stimulus page is presented for 5 seconds and then removed. The examinee then is instructed through modeling and gestures to replicate the sequenced order shown on the stimulus page. The examinee uses 1.5″ × 1.5″ response cards, each depicting one of the universal human figures, to reproduce the array shown on the stimulus page. The examinee's response has no time limits or bonus credit given for rapid performance. Materials needed include Stimulus Book 1, 10 Symbolic Memory Response Cards, and a stopwatch for timing stimulus exposure. The subtest is discontinued after the examinee obtains three consecutive scores of 0 (i.e., three consecutive failed items).

For the Nonsymbolic Quantity subtest, the examiner presents an easel-bound stimulus page in Stimulus Book 1, which includes an array of white and black domino-like objects with various numerical values. Each domino figure creates a numerical sequence, equation, analogy, or mathematical problem to be solved. The examiner points to the stimulus figure series, which ends with a red question mark. The examiner then waves a hand over the response options at the bottom of the page, points to the question mark, and shrugs to ask the examinee how the item should be completed. The examinee points to the response option presented below the stimulus that best completes the conceptual or numerical analogy, sequence, or problem. The subtest is discontinued after the examinee obtains three consecutive scores of 0 (i.e., three consecutive failed items).

The Analogic Reasoning subtest requires the examinee to solve analogies presented in a matrix format. The examinee is directed to indicate which one of several options best completes a two-cell or a four-cell analogy. Task solution requires the examinee to determine the relationships between objects. For example, in a four-cell matrix, the first cell may depict a fish, and the second water; the third cell may show a bird, and the fourth cell is blank. The examinee selects from several options the picture that best completes the matrix. In this case, a picture of the sky is a correct response. This reasoning subtest is not timed. Each correct response is assigned 1-point credit.

For the Spatial Memory subtest, the examiner briefly presents a series of grids on stimulus plates located on an administration easel. The grids show one or more green or black polka dots placed within cells (on the grid). The less difficult items use a 3 × 3 grid; the more difficult items require a

4 × 4 grid. The stimulus plate is shown for 5 seconds and then is removed from view. The examinee places response chips on a blank grid that is placed on the table top in front of him or her. Spatial Memory has no time limits, except for the 5-second exposure. Each correct response is assigned 1-point credit.

To administer the Numerical Series subtest, the examiner presents a stimulus page in Stimulus Book 3 with arrays of numbers or mathematical symbols that create analogies, sequences, or problems. The examiner waves a hand over the depicted numbers and motions to a red question mark. After pointing to the question mark, the examiner shrugs, asking the examinee to select the option that best completes the series or solves the problem. The examiner discontinues the subtest after the examinee obtains three consecutive scores of 0 (i.e., three consecutive failed items).

The Cube Design subtest requires the examinee to use up to nine cubes to replicate three-dimensional designs shown on a stimulus plate. Each cube has six facets: two white sides, two green sides, and two sides that contain diagonals (triangles), one green and one white. These cubes can be arranged to replicate the three-dimensional figures depicted on the stimulus plates. This task is timed, but the time limits are liberal, to emphasize assessment of ability rather than speed. Except for the very early items, which are scored either correct or incorrect and yield a maximum of 1 point per item, examinees may earn up to 3 points (per item). Each facet of the three-dimensional construction is judged to be either correct or incorrect. Each correct facet is assigned 1-point credit.

Materials and Scoring

In addition to the manipulatives (e.g., blocks, response chips, response grids,), general materials required to administer the UNIT2 include a stopwatch, a #2 lead pencil, a test booklet for recording the student's performance, and relevant demographic information. The stimulus plates for all subtests are contained in three easels.

Scoring is user-friendly and straightforward. Correct responses are printed on the test booklet to facilitate ease of scoring. Raw scores for each item are summed to provide a subtest total raw score, which are easily transformed to standard scores with either the tables provided in the UNIT2 manual or the UNIT2 Compuscore software (Bracken & McCallum, 2016a). The Abbreviated Battery is used for screening purposes; one of the Standard Batteries for most purposes, including placement decisions; and the Extended Battery for diagnostic purposes.

PSYCHOMETRIC PROPERTIES

Norming Procedures, Standardization Characteristics, and Technical Data

The UNIT2 was standardized and normed on a nationally representative sample of 1,603 students from 33 states; these individuals ranged in age from 5 to 21 years, with 50.8% male and 49.2% female representation. The stratification of the sample closely represented the U.S. population on all relevant variables, including sex, race, ethnicity, Hispanic origin, geographic region, special education status, parental education attainment, and household income (see the examiner's manual for details).

Reliability

Average UNIT2 coefficient alphas range from .89 to .98 for subtests and scales across the full age range; coefficients for composite scores are higher, ranging from .93 (Memory composite) to .98 (Standard Battery without Memory and Full Scale Battery). The average subtest reliability coefficients across age groups range from .89 (Spatial Memory) to .96 (Nonsymbolic Quantity, Analogic Reasoning, and Numerical Designs); Full Scale reliability coefficients range from .97 (at ages 5, 6, 7, 8, and 12) to .99 (ages 16 and 19). For the Standard Battery with Memory, the composite reliability coefficients range from .95 (ages 5 and 6) to .98 (age 17); for the Standard Battery without Memory, composite reliability coefficients range from .95 (age 5) to .99 (ages 16 and 21). For the Abbreviated Battery, composite reliability coefficients range from .94 (ages 5 and 6) to .98 (ages 12, 13, 14, 16, 17, 19, 20, and 21). FSIQ reliability coefficients are very high by race and ethnicity: All are .98, with the exception of the coefficient for American Indian/Eskimo examinees (.99). Full Scale composite reliability coefficients are all well above the recommended minimum (i.e., .90) for scores used in guiding selection/placement decisions (see Bracken, 1987; Bracken & McCallum, 1998; Wasserman & Bracken, 2013).

As an indicator of fairness, internal-reliability estimates are reported in the UNIT2 examiner's manual for special populations (e.g., children with learning disabilities or speech and language impairments) and for the important decision-making points (i.e., FSIQ of 70 ± 10 or 130 ± 10). These coefficients are similarly impressive and comparable to those reported for the entire standardization sample.

In order to assess stability, a sample of 199 participants was first divided into four age groups. Test–retest reliability over an average interval of 17.8 days was reported for the four groups and the combined sample. Practice effects for the combined age sample were small and averaged 1.58 points for the Abbreviated Battery, 2.66 points for the Standard Battery with Memory, 2.15 points for the Standard Battery without Memory, and 2.45 points for the Full Scale Battery. Obtained coefficients and those corrected for restriction and/or expansion in range are reported in the examiner's manual. Corrected subtest stability coefficients ranged from .75 (Spatial Memory) to .94 (Cube Design); corrected composite stability coefficients ranged from .86 (Memory) to .90 (Reasoning) for the overall sample. Stability coefficients for total test composites across the four batteries ranged from .85 (Abbreviated Battery) to .93 (Standard Battery without Memory and Full Scale Battery). All of the stability coefficients for the composites exceeded .80, which is indicative of strong test–retest reliability and stability. The typical test–retest gain score was small, consistently less than 0.30 standard deviation.

Interrater scorer consistency was also assessed by having two members of the publishing company staff (PRO-ED) independently score 50 protocols drawn at random from the normative sample. The resulting interrater coefficients for various subtests and composites ranged from .98 to .99, indicating excellent scoring consistency.

Validity

Data from the original UNIT provide a starting point for establishing UNIT2 validity, given the similarities across the two tests. Additional studies conducted as part of the UNIT2 norming process provide further evidence of content description validity, criterion prediction validity, and construct identification validity. For the initial determination of UNIT2 content validity, careful selection procedures were used to choose items; the items were then subjected to differential item functioning analyses to investigate the presence or absence of bias in the test's items. To examine criterion prediction validity, the UNIT2 was correlated with seven major intelligence tests. The correlations between the UNIT2 composites and criterion tests ranged from moderate to very high levels, suggesting that the UNIT2 correlates significantly and meaningfully with other tests of general intelligence.

Initially, UNIT and UNIT2 scores were correlated. The corrected correlation between the UNIT2 Standard Battery with Memory and the UNIT Standard Battery was .96, indicating that the two editions are highly related in content and constructs assessed. Consequently, the literature exploring the validity of the UNIT has considerable relevance to the findings for and use of the UNIT2. Correlations between the UNIT2 Full Scale Battery and the Cognitive Assessment System—Second Edition (CAS2; Naglieri, Das, & Goldstein, 2014) Full Scale were .66 for the CAS2 Standard Battery and .69 for the CAS2 Extended Battery. While these are large (and significant) correlations, they are slightly lower than those obtained when the UNIT2 was compared to other measures, probably because the UNIT2 and CAS2 were developed from slightly different models of intelligence. The correlations between the UNIT2 Abbreviated Battery, Standard Battery with Memory, Standard Battery without Memory, and Full Scale Battery and the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV; Wechsler, 2003) were .70, .83, .83, and .84, respectively. Correlations between the four UNIT2 batteries and the Stanford–Binet Intelligence Scales, Fifth Edition (SB5; Roid, 2003) Abbreviated Battery IQ (ABIQ) were .59 (UNIT2 Abbreviated Battery), .69 (UNIT2 Standard Battery with Memory), .73 (UNIT2 Standard Battery without Memory), and .73 (UNIT2 Full Scale Battery). Correlations between the UNIT2 Abbreviated Battery, Standard Battery with Memory, Standard Battery without Memory, and Full Scale Battery and the Comprehensive Test of Nonverbal Intelligence—Second Edition (CTONI-2; Hammill, Pearson, & Wiederholt, 2009) were .84, .82, .85, and .85, respectively. The UNIT2 Abbreviated Battery, Standard Battery with Memory, Standard Battery without Memory, and Full Scale Battery correlated with the Woodcock–Johnson III Tests of Cognitive Abilities (WJ III COG; Woodcock et al., 2001) in the large to very large range (.64, .74, .82, and .79, respectively). These studies indicate that the UNIT2 is a sound measure of global intelligence, but that it may not be strongly correlated with measures of processing speed. Speed is a factor downplayed in the UNIT and UNIT2 because processing speed is not valued in many cultures, at least to the extent that it is valued in mainstream U.S. culture. These findings support our intention to put less emphasis on speed as a measure of intelligence within the UNIT2. The UNIT2 Abbreviated Battery, Standard Battery with Memory, Standard Battery without Memory, and Full Scale Battery also correlated with the Universal Multidimensional Abilities Scales (UMAS; McCallum & Bracken, 2012a) at moderate to very large levels (.52, .63, .65, and .72, respectively).

Support for UNIT2 construct validity was provided also by comparing means and standard deviations for different examinee age groups (i.e., growth curves), comparing the performance of different groups to the normative sample, correlating the UNIT2 with measures of academic achievement, and conducting factor analyses to compare subtests to the constructs inherent in the UNIT2 model. The UNIT2 shows a strong relationship with age, and expected mean differences between various groups (individuals with low IQ, high IQ, autism spectrum disorder, language disorders, etc.), suggesting that the UNIT2 is an effective and fair tool for assessing various populations of students. In addition, validity studies described in the examiner's manual show relationships between the UNIT2 and various achievement tests across several populations, ranging typically from .54 to .79, with a few exceptions below or above this range.

Because the UNIT2 is based on a specific theoretical model, confirmatory factor analysis (CFA) was used to assess the degree of fit with the proposed model. As described in the UNIT2 examiner's manual, the structural validity of the UNIT2 was empirically investigated by contrasting four CFA models across five age ranges (ages 5–7 years, 8–10 years, 11–13 years, 14–17 years, and 18–21 years) and the total sample, using maximum-likelihood CFA. The four models examined included a one-factor model, a two-factor Reasoning × Memory model, a two-factor Reasoning × Quantitative model, and a three-factor Reasoning × Memory × Quantitative model. The results for these models were assessed by using multiple indices of fit: (1) Wheaton, Muthén, Alwin, and Summers (1977) relative chi-square (chi-square divided by degrees of freedom); (2) Tucker and Lewis's (1973) index of fit; (3) Bentler's (1990) comparative fit index; and (4) Browne and Cudeck's (1993) root mean square error of approximation. All four models fit the UNIT2 reasonably well, which supports interpreting the test as a measure of general ability, as well as interpreting its various Standard and Abbreviated Battery options. This factor analysis also supports an acceptable model at each age range examined, as well as the organization of subtests to scales on the UNIT2 (Bracken & McCallum, 2016b).

Fairness

The burden of ensuring fairness in testing is particularly salient for authors of nonverbal tests, in part because of an increasingly diverse society and the need to ensure sensitive and equally valid assessment for a wide variety of populations. The UNIT2 manual includes an entire chapter entitled and dedicated to "Fairness," which describes extensive efforts to ensure that the test is appropriate for use with all children in the United States (i.e., that construct-irrelevant variance is minimized for all relevant populations).

The UNIT and UNIT2 were formulated, and the tests were developed, on the basis of five core fairness concepts: (1) A language-free test is less susceptible to bias than a language-loaded test; (2) a multidimensional measure of cognition is fairer than a unidimensional one; (3) a test that minimizes the influence of acquired knowledge (i.e., crystallized ability) is fairer than one that does not; (4) a test that minimizes speeded performance is fairer than one with greater emphasis on speed; and (5) a test that relies on a variety of response modes is more motivating and thereby fairer than one relying on a unidimensional response mode. Several other steps were taken to ensure fairness. For example, in the initial item development phase, items were submitted to a panel of "bias experts"—individuals sensitive to inclusion of items that might be offensive to or more difficult for individuals within certain populations (e.g., Native Americans, Hispanics). Items identified by these individuals and those identified via statistical item bias analyses were removed. In addition, a number of statistical procedures were undertaken to help ensure fairness, including calculation of separate reliabilities, factor structure statistics, mean-difference analyses, and so forth for subpopulations, as described within the UNIT2 manual's "Fairness" chapter (e.g., presentation of reliability and internal and external validity data for several populations of interest, such as African Americans, Hispanic Americans, Native Americans, Asian Americans, and individuals with hearing impairments; reliability coefficients calculated separately for diverse groups for the Full Scale Battery composites; etc.). Importantly, reliability coefficients were .97 or above across genders, 6 different ethnicities, and 12 different exceptionalities. Of interest to many users of nonverbal tests are mean score differences between minority samples and matched nonminority samples. For example, the median score differences between a sample of 224 black/African American students and a matched sample of white/European American examinees drawn from the standardization sample was 1.56 for the subtests and 10.40 for composite scores. The median score differences for a sample of 215 Hispanic examinees and matched controls were 0.78 for the subtests and 4.95 for the composites. Of note, there have been several reviews addressing fairness of the original UNIT, and these have been very positive in general (e.g., Bandalos, 2001; Braden & Athanasiou, 2005; Fives & Flanagan, 2002; Sattler, 2008). These studies have relevance for establishing the UNIT2's fairness, given the theoretical and statistical evidence showing overlap between the two instruments.

As is apparent, considerable effort was expended to establish fairness for the populations of interest to users of nonverbal tests. Readers interested in additional information about UNIT2 assessment fairness and equity may want to explore the many studies described in the UNIT2 examiner's manual.

INTERPRETING THE UNIT2

As we noted in an earlier version of this chapter (McCallum & Bracken, 2012b), multidimensional test interpretation is complicated, in part because it requires examiners to engage in a number of steps, consult numerous tables, consider a variety of cognitive models, consider carefully the limitations of the instruments they use, and (finally and most importantly) make the test results relevant for real-world application. There are three basic interpretative strategies: *normative, base rate,* and *ipsative*. Although normative interpretation is the most common strategy for determining examinee strengths and weaknesses, it is possible to interpret performance ipsatively as well. Normative interpretation relies on comparing an examinee's standard scores to those of peers, using age-based or grade-based normative data. By contrast, ipsative interpretation relies on intraindividual comparisons of scores (e.g., comparing each subtest and/or composite scores to the examinee's subtest and/or composite averages). Subtest/composite scores that deviate from the examinee's means to a greater extent than would be expected by chance are considered personal strengths or weaknesses. Finally, base rate interpretation relies on determining how rare difference scores are in the population, as defined by the test standardization sample. Most test authors show base rates of subtest pairwise difference scores and base rates associated with differences between particular subtest scores and subtest averages. Some experts assume that difference scores occurring within the population no more frequently than 15% of the time should be considered rare; others are of the opinion that difference scores so large that they occur in the population only 10% of the time should be considered rare. Interpretation based on these strategies has been made somewhat more user-friendly recently because of computer-based scoring and interpretation software. But we caution that unquestioning reliance on these software solutions can lead to misleading conclusions, and requires that examiners use the computer-generated data as a starting point only. In the next section, we describe these strategies in more detail within the context of UNIT2 scores.

As described previously, the UNIT2 features four battery options: the Abbreviated (twosubtest) Battery, the Standard (foursubtest) Battery with Memory, the Standard (four-subtest) Battery without Memory, and the Full Scale (sixsubtest) Battery. The various batteries were designed to assess memory, reasoning, and quantitative reasoning, using both symbolic and nonsymbolic task demands. Interpretation of the UNIT2 begins with the examiner's consideration of which battery should be administered. Making a choice among the four batteries depends on several issues, including the purpose of the assessment (e.g., screening, diagnostic testing, placement), the estimated attention span of the student, the time available to conduct the assessment, and related concerns. Once the choice of batteries has been made and the UNIT2 has been administered, actual test interpretation is conducted in multiple steps that consider data successively, from the most global and reliable sources (e.g., FSIQ, scale scores) to increasingly specific yet less reliable sources (e.g., subtests, items).

UNIT2 results are interpreted from both inter- and intrachild (normative and ipsative, respectively) perspectives. Both procedures have been employed by a variety of authors over the years and have become commonplace for the interpretation of psychoeducational tests (Bracken, 1984, 1992, 1993, 1998, 2006a, 2006b; Bracken & McCallum, 1998; Kaufman, 1979; Kaufman & Kaufman, 1983; Kaufman & Lichtenberger, 1999; McCallum, 1991; Sattler, 1988, 1992). The following discussion for interpreting the UNIT2 flows from principles described by these experts and reflects specific strategies and guidelines outlined in the UNIT2 manual (Bracken & McCallum, 2016b).

Specific Interpretation Guidelines

Traditional normative and ipsative interpretation should proceed from the most comprehensive and reliable scores to the most specific, least reliable scores. Test composites (e.g., FSIQs and scale scores) tend to be the most reliable scores because they include sources of variation from all of the subtests and scales that comprise the test. As such, these molar data are more reliable than the more molecular scores from individual subtests. Composite cognitive ability scores also are the best predictors of important "real-world" outcomes, particularly academic and vocational success (Sattler, 2008). Consequently, the most defensible interpretive strategy is to initially address the overall composite score and stop the interpretive process. However, whenever there is considerable variability among examinees' performance across individual subtests in a battery, the overall composite is not an ideal reflection of an examinee's true *overall* ability. When significant subtest and scale variation occurs, further interpretation of the test is warranted (Kaufman, 1979; Kaufman & Lichtenberger, 1999). Therefore, the UNIT2 manual presents the following three-step sequence for interpreting results: (1) Interpret the global intelligence score; (2) interpret the construct-specific scores; and (3) interpret subtest performance, including pairwise subtest comparisons and ipsative subtest comparisons. These three interpretation steps are described below.

Step 1: Interpret the Global Intelligence Score

First, an examiner should describe an examinee's performance at the composite level on the Abbreviated, Standard, or Full Scale Battery composites both quantitatively (e.g., standard scores, confidence intervals, percentile ranks) and qualitatively (e.g., descriptive classifications), and within their bands of error (i.e., confidence interval). Quantitative descriptions are based on interpretation of obtained scores relative to population parameters. Scores on the UNIT2 conform to the traditional normal "bell curve," and UNIT2 standard scores can be compared to global scores on other tests using the same metric (i.e., M = 100, *SD* = 15), such as the various Wechsler scales and the Woodcock–Johnson cognitive and achievement batteries (e.g., see Schrank et al., 2014).

Score variability comes from two sources: reliable variance (shared and specific), and error variance. Because random error is normally distributed, obtained scores should be considered within a band of confidence that frames the obtained score by one or more standard error(s) of measurement (*SEM*), as determined by the level of confidence desired (e.g., 68%, 95%, 99%). Confidence intervals built around obtained scores define the probability that a given range of scores would include the examinee's "true" score with a given level of confidence. In addition to the *SEM*, the UNIT2 also reports bands of error associated with the "estimated true score," which takes into account regression toward the mean. As such, bands determining estimated true scores become more elliptical as scores move toward the extremes. The UNIT2 band of error (standard error of the estimate) can be found in Table 6.2 in the examiner's manual. Finally, qualitative descriptions can be used to describe levels of examinee functioning, using classifications provided in the UNIT2 examiner's manual. Qualitative classifications for the UNIT2 range from *very superior* to *very delayed*.

Step 2: Interpret the Construct-Specific Scores

The next step of UNIT2 interpretation focuses on variability between the Memory, Reasoning, and Quantitative composites as they contribute to the estimate of overall cognitive functioning. If scores on these scales produce significant variability (i.e., significant differences between themselves), the global intelligence scale will serve as a limited estimate of the examinee's global ability, and performance on the UNIT2 construct-specific composites should be interpreted.

The Memory, Reasoning, and Quantitative composites should be described both quantitatively and qualitatively. These scores should be examined for statistically significant and meaningful differences between each other. If a difference between two scales is statistically significant (i.e., so large that it would not be likely to occur by chance), such a difference should be considered important, at least initially. As suggested by Kaufman and Lichtenberger (1999), a probability level of .05 is recommended to determine statistical significance; however, significant differences are not necessarily clinically meaningful or rare. If significant differences exist, their rarity within the general population should be considered (see Step 3). Tables 6.1 and 6.2 in Appendix E of the examiner's manual present scale deviation values considered significant.

Step 3: Interpret Subtest Performance

As authors of the UNIT2, we recommend interpretation at the most global level possible; however, significant, meaningful variability between scales should lead the examiner to consider individual subtest variability. Section 7 of the Examiner Record Form provides space to calculate normative and ipsative pairwise subtest comparisons. With the ipsative approach, a statistically significant difference necessitates further analysis. A subtest score that is significantly greater than the mean subtest score reflects a potential area of relative strength, while a subtest score that is significantly lower than the mean score reflects a potential area of relative weakness. The abilities associated with individual subtests should be used to generate hypotheses or possible explanations for individual subtest variations. Cautious interpretation of differences between subtests is recommended because their reliabilities, while robust, are lower than those for the composites. Item response patterns within a subtest can also be examined for clues about specific areas of ability or challenges.

The UNIT2 manual provides hypotheses describing examinees with particular strengths or weaknesses on the global scale scores. For example, examinees who have stronger memory (than reasoning) may reproduce visual stimuli better than they can solve problems based on the recall of stimulus juxtapositions and relationships. Table 4.11 in the UNIT2 manual shows hypotheses related to scale variations. Table 4.12 in the UNIT2 manual also presents the primary and secondary abilities assessed by each UNIT2 subtest, to assist with interpretation of strengths and weaknesses. Finally, the UNIT2 examiner's manual provides two case studies to help examiners learn to interpret UNIT2 scores.

Sound test interpretation can be conducted only when tests possess reasonably good psychometric properties. Several authors (e.g., Bracken, 1987; Bracken & McCallum, 1998; Wasserman & Bracken, 2013) have recommended basic rule-of-thumb criteria for acceptable psychometric characteristics. For example, global scores used for making placement decisions should evidence reliability at a level of .90 or better; scores used for screening purposes should have reliability at a level of .80 or better. Also, subtest and scale floors, ceilings, and item gradients should be sufficiently sensitive to capture small differences in actual ability, at a range of ±2 standard deviations. In addition, subtest specificity must meet commonly accepted criteria before subtests can be interpreted as measures of unique abilities or skills, in addition to their contribution to their scale or the total test score. That is, even though subtests within an instrument contribute to the measurement of general cognitive ability, each subtest may be a reasonably good measure of some specific cognitive skill or ability.

Finally, intelligence test scores should not be used in isolation. Critics of subtest interpretation (e.g., McDermott, Fantuzzo, & Glutting, 1990) typically have not considered the clinical value of subtest analysis when it is employed as one aspect of data analysis that may be confirmed or refuted through other data sources (i.e., triangulation of data). Thus UNIT2 subtest analysis should be conducted to generate hypotheses about a child's unique intellectual strengths and weaknesses, and should *never* be used without additional extratest information that will allow the examiner to further evaluate the hypotheses that are generated. UNIT2 interpretation is facilitated by using the worksheets and tables printed in the test booklet. The booklet also provides a graph for charting an examinee's subtest and composite profile, as well as a checklist for indicating test validity and related notes and observations (e.g., comments about the examinee's physical appearance, mood, activity level, attention/concentration, visual–motor skills, problem-solving attack skills, language use), and for providing an assessment of the testing situation. We present a case in an appendix to this chapter as an illustration of how the UNIT2 can be used.

ADDITIONAL CLINICAL APPLICATIONS

The UNIT2 can be administered to non-English-speaking populations easily, without the traditional language demands of conventional intelligence tests or costly translations. Although no gestures are completely universal, the gestures chosen for use in the UNIT and UNIT2 (e.g., affirmative head nods and pointing) provide ubiquitous modes of communication across most cultures. Also, an effort was made to employ universal item content (i.e., objects found in all industrialized cultures). Thus use of the UNIT2 with children who come into the United States from other countries is facilitated. In addition, the format is appropriate for children with deafness/hearing impairments and for those who have other types of language deficits (e.g., selective mutism, severe dyslexia, speech articulation difficulties).

A final clinical application of UNIT2 results is described by Wilhoit (2017). Specifically, Wilhoit builds on the cross-battery assessment (XBA) procedures described by McGrew and Flanagan (1998) and revised/updated by Flanagan, Ortiz, and Alfonso (2007, 2013) to describe application of XBA to a number of nonverbal instruments.

One important assumption of XBA is that subtests can be selected from different batteries and used to assess particular cognitive constructs, thereby increasing assessment precision and efficiency. This technique is particularly useful when there is no need to administer and interpret a particular test in its entirety (e.g., the referral question does not require that an FSIQ be obtained from a specific cognitive test). To aid in the application of XBA, McGrew and Flanagan provided a cognitive nomenclature based on the work of several researchers, particularly Cattell (1963), Horn (1968, 1994), and Carroll (1993). This nomenclature—referred to in recent years as the CHC system or model—is embedded in a three-tier hierarchical model. Stratum III represents *g*, the general cognitive energy presumed to underlie performance across all tasks individuals undertake. Stratum II represents relatively broad abilities that can be operationalized fairly well as factors from a factor analysis (e.g., short-term memory, long-term memory, fluid ability, acquired knowledge, visual processing, auditory processing, and processing speed). Stratum I represents abilities at a more specific level, and can be assessed relatively purely by many existing subtests; two or more of these subtests can be used to operationalize stratum II abilities. Using this system, McGrew and Flanagan (1998) characterized subtests from most existing batteries as measures of stratum I and stratum II abilities, and provided several caveats about the use of these operationalizations. Application of XBA is somewhat detailed; it requires the use of worksheets containing the names of tests and subtests, and the broad stratum II and stratum III abilities those subtests measure. Using the worksheets, an examiner can determine strengths and weaknesses according to operationalization of the CHC model by subtests from various nonverbal measures. Assessment of stratum II abilities is the primary focus. Typically, each subtest from nonverbal tests assesses a narrow stratum I ability, and two or more can be used to provide a good assessment of stratum II. The six stratum II abilities assessed by nonverbal tests include fluid intelligence (Gf), crystallized intelligence (Gc), visual processing (Gv), short-term memory (Gsm), long-term memory (Glr), and processing speed (Gs). The other ability typically included in XBA, auditory processing (Ga), is not assessed by nonverbal tests and is not included on the worksheets. The XBA worksheets allow an examiner to calculate the mean performance by averaging scores from all subtests. Each stratum II ability score (determined by averaging two or more stratum I measures within that stratum II ability) can be compared to the overall stratum II average in an ipsative fashion. Assuming that all subtests use a mean of 100 and a standard deviation of 15 (or have been converted accordingly), each average stratum II ability score that is more than 15 points from the overall mean may be considered a strength or a weakness, depending on the direction of the difference. Wilhoit (2017) provides the worksheets for this application of the UNIT2 (and other nonverbal tests). Importantly, the stratum II abilities have been linked to several important real-world products (e.g., processing speed and short-term memory underpin the ability to learn to decode words quickly, according to Mather & Jaffe, 2002, 2011). Consequently, using XBA can aid in diagnosing academic and other problems.

In summary, the UNIT2 offers a more comprehensive assessment of intelligence than the original UNIT. The two newly added subtests expand the UNIT's representation of the CHC model, by adding a quantitative factor. Thus the UNIT2 addresses more of the dimensions included in the CHC model, but does so in a completely nonverbal manner, which allows practitioners a sound substitute for existing verbally loaded CHC assessment procedures.

INNOVATIONS IN THE MEASUREMENT OF COGNITIVE ABILITIES

Several features set the UNIT2 apart from all or most existing nonverbal scales.

1. The UNIT2 is administered solely through the use of examiner demonstrations and gestures. The liberal use of sample, demonstration, and (unique) checkpoint items ensures that the examinee understands the nature of each task prior to attempting the subtest for credit.

2. The test comprises a variety of subtests that provide the opportunity for both motoric and motor-reduced (i.e., pointing) responses. Admin-

istration of UNIT subtests can be modified so that only a pointing response is required on five of the six subtests. The use of motoric and motor-reduced subtests facilitates administration by optimizing motivation and rapport. For example, a very shy child may be encouraged initially to point only; later, as rapport is gained, other, more motorically involved responses may be possible. Also, use of the motor-reduced subtests may be indicated for children with limited motor skills.

3. Subtests contain items that are as culturally fair as possible. We have included colorized line drawings and objects that are recognizable to most individuals from all cultures.

4. The test is model-based. That is, we have included subtests designed to assess reasoning (a higher-order mental processing activity), as well as complex memory and quantitative thinking. Also, we have included symbolically loaded subtests as well as less symbolically laden ones. Interpretation of the UNIT is facilitated because of these theoretical underpinnings.

5. The UNIT2 manual contains results of multiple studies comparing the UNIT2 to other tests and showing how important populations function on the test relative to individuals from the mainstream culture (African Americans, Native Americans, Asian Americans, Hispanic Americans, individuals who are deaf or hard of hearing, or those whose primarily language is not English).

6. Administration time can be controlled by the examiner, depending on the number of subtests administered. The UNIT2 includes three administration formats: a two-subtest version, a four-subtest (standard) version, and a six-subtest (extended) version.

7. Reliability estimates were calculated for two critical cut points (i.e., for those with FSIQs around 70 and those with FSIQs around 130).

8. An unprecedented array of support resources were created for the original UNIT, including a training video, a university training manual, and a computerized scoring and interpretation software program. Given the similarities between the UNIT and the UNIT2, these resources will help novice examiners become familiar with the UNIT2. Of course, the computerized scoring system has been revised and updated on the basis of the new standardization data.

9. No test is completely free of the influence of culture and language, and the UNIT2 is no exception. Any test completely devoid of these influences is unlikely to predict important outcomes. However, the UNIT2 was designed to minimize language and cultural influences on test scores, given the goal of assessing those with language deficits and those from culturally different environments. The UNIT2 manual provides the authors information regarding the extent of cultural loading and linguistic demands on each subtest, based on the model described by Flanagan and colleagues (2007, 2013). Most subtests reflect low cultural and linguistic demands, as expected.

10. Not all experts agree that a nonverbal test provides an optimal assessment of at-risk populations—that is, those with language deficits and those from culturally different environments (e.g., see the discussion in Flanagan et al., 2013, Chapter 5). However, most experts note the potential advantages of using such tests for individuals in certain at-risk populations (e.g., see the chapters by Braden; Frisby; Green, Bardos, & Doropoulou; Jaquett & Kirkpatrick; Johnsen; Moore, McCallum, & Bracken; Roid & Koch; and Wasserman [two chapters] in the 2017 *Handbook of Nonverbal Assessment*).

11. Examiners who are philosophically opposed to using a nonverbal test that relies on memory have an option: They can now use the four-subtest Standard Battery without Memory within the UNIT2. This objection, however, applied minimally to the original UNIT because its memory subtests assessed complex memory and each subtest had a strong *g* loading (above .60).

Appendix 20.1 includes a case study that demonstrates how the UNIT2 and four other test batteries can be integrated into a comprehensive evaluation. All personally identifiable information has been altered in the case study report to preserve the confidentiality of the examinee.

APPENDIX 20.1

Brief Case Study

Name: Ryan Daniel Ross

Age: 7 years, 6 months

Date of birth: 02/14/09 Grade: Entering 1

School: Knox Elementary

Date(s) of assessment: 07/14/16; 07/30/16

Examiner: Sherry Mee Bell, PhD, NCSP,
Licensed Psychologist

REASON FOR REFERRAL AND BACKGROUND INFORMATION

Ryan was referred to determine his current cognitive, academic, and social-emotional functioning and to obtain information to facilitate his educational planning. He lives with his parents, who provided background information, and an older sister, Lauren. Both parents completed a 4-year college degree and are employed full-time; English is the only language spoken in the home. Ryan's parents reported a healthy pregnancy and delivery. Ryan's birth weight was within normal limits, although his developmental milestones were mildly delayed. Ryan walked independently at age 1 year, 5 months (1:5), and talked at about age 3; his speech and language development was significantly delayed. Ryan was toilet-trained (at about 3 years, bladder, and between ages 4 and 5, bowels). His tonsils and adenoids were removed at age 4:6, providing relief of chronic middle-ear infections. Ryan's vision and hearing have been tested within the last year, and his auditory and visual acuity are within normal limits. Family history is generally negative for psychiatric and learning problems, although two first cousins (maternal side) have received speech and language services in school.

Due to apparent delays in speech and language skills, Ryan was evaluated at the University Hearing and Speech Center at age 4, during the summer of 2013. According to this assessment, Ryan exhibited a communication disorder characterized by delayed receptive and expressive language skills, as well as irregularities and delay in his development of articulation skills. He exhibited difficulty naming and identifying objects and following directions; in addition, he exhibited instances of echolalia. Ryan's spontaneous speech was characterized by strings of unintelligible, reduplicative utterances, interspersed with some intelligible words. Based on the speech–language evaluation, Ryan was deemed eligible for and has been receiving special education services through the local school system (because of developmental delays) since August 2013.

ASSESSMENT INSTRUMENTS

Because of Ryan's documented language delays, a combination of language-loaded and non-language-loaded tests was administered, in part to rule in or out disorders often associated with significant language delays (e.g., autism, intellectual disability). These included the Universal Nonverbal Intelligence Test—Second Edition (UNIT2), a nonverbal, multidimensional assessment of cognitive abilities; the Peabody Picture Vocabulary Test, Fourth Edition (PPVT-4), a measure of receptive language skills; the Expressive Vocabulary Test, Second Edition (EVT-2), a measure of expressive language skills; selected subtests from the Woodcock–Johnson IV Tests of Achievement (WJ IV ACH), a battery assessing academic achievement; and the Clinical Assessment of Behavior (CAB), a comprehensive assessment of social, emotional, and behavioral functioning.

RELEVANT TEST OBSERVATIONS AND BEHAVIORS

Ryan is short for his chronological age and is slender. He presented as somewhat shy, but he separated from his parents upon request. Ryan seemed to put forth good effort during both assessment sessions and responded well to praise and encouragement. However, he had difficulty following oral directions at times, and some instructions had to be repeated or rephrased. Occasionally he whispered his answers, especially when he seemed unsure of himself. As a result of his cooperative behavior, the test results are considered to represent a valid estimate of Ryan's current level of functioning.

ASSESSMENT TEST RESULTS

On the UNIT2, Ryan achieved a Memory index score of 100, a Reasoning index score of 94, a Quantitative index score of 103, and a Full Scale Battery score of 99 (47th percentile). The range of scores from 96 to 102 captures Ryan's true Full Scale IQ (FSIQ) with 90% confidence. The composite indices of the UNIT2 have a mean of 100 and a standard deviation of 15, consistent with mainstream intelligence tests. The UNIT2 subtests have a mean of 10 and a standard deviation of 3; Ryan's subtest scores were as follows: Symbolic Memory, 9; Nonsymbolic Quantity, 11; Analogic Reasoning, 9; Spatial Memory, 11; Numerical Series, 10; and Cube Design, 9.

Ryan displayed relatively little variability on these nonverbal cognitive tasks. He performed somewhat more strongly (a little more than half a standard deviation higher) on quantitative versus reasoning tasks, and his memory scores were solidly average. The relative strength in quantitative versus reasoning abilities is consistent with Ryan's deficits in language, given that language comprehension and expression require reasoning and problem solving. Ryan's results on the UNIT2 indicate overall average cognitive abilities, which are significantly stronger than previous estimates of his language skills.

Ryan was administered the PPVT-4, Form A. Results yielded a standard score of 75, which is ranked at the 5th percentile and yields an age equivalent of 4:9. Similarly, on the EVT-2 (Form A), Ryan achieved a standard score of 78, which is ranked at the 7th percentile and yields an age-equivalent of 5:6. Results indicated that Ryan's receptive and expressive language skills continue to be somewhat delayed relative to those of his peers and to his overall cognitive abilities (approximately 2 to 2½ years below his chronological age). Furthermore, his receptive and expressive skills are relatively commensurate, indicating generally even, though delayed, language development.

Ryan was administered several subtests from the WJ IV ACH. These tests have a population mean of 100 and standard deviation of 15. Two measures each of reading, math, and writing were administered. The Word Attack subtest was not administered, due to Ryan's significant speech articulation irregularities. Age equivalents (AE), standard scores (SS), and standard score confidence bands are reported in Table 20.A.1.

TABLE 20.A.1. Ryan's WJ IV ACH (Form A and Extended) Results

CLUSTER/subtest	AE	SS (68% band)
READING	5:4	58 (55–61)
MATHEMATICS	6:9	90 (87–92)
WRITTEN LANGUAGE	6:3	80 (77–84)
ACADEMIC SKILLS	5:9	69 (67–71)
ACADEMIC APPLICATIONS	6:3	79 (76–82)
BRIEF ACHIEVEMENT	5:9	69 (66–71)
Letter–Word Identification	5:1	55 (52–59)
Applied Problems	7:0	92 (87–98)
Spelling	5:9	72 (67–76)
Passage Comprehension	5:7	64 (60–68)
Calculation	6:7	87 (84–90)
Writing Samples	6:7	88 (83–93)

Note. Norms based on age 7:6 were used. Composite (cluster) scores are reported in ALL CAPS.

The WJ IV ACH scores were based on age norms to allow direct comparisons with the other assessments administered (i.e., the UNIT2, PPVT-4, and EVT-2). However, it should be noted that Ryan spent an additional year in kindergarten (following participation in special education preschool) and has not been exposed to the first-grade curricula experienced by typical 7-year-olds. Nonetheless, these scores are consistent with Ryan's identified language delays. Ryan's reading (letter–word recognition and beginning reading comprehension) and spelling are significantly weaker than age expectations. His beginning writing skills are also low average. These areas of achievement are consistent with his performance on language tests, but much weaker than his overall cognitive abilities as measured by the UNIT2. His math skills (math reasoning and calculations) are in the average to low average range and more consistent with his UNIT2 quantitative thinking performance.

Ryan's mother completed the CAB, Extended Form. Her ratings yielded typical scores on the Respondent Veracity Scales, which support the validity of her responses, and her ratings yielded scores generally in the average range. CAB scores have a population mean of 50 and standard deviation of 10. Ryan's overall CAB Behavior Index was 54 (64th percentile, in the average range), indicating no significant global emotional or behavioral difficulties. Ryan's scores on the Clinical Scales were all in the average range: Internalizing Behaviors (59, 80th percentile); Externalizing Behaviors (43, 24th percentile); and Critical Behaviors (43, 25th percentile). His scores on the Adaptive Scales were as follows: Social Skills (42, 21st percentile); Competence (39, 14th percentile); and Adaptive Behaviors (45, 27th percentile). These results indicate a mild adaptive weakness on the Competence scale, which includes questions on language competence. Ryan's cluster score for Anxiety on the CAB was 60 (84th percentile, indicating mild clinical risk); his cluster scores for Depression, Anger, Aggression, Bullying, Conduct Problems, Attention Deficit/Hyperactivity, Autistic Spectrum Behaviors, Learning Disability, and Intellectual Disability were all in the average range. Furthermore, scores on the Executive Functioning scale and the Gifted and Talented scale were in the average range. In general, these scores suggest that Ryan's mother perceives that her son exhibits no significant emotional or behavioral difficulties. He has developed a tendency to be slightly anxious and withdrawn; this is likely related to his language delays, which impede communication. Ryan's CAB results do not suggest the presence of behaviors consistent with global cognitive delay (intellectual disability) or autism.

SUMMARY AND RECOMMENDATIONS

Assessment results tentatively suggest a *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5; American Psychiatric Association, 2013) diagnosis of language disorder, with both receptive and expressive delays (F80.2). Ryan is being referred for a medical examination to assist in determining the exact nature of his developmental delay and/or to rule out any organic or medical etiology.

Results of both the current assessment and the medical exam should be shared with school personnel to aid in educational planning for Ryan. At school, participation in a regular classroom with special educational support is recommended. Ryan decidedly appears eligible for intensive direct and consultative speech and language services. In addition, he is likely to need support from the school resource teacher, in either an inclusion or pull-out format, to make adequate progress on academic assignments. Modifications and adaptations in Ryan's assignments will be needed. A multisensory approach (particularly heavy use of visual, pictorial, and graphic representations of content to be learned) should be beneficial for Ryan. Grading modifications will be needed, and teachers are encouraged to conduct error analysis (with Ryan) to determine which kinds of tasks give him more difficulty. In the classroom, Ryan may benefit from being paired with a "study buddy" who can prompt Ryan on how to complete tasks and assignments. Ryan is at risk for developing a specific learning disability in reading, related to his language delays. At school and at home, he needs frequent exposure to children's literature and other content that is motivating and that will support development of vocabulary and store of knowledge. Ryan's educational and developmental progress should be monitored routinely.

PART IV

Relevance of Tests of Intelligence, Cognitive Abilities, and Neuropsycholgical Processes in Understanding Individual Differences

CHAPTER 21

Use of Intelligence Tests in the Identification of Giftedness

David E. McIntosh
Felicia A. Dixon
Eric E. Pierson

This chapter begins by providing a brief historical overview of giftedness, with an emphasis on identifying the major figures in the field. The theoretical formulation of intelligence and the conceptual links between intelligence and giftedness are also discussed from a historical perspective. The evolution of multitrait theories of intelligence, the impact of advances in psychometrics on gifted assessment, and the increase in the number of theory-based cognitive measures are examined. The refinement of theory of intelligence centering on the Cattell–Horn–Carroll (CHC) model is discussed.

A significant portion of the chapter focuses on the definition of *giftedness*. The distinction between the terms *gifted* and *talented* is made. The most recent definition of *gifted and talented* provided within the Every Student Succeeds Act of 2015 (ESSA) is presented and discussed, along with the broader and more inclusive definition offered by the National Association for Gifted Children (NAGC). Renzulli's (1978) multitrait definition, Tannenbaum's (1983) conception of giftedness as a psychosocial construct, Sternberg's implicit theory of giftedness (Sternberg & Zhang, 1995), and the differentiated model of giftedness and talent (Gagné, 2004) are reviewed. The implicit links among definitions, cognitive theory, and cognitive assessment are explored.

The issues of multiple intelligences versus many factors of intelligence are also considered. Specifically, Sternberg's triarchic theory of intelligence (Sternberg, Chapter 5, this volume; Sternberg & Williams, 2002) and Gardner's theory of multiple intelligences (Chen & Gardner, Chapter 4, this volume; Gardner, 1999) are reviewed. An extensive review of factor-analytic research is provided, exploring the multidimensional abilities of gifted children with commonly used measures of intelligence. Although factor-analytic research with gifted samples has for the most part supported Kaufman's (1975, 1979) two-factor model, there is a growing body of confirmatory-factor-analytic research studying more complex models of intelligence. The methodological and statistical issues contributing to differences across studies are also examined.

The process of gifted identification is then reviewed. Clark's (1997) and Borland's (1989) recommended approaches for identification are discussed. The importance of demonstrating links among a school's definition of giftedness, the identification process, and educational programming is considered. In addition, important issues to consider during the identification of cognitively gifted minority children are explored within the chapter. Alternative approaches are provided for identifying gifted children with learning disabilities.

A major portion of the chapter focuses on discussing special issues related to the intellectual assessment of gifted children. The importance of considering the theoretical differences among intelligence measures, and the importance of using theory-based measures, are both discussed. The need for a better understanding of the relationships between screening procedures and the final decision outcomes based on intelligence tests is emphasized. Implications of using a single composite IQ score and setting specific IQ "cutoff" scores when one is making identification decisions are examined. The chapter concludes with specific recommendations on the effective use of intelligence measures in the identification of giftedness.

HISTORICAL OVERVIEW OF INTELLIGENCE AND GIFTEDNESS

Although America's interest in giftedness has been magnified since the late 1800s, giftedness has been of general interest to virtually all societies in recorded history (Colangelo & Davis, 1997). However, until Francis Galton (1822–1911) established the conceptual link between intelligence and giftedness, there had been little research studying intellectual differences among humans (Clark, 1997). Using the work of his cousin Charles Darwin (1859) as a basis, Galton developed the theory of *fixed intelligence,* which essentially ignored the effects of the environment and emphasized the hereditary basis of intelligence. This theory of fixed intelligence dominated the literature for nearly half a century. Not until the mid-1950s, when research conducted by Jean Piaget, Maria Montessori, Beth Wellman, G. Stanley Hall, Arnold Gesell, and others was published, did researchers begin to question the fixed-intelligence model and begin to consider an interactive view of intelligence.

Along with the theoretical formulation of intelligence came the need to develop ways to assess intelligence. Interestingly, although Francis Galton was credited with developing the first intelligence test, Alfred Binet is more widely known for developing the first intelligence test in 1905, with the specific goal of differentially placing children in special education or regular classrooms. Binet has also been credited with establishing the concepts of *mental age* and *intelligence quotient* (IQ). As Colangelo and Davis (1997) deftly point out, it was Binet's concept of mental age that had implications for the identification of giftedness. Essentially, the concept of mental age implied that children demonstrate growth in intelligence; therefore, children may be behind, consistent with, or ahead of their peers intellectually (Colangelo & Davis, 1997). Consequently, some children identified will demonstrate advanced levels of intelligence.

In 1916, Lewis Terman published the famous Stanford–Binet Intelligence Scale, which has seen four revisions to date. Not only was Terman recognized for developing one of the most popular measures of intelligence, but he was also instrumental in one of the most significant longitudinal studies on giftedness of the 20th century, earning him distinction as the "father of gifted education" (Clark, 1997; Colangelo & Davis, 1997; Davis, Rimm, & Siegle, 2011). Soon after the development of the Stanford–Binet Intelligence Scale, the popularity of intelligence testing soared. In fact, it soared so greatly that many schools based educational placement decisions solely on IQ scores. Unfortunately, many schools continue to identify gifted students by using a single measure of cognitive ability. The benefits and limitations of such an approach are discussed later.

Another landmark event that was instrumental in the public's interest in giftedness occurred in 1957, when the Soviet Union launched the world's first human-made satellite, *Sputnik.* The fact that the Soviets had both the scientific and technological power to accomplish this feat was viewed by some Americans as a shocking defeat to U.S. education. The results were an increase in the focus on educating gifted children in more advanced classes, especially in science and mathematics, and a call to action for a "total talent mobilization" (Davis & Rimm, 1998). In the United States, *Sputnik* was a wake-up call; new programs and schools were designed for high-ability students, with the purpose of keeping ahead globally. Modern societal concerns about annual academic progress and "failing schools" echo these historic concerns.

Over the last 30 years, new theories of intelligence, advances in psychometrics, and advances in technology have resulted in a renewed focus on the identification of gifted individuals. The focus on neurobiological data and mental processes has resulted in the development of new theories of intelligence. Gardner (1983, 1993, 1999; see also Chen & Gardner, Chapter 4, this volume) has proposed a theory of *multiple intelligences,* which focuses on eight areas of intellect (with a ninth one, *existential,* proposed): *linguistic, musical, logical–mathematical, spatial, bodily–kinesthetic, interpersonal, intrapersonal,* and *naturalistic.* The significance of his theory lies not so much in the eight identified areas of intellect as in the underlying assumptions that form the basis of his theory. To be specific, Gardner has emphasized the neurobiological influences on intelligence and the importance of better understanding the interaction between genetics and environment in the development of intelligence. Likewise, the *triarchic theory* of intelligence developed by Sternberg (1985; see also Sternberg, Chapter 5, this volume) has focused on better understanding three kinds of mental processes related to giftedness: *analytic, synthetic,* and *practical.* The difficulty with these theories of intelligence has been in determining how to assess and apply the various constructs presented by the authors. However, there have been several attempts to apply Gardner's multiple-intelligences theory and Sternberg's triarchic theory within school settings, with varying results (Coleman & Cross, 2005).

There has also been a renewed interest in the use of Luria's theory of neuropsychology in the development of cognitive tests (Kaufman & Kaufman, 2004; Naglieri & Das, 1997). Although many psychologists and neuropsychologists find this theory clinically helpful in understanding patterns of deficits in individuals, it is important to recognize that Luria's theory was drawn from a tradition of analyzing individuals with head injury. Most often, people reflect upon Luria's work with individuals with head trauma. However, Luria (1987) also wrote and studied individuals with amazing talents and abilities in memory. Those working with gifted and talented students may want to consider possible applications of this theory in contrast to the dominant CHC theory.

Long before Gardner and Sternberg developed their theories, L. L. Thurstone (1938) proposed his theory of *primary mental abilities.* According to Thurstone's theory, seven primary intelligence factors or abilities were measured in tests of intelligence: (1) *word fluency,* the ability to think of a lot of words, given a specific stimulus; (2) *verbal comprehension,* the ability to derive meaning from words; (3) *number* or *numerical ability,* the ability involved in all arithmetic tasks; (4) *memory,* the ability to use simple or rote memory of new material, both in verbal and in pictorial form; (5) *induction,* the ability to examine verbal, numerical, or pictorial material and derive from it a generalization, rule, concept, or principle; (6) *spatial perception,* the ability to see objects in space and to visualize varying arrangements of those objects; and (7) *perceptual speed,* the ability to discern minute aspects of elements of pictures, letters, and words as rapidly as possible. Feldhusen (1998) has suggested that close examination of these seven abilities reveals some parallels to the popular multiple intelligences of Gardner in the types of abilities mentioned. Thurstone's theory of primary mental abilities proposed that students' achievement in school could best be understood by their relative amount of ability in these seven areas. The end of the 1990s and the beginning of the new century saw a consolidation of theory that resembles the model originally proposed by Thurstone. Specifically, this period saw the consolidation of Gf-Gc theory and the work of Carroll into the CHC model of intelligence (Schneider & McGrew, Chapter 3, this volume; Strauss, Sherman, & Spreen, 2006). Similar to Thurstone's model, CHC theory suggests that intelligence can be thought of as having seven primary ability areas: Gf (*fluid intelligence*), Gc (*crystallized intelligence*), Gsm (*short-term memory*), Gv (*visual processing*), Ga (*auditory processing*), Glr (*long-term storage and retrieval*), and Gs (*processing speed*).

Advances in psychometrics and technology have led to the development of cognitive measures that are theory-driven and reflect the multitrait nature of intelligence. In the past, cognitive measures were developed with little or no consideration of intelligence theory. Consequently, there was an overreliance on the unitary construct of intelligence, *g* (Flanagan & Ortiz, 2002). Following the convergence of theories surrounding the development of the CHC theory, many of the most commonly administered tests related to gifted assessments in the past (the Stanford–Binet and the Wechsler series) have been aligned with CHC theory by the test publishers (O'Donnell, 2009; Strauss et al., 2006; Warne, 2016). These are discussed in more detail later.

While current trends in test publishing and research have moved toward an increased emphasis on instruments built around theories of intelligence, it is important to keep in mind that earlier measures used with the assessment of giftedness had as their primary goal the classification of individuals along a unitary dimension of intelligence. As a result of changes in how estimates of IQ are obtained and in the nature of the tests, a child who was classified as gifted in the 1930s–1970s may look very different intellectually from what a psychologist looking at a gifted child in the current decade would see.

There is a renewed interest in providing gifted students with specific programming to meet their educational needs. At the heart of this renewed interest is an often hotly debated issue: How should children be identified for these special programs? What should guide the process of identification? Central to this issue is the importance of establishing a clear definition of *giftedness* to guide the development of services for the population defined.

THE ISSUE OF DEFINITION

The terms *gifted* and *talented* have been used in a variety of ways to describe individuals who perform at a superior intellectual level. *High-ability* or *high-functioning* have been terms frequently used in order to avoid using either *gifted* or *talented* because these terms have been problematic over the years. Borland (1989) has stated that there is a rupture between the word *gifted* in its various usages and a clearly and consensually defined group of children in schools. Hence the dichotomy between what the term actually means and how it is frequently used has caused some confusion about how to regard the dimensions of giftedness. Similarly, people have often disagreed over what *gifted* and *talented* mean in terms of individual characteristics, behaviors, and need for services.

Tannenbaum (1997) has defined *giftedness* as potential for becoming acclaimed producers. Gagné (1999) has differentiated between *gifts,* which he calls *aptitudes,* and *talents,* which he calls *expressions of systematically developed abilities or skills* in at least one field of human activity. According to Gagné, catalysts—environmental, intrapersonal, and motivational—transform intellectual, creative, socioaffective, and sensory–motor gifts (abilities, aptitudes) into talents (performances) in the academic, technical, artistic, interpersonal, and athletic areas (see also Davis & Rimm, 1998). Cox, Daniel, and Boston (1985) have avoided the term *gifted,* preferring to call these students *able learners.* Renzulli and Reis (1997) prefer *gifted behaviors,* which can be developed in certain students at certain times and in certain circumstances. Treffinger (1995) likes the term *talent development,* calling the shift a fundamentally new orientation to the nature of the field. Best-selling authors (e.g., Coyle, 2009; Gladwell, 2008) have embraced talents and gifts in their books, defining these constructs outside the cognitive dimensions present in most of the previous definitions: "[Talent is] the possession of repeatable skills that don't depend on physical size" (Coyle, 2009, p. 11), and "Outliers are those who have been given opportunities—and who have had the strength and presence of mind to seize them" (Gladwell, 2008, p. 267). For Gladwell (2008), at least, the gift is the opportunity as much as (or even more than) the innate traits. Many others have used the terms *gifted* and *talented* synonymously. If one standard definition were always used, the confusion would be nonexistent. This confusion in definitions has indeed been a major issue to both those concerned with studying gifted individuals and those concerned with educating them.

The definition of *gifted and talented* provided within the Every Student Succeeds Act of 2015 (ESSA; Pub. L. 114-95, 2015) is as follows:

> Students, children, or youth who give evidence of high achievement capability in areas such as intellectual, creative, artistic, or leadership capacity, or in specific academic fields, and who need services and activities not ordinarily provided by the school in order to fully develop those capabilities. (p. 398)

Although this definition has served the purpose of informing schools of what areas should be considered in serving gifted students, it really does not inform anyone of specific ways to find these people and is perhaps too broad for most school districts to operationalize effectively. In contrast, it does demonstrate the current trend in widening the perspective in order to allow more people to be served. Indeed, multitrait definitions tend to be the norm today.

In contrast, the definition from the National Association for Gifted Children (NAGC; 2010) is broader and more inclusive than the one provided in the ESSA, and it includes a wider range of skills and abilities than are usually addressed in schools:

> Gifted individuals are those who demonstrate outstanding levels of aptitude (defined as an exceptional ability to reason and learn) or competence (documented performance or achievement in top 10% or rarer) in one or more domains. Domains include any structured area of activity with its own symbol system (e.g., mathematics, music, language) and/or set of sensorimotor skills (e.g., painting, dance, sports). (p. 1)

This definition may also be too broad for schools in terms of directions for identifying the population to be served, but it does focus on the areas of exceptionality that are considered important to serve.

Renzulli (1978) has proposed a multitrait definition of giftedness that focuses on three interlocking clusters of traits: above-average, but not necessarily superior, ability; motivational traits that Renzulli calls *task commitment*; and creativity. According to Renzulli, "it is the interaction among the clusters that . . . [is] the necessary ingredient for creative/productive accomplishment" (p. 182). The form of giftedness characterized by high scores on standardized tests and model classroom behavior has been termed *schoolhouse giftedness* by Renzulli and Reis (1997).

Tannenbaum (1983) has defined *giftedness* as a psychosocial construct. He states that gifted individuals are those "with the potential for becoming critically acclaimed performers or exemplary producers of ideas in spheres of activity that enhance the moral, physical, emotional, social, intellectual, or aesthetic life of humanity" (p. 86). The key to this definition is the focus on the gifted individual as a producer of ideas.

Sternberg and Zhang (1995) have developed an implicit theory of giftedness that embodies five criteria: *excellence, rarity, productivity, demonstrability,* and *value.* Stating that implicit theories are relativistic because what is perceived as giftedness is based on the values of the particular time period or place in existence, Sternberg and Zhang have argued for the need for implicit theories to fill in the gaps left by explicit theories (i.e., those that specify the content of what it means to be gifted). "The problem is that in the science of understanding human gifts, we do not have certainties. There are no explicit theories known to be totally and absolutely correct, nor are there likely to be any in the foreseeable future" (p. 91).

In contrast to multitrait or all-encompassing definitions of giftedness are the definitions centering around the cognitive aspects of reasoning and judgment that can be found in a test score. To this end, the Binet–Simon test (Binet & Simon, 1905) was developed as an early paper-and-pencil test that attempted to measure intelligence. A revision of this test later became known as the Stanford–Binet Intelligence Scale (Terman, 1916), and this IQ-based definition is still widely accepted today (Coleman & Cross, 2005). Terman (1925a), the father of the gifted movement in this country, was perfectly content with defining giftedness as the possession of a very high IQ.

Using the Stanford–Binet to identify a population of gifted children, Lewis Terman and his research team were interested in investigating intelligence and achievement in a group of high-functioning children in the 1920s. Terman (1925b) wrote the following about gifted children:

> When the sources of our intellectual talent have been determined, it is conceivable that means may be found which would increase our supply. When the physical, mental and character traits of gifted children are better understood, it will be possible to set about their education with better hope of success. . . . In the gifted child, Nature has moved far back the usual limits of educability, but the realms thus thrown open to the educator are still *terra incognita.* It is time to move forward, explore, and consolidate. (pp. 16–17)

Specifically, Terman's team asked the following questions: Do precocious children become exceptional adults? Do high-IQ adults exhibit a disproportionate degree of mental health problems? Are brilliant children also physically superior? Does having a high IQ correlate with excellent school performance? Can gifted children be expected to display exceptional adult career achievements as eminent scientists, scholars, artists, and leaders? If high-ability children become extraordinary adults, what can be learned from the personal and educational antecedents that seem to nurture their development? (Sabotnik & Arnold, 1994). Terman's group's research focused on the lives of those high-functioning individuals who had scored in the top 1% on the Stanford–Binet Intelligence Scale, and on what could be learned about their lives to create educational opportunities that would serve similar people. They concluded from their research that superior children apparently became superior adults (Oden, 1968).

Leta Hollingworth's (1942) work with high-IQ students (i.e., children with IQs over 180) at the Speyer School in New York City was also important in informing researchers about the impact of an enrichment program for gifted students on their adult achievement and values. In 1981, several adults who had formerly attended the school were interviewed concerning the school's impact on their lives (White & Renzulli, 1987). Among those interviewed, three were from the group in Hollingworth's early study. They stated that the school provided lifelong love for learning, pleasure in independent work, and joy in interacting with similar high-ability students (Sabotnik & Arnold, 1994). Hence, both Terman's and Hollingworth's noteworthy research depended in large part on the IQ score measured for each individual and on what these high-ability individuals became later in life.

On the contrary, Simonton (2008) used Winner's (1996) definition of giftedness—"A gifted child or adolescent is someone who masters a particular domain at a faster rate than the average youth" (p. 253)—in his historiometric study of 291 eminent African Americans. Multiple-regression analyses indicated that adulthood eminence and creative achievement were positively correlated with early giftedness. Simonton offered two main implications, one theoretical and one practical, for this study. Theoretically, his inquiry established an impressive developmental continuity across the lifespan: Precocious development in childhood and adolescence predicts the magnitude of eminence and achievement in adulthood. Practically, his study indicated that giftedness must not be evaluated according to a "one-size-fits-all" procedure, but rather according to the occurrence of precocious behaviors that are specific to a given culture and achievement domain. The variety of gifts manifested in these precocious individuals would not have been identified by a score on a standard intelligence test.

A new paradigm has recently been developed that addresses the issue of identification in a different way. This paradigm is called *advanced academics* (Peters, Matthews, McBee, & McCoach, 2014); the idea is that instead of identifying giftedness as a stable trait, the authors advocate assessing students' need for a particular program as well as their probability of success in the program. The overarching goal is to better match instruction and teaching with each student's current level of mastery and need. Thus the advanced academics paradigm ignores the controversial question of who is or is not gifted, or even if such a thing as giftedness exists. Instead, academic needs form the foundation on which programs and services are built. The authors state:

> Academic need is not a property of individuals, but rather emerges from an interaction between a student and a particular academic environment—a particular teacher, subject, curriculum, and peer group. As such, academic need is not expected to be a stable trait across contexts, schools, or teachers, but rather a (hopefully) temporary condition that arises when the instructional pacing, depth, and/or content are not sufficiently rigorous as to require full engagement and effort from the student. (p. 40)

Dai and Chen (2013) examine three paradigms in gifted education that currently exist: (1) the *gifted child* paradigm, (2) the *talent development* paradigm, and (3) the needs-based *differentiation* paradigm. Identification of the three paradigms is based on historical and theoretical grounds. Each paradigm is carefully defined and describes the current trends in serving gifted students according to how gifted educators best define giftedness.

Gridley, Norman, Rizza, and Decker (2003) have proposed a definition of giftedness based on the CHC theory of intelligence. This theory combines Cattell and Horn's model of Gf (fluid) and Gc (crystallized) intelligence with Carroll's standard multifactorial model. Carroll's model (see Schneider & McGrew, Chapter 3, this volume) suggests that cognitive abilities exist at three levels or *strata*: (1) a lowest or first stratum composed of numerous narrow abilities; (2) a second stratum consisting of about 8–10 broad abilities; and (3) a third stratum comprising a single general intellectual ability, commonly called *g*. Gridley and colleagues' definition is as follows:

> Intellectually gifted students are those who have demonstrated 1) Superior potential or performance in general intellectual ability (Stratum III) and/or 2) Exceptional potential or performance in specific intellectual abilities (Stratum II) and/or 3) Exceptional general or specific academic aptitudes (Strata I and II). (p. 291)

The practicality of Gridley and colleagues' definition is that it suggests that giftedness can be measured by a test. The authors state that they do not "focus on the genetic causes of gifts, but rather . . . on gifts as intellectual abilities and talents as special academic aptitudes being of equal value in their need for nurturing and development" (pp. 290–291).

Most professionals regard giftedness in school as an academic need to be served (e.g., Coleman & Cross, 2005; Rizza, McIntosh, & McCunn, 2001). In order to be served appropriately, students must be identified, and standardized tests are the major methods used for identification purposes. Although a standardized test is available to measure each dimension in the federal definition, most programs for gifted individuals are particularly interested in intelligence tests because most gifted programs focus on serving students of high cognitive ability.

Gallagher (1995) has stated that an IQ test is merely one measure of the development of intellectual abilities at a given time. It gives an indication of a child's current development, so that children can be compared to one another on such characteristics as their store of knowledge, reasoning ability, and ability to associate concepts—all of which are important predictors of academic success. IQ tests still remain the single most effective predictors of academic success that we have today. There is evidence (Rindermann, 2007) to suggest that one of the reasons why measures of intelligence are such good predictors of academic success is that they measure a single innate construct overlapping with academic achievement. It is also likely that this single innate construct has shared measurement error with common measures of academic achievement. Pyryt (1996) agrees with this focus on the best measures currently available, stating that IQ tests are very useful for making legal decisions regarding the eligibility for participation in gifted programs. IQ tests still serve as important tools for recognizing the special education needs of intellectually gifted students.

The modern IQ test, with its age-based normative comparison, allows for students' level of giftedness to be classified by a method such as that suggested by Gagné (2004) and encouraged by Baer and Kaufman (2004). It is important to recognize that this classification system may be difficult to implement, as the item ceilings for different measures of intelligence may limit the ability of individuals to be classified at the highest level or to maintain a high level of classification at different ages.

THE ISSUE OF ONE VERSUS MANY FACTORS IN INTELLIGENCE

Defining Intelligence(s)

The IQ score, a unidimensional construct used for many purposes, has been historically very important in identifying and understanding giftedness. In fact, as noted earlier, the idea that a child is intellectually precocious has often been synonymous with a high IQ score. Those arguing against the idea of an IQ score have stated that this measure leads to a narrow view of intelligence that is tied to the skills most valued in schools—linguistic and logical–mathematical skills (Ramos-Ford & Gardner, 1997). In addition, Ramos-Ford and Gardner note that a majority of children are still admitted to specialized educational programs for gifted students on the basis of an IQ score of 130, or two standard deviations above the mean on an intelligence test. A score of 129, virtually the same score, will keep another student out of such a program. This cutoff score process is problematic and all too prevalent in school programming for gifted students.

Arguing for a theory of multiple intelligences, Gardner (1999) has defined *intelligence* as an ability or set of abilities that permits an individual to solve problems or fashion products that are of consequence in a particular cultural setting. Ramos-Ford and Gardner (1997) conclude, "A multiple intelligences approach to assessment and instruction strives toward identifying and supporting the 'gifts' in every individual" (p. 65).

Sternberg's triarchic theory of intelligence suggests that intelligence includes "applying component processes to novel tasks for the purposes of adaptation to, shaping of, and selection of environments" (Sternberg & Williams, 2002, p. 148). Sternberg has described both his triarchic theory of intelligence and Gardner's theory of multiple intelligences by using a systems metaphor. Sternberg's metaphor suggests that to understand the various aspects of intelligence working together as a system, one needs to understand the integration within the system itself (Sternberg & Williams, 2002). Although these theories have gained popularity in recent years, they lack empirical data to support their effectiveness (Sternberg & Williams, 2002).

Sternberg and Williams (2002) state, "Perhaps the most difficult challenge in the study of intelligence is figuring out the criteria for labeling a thought process or a behavior as intelligent" (p. 1). One must establish criteria to use in trying to decide what constitutes intelligence. Early experts suggested that intelligence is based on adaptation to the environment (e.g., Colvin, 1921, and Pintner, 1921; both cited in Sternberg & Kaufman, 2001). Later, Boring (1923; cited in Sternberg & Kaufman, 2001) suggested that intelligence could and should be defined operationally as that which intelligence tests test. Current definitions by both experts and laypersons suggest that adaptation to the environment, whether with practical problem-solving ability or academic skills, is still the essential theme in defining intelligence. Sternberg and Williams have further suggested three criteria to understand the mental processes and behaviors that can be labeled intelligent: correlation of a target thought or behavior with cultural success, or *cultural adaptation*; mental skills development, or *cultural and biological adaptation*; and evolutionary origins and development, or *biological adaptation*.

With these emphases in mind, then, individuals who are called gifted will be those who can best adapt to their environments, and the purpose of finding these individuals through identification processes in schools will be to maximize their abilities in doing so.

Factor-Analytic Research

Extensive factor-analytic research has been conducted with the goal of exploring the multidimensional nature of intellectual abilities among gifted children. The majority of this research has used the Wechsler Intelligence Scale for Children—Revised (WISC-R; Wechsler, 1974), the WISC-III (Wechsler, 1991), and the WISC-IV (Wechsler, 2003) (Brown & Yakimowski, 1987; Macmann, Plasket, Barnett, & Siler, 1991; Mishra, Lord, & Sabers, 1989; Reams, Chamrad, & Robinson, 1990; Rowe, Dandridge, Pawlush, Thompson, & Ferrier, 2014; Watkins, Greenwalt, & Marcell, 2002). In general, factor-analytic studies have consistently found support for the Verbal Comprehension and Perceptual Organization two-factor model (Karnes & Brown, 1980; Sapp, Chissom, & Graham, 1985; Watkins et al., 2002) proposed by Kaufman (1975, 1979). Among the two-factor models, the Verbal Comprehension factor was typically composed of the Similarities, Vocabulary, Comprehension, and Information subtests. More variability was displayed across studies in the composition of the Perceptual Organization factor. The majority of the studies found that the Block Design and Object Assembly subtests loaded on the Perceptual Organization factor, while the Picture Completion and Picture Arrangement subtests were found to load inconsistently across studies on this factor.

Although factor-analytic studies generally have supported a two-factor model, there has been varying support for a three-factor model (Brown, Hwang, Baron, & Yakimowski, 1991; Brown & Yakimowski, 1987; Karnes & Brown, 1980; Macmann et al., 1991). The specific composition of the third factor has varied significantly across studies. For example, several studies found that the Information, Arithmetic, and Coding subtests primarily composed the third factor (Brown & Yakimowski, 1987; Brown et al., 1991), whereas Sapp and colleagues (1985) found that the Information, Arithmetic, Vocabulary, and Block Design subtests primarily composed the third factor. In addition, Karnes and Brown (1980) noted that the Arithmetic and Picture Completion subtests composed the third factor (Freedom from Distractibility).

Only limited factor-analytic research has been conducted among gifted children with cognitive measures other than versions of the WISC (Cameron et al., 1997). Cameron and colleagues (1997) conducted a confirmatory factor analysis using the Kaufman Assessment Battery for Children (K-ABC; Kaufman & Kaufman, 1983). Although they compared four models of intelligence, they determined that Horn and Cattell's theory of fluid–crystallized intelligence provided the broadest understanding of the cognitive functioning of children referred for gifted services (Cameron et al., 1997).

The factor structures of cognitive measures have also been studied among gifted members of ethnic minority groups (Greenberg, Stewart, & Hansche, 1986; Masten, Morse, & Wenglar, 1995; Mishra et al., 1989). Factor-analytic research conducted by Greenberg and colleagues (1986) supported the WISC-R Verbal Comprehension and Perceptual Organization two-factor model with a sample of gifted black children. Another study, which examined the factor structure of the WISC-R with Mexican American children referred for intellectually gifted assessment (Masten et al., 1995), was unable to adequately replicate the factor structure proposed by Kaufman (1975). In contrast, the cognitive constructs of gifted Navajo children were similar to the Freedom from Distractibility and Perceptual Organization factors identified in research based on the standardization sample of the WISC-R (Mishra et al., 1989).

The variability in results among factor-analytic studies appears to stem primarily from methodological and statistical differences. Macmann and colleagues (1991) noted that restriction in variance due to sample selection might have contributed to differences in the composition of factors. There also appears to be great disparity across studies related to sample sizes. Although the majority of studies used large samples (e.g., Macmann et al., 1991; Watkins et al., 2002), several studies used samples with fewer than 150 participants. Factor-analytic research using gifted ethnic minority children utilized the smallest samples, with some using fewer than 100 participants (e.g., Masten et al., 1995; Mishra et al., 1989).

A lack of consistency across studies in the criteria used for determining giftedness has also made it difficult to compare factors across studies. The criteria for inclusion ranged from a WISC Full Scale IQ of 120 and higher to 130 and higher. In addition, it was not uncommon for the criteria for inclusion to include participants with a WISC Full Scale IQ, Verbal IQ, and/or Performance IQ of 130 or higher. Gifted eligibility for some studies included children who did not meet the stated IQ criteria but did demonstrate advanced academic performance. The study conducted by Brown and Yakimowski (1987) demonstrates how selection criteria can influence the composition and the number of factors identified. They studied the WISC-R scores for three different groups of children: children who scored in the average range (IQ score between 85 and 115), children who scored 120 or higher (high-IQ group), and children in gifted programs (gifted group). The average group displayed the two-factor model commonly associated with the WISC-R; however, a four-factor solution was identified for the gifted group, and a five-factor solution was identified for the high-IQ group. The additional factors suggested that children in the high-IQ and gifted groups processed information differently from the children with average cognitive abilities (Brown & Yakimowski, 1987). Thus the composition of the sample appears to have had an influence on the number and types of factors generated.

The use of different combinations of WISC subtests in factor analyses also contributed to the different composition of the factors and to whether two- or three-factor models were generated. The 10 regularly administered WISC-R subtests were consistently utilized in the factor analyses, while the Digit Span and Mazes subtests were often excluded. Studies that included the Digit Span subtest found it to load consistently on the same factor with the Arithmetic subtest (Brown & Yakimowski, 1987; Watkins et al., 2002).

The type of extraction method used, the criteria used to determine the number of factors to interpret, and the criteria used to determine the composition of factors also varied greatly across studies. The type of extraction method used (e.g., maximum-likelihood, principal-components, principal-axis) could have influenced the number of factors generated and the composition of those factors. In addition, a vast array of criteria was used across studies for determining the number of factors to interpret. Specifically, the scree test, the chi-square statistic, eigenvalues greater than 1.00, and various combinations of these techniques were used by researchers for making the determination of how many factors were identified. Differences were also found across studies in the type of rotation methods (e.g., varimax, oblique), resulting in differences among factors. There were considerable differences in the criteria used to determine whether a subtest loaded on a specific factor. Although some studies failed to indicate the criteria used for identifying significant factor loadings, the studies that did provide criteria for significant loadings tended to range from .30 to .50. Given these differences in methodology and statistical techniques across the factor-analytic studies, it is not surprising to find some differences in the cognitive constructs of gifted children on intelligence measures.

Some of the consistency of the findings related to the structure of intelligence in gifted samples may also reflect the structure of the instruments that were used to assess it. The WISC-R and WISC-III were not closely tied to any theory of intelligence (O'Donnell, 2009). As a result, much of the structure of the WISC at that time focused narrowly on measures of Gf and Gc, while underrepresenting other abilities. Consequently, even if the individuals had possessed differing factor structures in these areas, they were not measured and would not emerge in the analysis.

These earlier factor-analytic structures were important in helping to improve our understanding of the continuity and similarity for the structure of intelligence in gifted samples with the rest of the population. It is important to recognize that studies using an exploratory approach are apt to dismiss more complex models in favor of simpler parsimonious models (two- or four-factor models vs. a seven- or eight-factor model). In part, the exploratory approach may sometimes hide existing factors. These occasions are more likely to occur when sample size is relatively limited and when the variance of the sample is limited, both of which have occurred in the past in the literature on giftedness. From a statistical viewpoint, then, the inclusion of individuals who may not have met all previous gifted criteria may actually have improved the ability of the models to fit because it added needed variance to the samples.

In summary, factor-analytic research using gifted samples has for the most part confirmed the presence of Kaufman's two-factor model. In addition, the WISC-R/WISC-III subtests that compose the Verbal Comprehension factor have been replicated across numerous studies, suggesting significant stability of this factor with gifted children. Less stability has been shown in the composition of the Perceptual Organization factor, and even less stability has been shown in relation to a third factor. Although the majority of the research has been exploratory, a few confirmatory-factor-analytic studies have been published (Brown et al., 1991; Cameron et al., 1997). However, there is a continued need to study hierarchical models of intelligence with gifted samples. There is also a need to demonstrate the utility of considering multiple cognitive constructs in identifying giftedness.

THE ISSUE OF IDENTIFICATION

The Process of Identification as Related to the Definition

Several authors previously mentioned have discussed the importance of cognitive ability measures for the identification process. A very controversial part of serving gifted students is the process of locating the population to be served—a process known as *identification*. Clark (1997) has suggested the following considerations in a comprehensive identification program:

- Evidence that students demonstrate extraordinary ability in relationship to their age-level peers.
- Evidence of the range of capabilities and needs.
- Processes that measure potential as well as achievement.
- Methods that seek out and identify students from varying linguistic, economic, and cultural backgrounds, and special populations.
- Implications for educational planning.

This comprehensive list of services has opened the door to much controversy as to what a school should do for this special population. Borland (1989) has cautioned that defining the target population is the first and most important step in programming for gifted students. In other words, if a school selects a narrow definition or one based exclusively on cognitive ability, then the school's program should reflect this definition. On the other hand, if the school chooses to adopt the ESSA's definition, then a very comprehensive array of services should be available. A major issue in identification of gifted and talented youth has been the validity of the identification process with respect to program goals and services (Feldhusen & Jarwan, 1993). Because placement decisions are the goal of identification, all measures used are very important.

Identification generally begins with a screening procedure, in which students are selected first on the basis of their performance on a group achievement test. Students who score the highest on this general group test, according to the school's criteria, form a talent pool. Next, the talent pool's members take a more selective test (perhaps a more precise instrument with a lower standard error of measurement). High-ability students often score very highly on group tests, and a *ceiling effect* may occur, in which their scores cluster near the very top of possible scores on the test. It is sometimes incorrectly assumed that all of these children are equally talented and need a similar program. However, this is not always the case. More precise tests that address this ceiling effect are preferred, so that those identified for the program are truly those students most capable (if that is the definition of the target population for the specific school's program). After this second screening step, all measures to be considered in identification are added, and the top students are identified for the program. One approach to addressing the ceiling effect common with group measures may be to use individually administered intelligence tests, such as the WISC-V (Wechsler, 2014a); the Stanford–Binet Intelligence Scales, Fifth Edition (SB5; Roid, 2003); or the Woodcock–Johnson III (WJ III; Woodcock et al., 2001) or WJ IV (Schrank, McGrew, & Mather, 2014). However, whatever test is administered, the ceiling effect must be considered in selecting tests that truly measure the abilities to be served. Another strategy that has received some popularity over the years is the use of out-of-age tests with students believed to be gifted. The higher ceilings of these instruments allow for students to be challenged and fit with a historical definition of advanced mental age. One problem with this approach is that because the tests were given to children not in the normative sample, age-based norms cannot be used, and comparisons cannot be made. As a result, application of a proportion estimate such as that suggested in Gagné's (2004) classification system is inappropriate.

Zhu, Cayton, Weiss, and Gabel (2008) published an extended set of normative tables for use in assessing gifted children. These tables are designed for use with children who reach the ceiling of the traditional normative set for their age on one or more subtests of the WISC-IV (Wechsler, 2003). These extended tables are intended to help differentiate between gifted and highly gifted individuals. Given the frequency of individuals with IQ scores above 150, the degree to which clinicians will need to resort to these tables is limited. In addition, the tables are believed to be more beneficial in tracking progress or growth of gifted children, as they should be more sensitive to performance above the original ceiling of the test.

Recently, Raiford, Drozdick, Zhang, and Zhou (2015) developed expanded index tables for the

WISC-V (Wechsler, 2014), which may be desired by some who are assessing gifted students. The two expanded index tables are the Verbal (Expanded Crystallized) Index (VECI) and the Expanded Fluid Index (EFI). These indexes allow for standard scores up to 155. The advantage of these tables is that they provide a broader assessment of two historically important areas of gifted assessments. Also, others have attempted to reduce ceiling effects for children and adolescents with other instruments, including the Stanford–Binet, by creating a Gifted Composite (McGowan, Holtzman, Coyne, & Miles, 2016).

Identification of Gifted Minority Students

A major issue in identification of gifted students relates to the representation of minority students in gifted programs. According to Ford and Harris (1999), projections are that minority students will account for almost half (46%) of all public school students by the year 2020. This increase in minority students at the national level has not been reflected in gifted education. In fact, according to Gallagher (2002), national surveys indicate that only 10% of students performing at the highest levels are culturally, linguistically, and ethnically diverse students, even though these diverse students represent 33% of the school population. A major focus of attention in gifted education is the goal of parity in gifted programs among all members of society, but this parity has not been easy to achieve. Although the Jacob Javits Act of 1988 helped initiate programs for gifted racial minority students from economically disadvantaged areas, the problem of finding and/or developing useful tools to identify these students still exists. Efforts to find more valid, reliable, and useful instruments to assess giftedness and potential among minority students, and to increase teacher training in identification and assessment so as ultimately to increase the referral of minority students to gifted services, are paramount in helping to find and serve these underrepresented students (Ford & Harris, 1999).

In July 1997, the NAGC adopted a policy statement on testing and assessment of gifted students, in which it called for more equitable identification and assessment instruments and procedures. The notions of fairness and accountability underlie the proposal. In this position paper on the use of tests in the identification and assessment of gifted students, the following issues were addressed:

> Given the limitations of all tests, no single measure should be used to make identification and placement decisions. That is, no single test or instrument should be used to include a child in or exclude a child from gifted education services. The most effective and equitable means of serving gifted students is to assess them—to identify their strengths and weaknesses, and to prescribe services based on these needs. Testing situations should not hinder students' performance. Students must feel comfortable, relaxed, and have a good rapport with the examiner. Best practices indicate that multiple measures and different types of indicators from multiple sources must be used to assess and serve gifted students. Information must be gathered from multiple sources (caregivers/families, teachers, students, and others with significant knowledge of the students), in different ways (e.g., observations, performances, products, portfolios, interviews) and in different contexts (e.g., in-school and out-of-school settings). (NAGC, 1997, p. 52)

This call for a different, more inclusive way to find and serve gifted minority students is a call for diversity in programs that have typically been labeled "elitist" by many. To widen the representation, school personnel must be educated to use multiple measures to find these underrepresented students. A change in identification practices must encourage the examination of gifted individuals in cultural and environmental contexts, and must provide a basis for recognizing talents without penalizing students for certain learning styles and expressions (Frasier et al., 1995).

Assessments used to identify gifted and talented students may represent a clash between cultures, in which the mainstream culture is unable to recognize or underestimates the abilities of underrepresented minority students (Briggs & Reis, 2004). One issue that has prevented the identification of gifted minority students is that of test bias. Reynolds and Kaiser (1990), in discussing the issue of content validity and its relation to test bias, have stated:

> An item or subscale of a test is considered to be biased in content when it is demonstrated to be relatively more difficult for members of one group than for members of another in a situation where the general ability level of the groups being compared is held constant and no reasonable theoretical rationale exists to explain groups' differences on the item (or subscale) in question. (p. 625)

Items on tests often tap experiences that are relevant to middle-class students. Those from impoverished families may simply not comprehend such items, and therefore may miss questions because of environmental deficiencies rather than actual lack of intelligence. Such problems point to the bias that underlies *content validity* in both achievement and intelligence tests.

In addition, bias in *construct validity* is of concern. The fact that different groups define giftedness and intelligent behaviors in a variety of ways makes the measurement of these constructs difficult and often invites bias. Again, if the construct in question is always defined in middle-class terms, impoverished students may not be found and served.

Finally, bias is also seen in terms of *predictive validity*—the extent to which an instrument predicts the future success of a person in various situations. If teachers read the results of an intelligence test and therefore judge a student's future worth on the basis of these results, the student may not fare well. In fact, teachers' expectations may diminish because of perceived deficiencies that may not be accurate indicators of the student's ability. For these reasons, assessment issues with minority students are of major concern in the identification of students for programs.

Ford and Harris (1999) have suggested the following options when evaluators are considering how best to assess ability and potential in linguistically, racially, and culturally diverse students:

- Adapt instruments (e.g., modify the instruments in terms of their language demands).
- Renorm the selected instruments on the basis of local norms and needs.
- Modify predetermined cutoff scores for minority students.
- Use an alternative nonverbal cognitive measure thought to assess the same construct.

The issue of diversity in membership in gifted programs is currently a major issue. Educators must understand its importance and must respond to the need for alternative identification tools if they desire to provide high-quality education for all.

Identification of Gifted Students with Learning Disabilities

Another group of students who are often missed in the identification process is the group of those who are gifted but have learning disabilities. Although this description seems to be an oxymoron, Davis and Rimm (1985; Davis et al., 2011) have noted that estimates of the number of such students in U.S. schools range from 120,000 to 180,000. Identification of students with both talents and disabilities is problematic and challenges educators (Olenshak & Reis, 2002; Sternberg & Grigorenko, 1999). Historically, most school personnel have relied on discrepancy formulas between intelligence and ability test scores; analyses of intelligence test results for differences across subtests (*scatter*); and multidimensional approaches that incorporate qualitative data, such as structured interviews and observations (Lyon, Gray, Kavanagh, & Krasnegor, 1993). With the ESSA revisions and the filtered changes likely to be enacted through different states to comply with this law, school districts will depend more heavily on dynamic and locally normed assessments. As a result, the provision of special education services to children who have learning disabilities and are also gifted is likely to increase the delay in identification, with the exception of those individuals with severe disabilities or multiple areas of disability.

Furthermore, the identification of these students is complicated because their gifted abilities often mask their disabilities, or, conversely, their disabilities may disguise their giftedness (Volker, Lopata, & Cook-Cottone, 2006). These problems may exclude students from inclusion in either programs for gifted individuals or programs for those with learning disabilities (Baum, Owen, & Dixon, 1991; Olenshak & Reis, 2002). This is also true for students with other exceptionalities, such as attention-deficit/hyperactivity disorder and high-functioning autism spectrum disorder. Astute educators are aware of these major issues in identification and search for ways to include rather than exclude all gifted students. As a result of the tendency for gifted students to exhibit higher levels of functioning globally when compared with other students, even in areas of suspected disability, it may be more beneficial for psychologists and committees to take an ipsative approach to analyzing test data. This method is consistent with that recommended by Volker and colleagues (2006); it is also a pattern approach consistent with the more recent ESSA.

Identification of Gifted English-Language Learners

English-language learners (ELLs) are underrepresented in programs that serve gifted students (Lohman, Korb, & Lakin, 2008). Indeed, according to Harris, Plucker, Rapp, and Martinez (2009), the lack of attention to giftedness in underrepresented populations such as ELLs is a critical weakness in the identification literature because of the concomitant rapid increase in the number of ELLs in the United States. For example, in 1979, approximately 1 in 10 school-age children spoke a language other than English at home; by 2003, the proportion had risen to nearly 1 in 5 (9.9 million) children (National Center for Education Statistics, 2005). Harris and colleagues state that between the 1989–1990 and 2004–2005 school years, ELL enrollment in public schools more than doubled, from 2,030,451 to 5,119,561 students (National Center for Education Statistics, 2008).

This problem of identifying a rapidly growing population provides challenges for administrators seeking unbiased identification methods. Coleman and Cross (2005) argue that the identification of culturally different gifted students is a perplexing problem because their average performance on aptitude and achievement tests tends to be one standard deviation below the mean when general norms are used. Ortiz and Dynda (2005) state that if there is to be any validity to conclusions drawn by practitioners, four issues concerning test bias must be understood: (1) acknowledging the cultural content embedded in any given test; (2) understanding the linguistic demands inherent in any given test; (3) appreciating meaningful differences in norm sample representation for diverse individuals; and (4) recognizing the limitations of "nonverbal" assessment. (See also Ortiz, Piazza, Ochoa, & Dynda, Chapter 25, this volume.)

Administrators of gifted programs in schools have looked for a suitable means for identifying ELL students that would increase representation of these learners without relying solely on language as the major requisite for testing. Nonverbal tasks have long been present in intelligence tests, providing one indicator of ability for students who are native speakers of the language, while perhaps serving as the only indicator of ability for examinees who are not fluent speakers of the language (Lohman et al., 2008). Nevertheless, finding the right test and using the appropriate norm group for comparisons are essential aspects of identifying gifted ELL students.

Multiple Means of Assessment

For all these reasons, multiple means of assessing students are often used. Test scores are one group of determinants. Others include nominations by teachers, students, parents, and peers. In addition, checklists often tap areas of strength in students. Performance assessments, such as portfolios and auditions, are often valuable in the identification of gifted and talented students for programs. Of course, the parameters of the program must be considered in the design of any identification criteria. In addition, determining a reasonable formula that takes into account all the criteria and determines the students who then emerge as those who qualify for the program is a difficult and challenging problem for educators who manage gifted programs in schools.

SPECIAL ISSUES

Competing Theoretical Approaches

Although a lack of consideration of theory when evaluators are selecting cognitive measures is a concern in intellectual assessment with all children (Flanagan & Ortiz, 2002), an atheoretical approach appears to predominate within the schools when cognitive measures to identify gifted children are being chosen. This pattern is not unique to school professionals and reflects the greater historical need for these instruments to be able to differentiate between those who will succeed and those who will not despite educative efforts (Strauss et al., 2006). The selection of cognitive measures is often based on ease of administration, cost, and familiarity with the test. In addition, many current psychologists choose to employ theory-based instruments. Examples include the WJ IV (Schrank et al., 2014), the SB5 (Roid, 2003), the WISC-V (Wechsler, 2014a), and the Cognitive Assessment System—Second Edition (CAS2; Naglieri, Das, & Goldstein, 2014). All but the last is based on or mapped onto the CHC theory of intelligence, and the CAS2 is based on the *planning, attention, simultaneous, sequential* (PASS) model. The Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004) draws upon the theoretical model of Luria's neuropsychological theory and CHC theory.

Although the current advances in instrument development have led to a plethora of choices, this plethora can create additional confusion when evaluators are trying to select a measure for identifying cognitively gifted children. The problem is that different measures of intelligence, regardless of theory, assess different skills; the result is that some children are not offered opportunities to participate in gifted programs (Simpson, Carone, Burns, Seidman, & Sellers, 2002; Tyler-Wood & Carri, 1991). The implications of using a specific measure of intelligence should be considered prior to its selection. For example, subtests on the CAS2 were selected to focus primarily on intelligence as a problem-solving and reasoning ability that generalizes across areas, whereas the WJ IV may assess this problem-solving ability in specific ability areas (e.g., auditory processing). Characteristics of the gifted children identified, available programming that addresses the specific characteristics of the children identified, and the extent to which nonmodal gifted children (e.g., children from impoverished backgrounds, gifted children with disabilities) are excluded should all be considered when a specific measure of intelligence is chosen. Therefore, it is essential that the theoretical differences in intelligence measures be considered—and, more important, that theory-based measures be utilized during the identification process. This view is consistent with that of Flanagan and Ortiz (2002), who advocate theory as the center of all intellectual assessment activities. The process of identifying cognitively gifted children is complex enough without starting the identification process with an atheoretical or outdated measure of intelligence.

Linking Screening Procedures with Intelligence Measures

The majority of schools have developed some type of system for identifying gifted children, albeit some systems are better than others. Usually included within the system is a procedure for screening children and thus reducing the number who are eventually referred for more comprehensive testing. Unfortunately, the comprehensive testing typically includes the administration of a single standardized measure of intelligence. And in any case, many evaluators fail to study the accuracy of screening procedures related to the final decision on whether children receive gifted programming, which is often based on individualized measures of intelligence.

Although many would consider screening to be the crucial point in the identification process, predictive validity must be established between the screening procedure and the intellectual measure(s) used to ensure the accuracy and utility of the identification process. The difficulty with demonstrating predictive validity is that screening procedures can vary from teacher nominations to the use of group intelligence tests (Coleman & Cross, 2005). Considering the wide variety of screening methods used, relationships between screening procedures and intellectual measures can range from very low to very high. Screening processes and tools to identify gifted and talented abilities unlikely to be identified through the use of a standardized intelligence test also need to be selected and utilized. To be clear, a screening procedure that is more highly related to a selected intelligence test will result in a higher level of agreement at different points in the identification process. However, those who are gifted and talented in such domains as leadership or music may not be identified as such on an IQ measure. Coleman and Cross (2005) recommend using a fairly liberal screening threshold, to avoid missing children who may qualify for gifted programming. This approach seems advisable, given the lack of research exploring the relationships between many of the screening procedures used and the final decision outcomes based on intelligence tests. This process is consistent with Gagné's (2004) suggestion that those in the top 10% be considered gifted.

Use of a Single Test Composite Score

The use of a single cognitive test composite score as the primary criterion for determining giftedness is highly common within schools. In the past, the WISC-R (Wechsler, 1974) and the fourth edition of the Stanford–Binet (SB-IV; Thorndike, Hagen, & Sattler, 1986) were the most commonly used cognitive measures in the schools (Coleman & Cross, 2005). Coleman and Cross (2005) also note that one of these measures was commonly used as the final decision criterion for determining giftedness. In fact, school districts and states have defined giftedness solely on the basis of WISC IQ cutoff scores (Fox, 1981; Karnes, Edwards, & McCallum, 1986). Others have suggested that the use of strict IQ cutoff scores is too restrictive and does not consider other characteristics of giftedness (Renzulli & Delcourt, 1986; Renzulli, Reis, & Smith, 1981). However, because of the overwhelming use of intelligence tests, there is a need to discuss the implications of using a single IQ score for making decisions on giftedness.

Implications of Using Cutoff Scores

One of the crucial decisions made by any school system is where to set the IQ "cutoff" score. It is clear from reviewing the literature that there is little, if any, consensus on where the cutoff score should be set. This makes it extremely difficult not only to evaluate decision outcomes across studies, but also to interpret research on giftedness in general. In the literature, the inconsistency is quite evident. For example, Karnes and Brown (1980) used a cutoff score of 119; Hollinger (1986) used a cutoff score of 130; and Fishkin, Kampsnider, and Pack (1996) used a cutoff score of 127. However, most studies use an overall IQ score that is at least two standard deviations above the mean. Currently, this would translate into a WISC-V and an SB5 Full Scale IQ of 130. It should be noted that the SB5 has a standard deviation of 15. It is also important to understand that the historic method of calculating IQ used in early work on giftedness was built around a mental age formula; as a result, gifted individuals might obtain an IQ of 200, but today that is not possible. The point of this lengthy review of cutoff scores is that, regardless of where a school system sets a cutoff score, it is still too rigid an approach.

Many school systems fail to understand the basic psychometric process of how scores are derived, or the pitfalls of placing so much weight on a single score. To be specific, when placement decisions are being made, it is important to consider the standard error of measurement (*SEM*), which allows an evaluator to estimate a range of scores based on the obtained score. For example, suppose a child obtains a Full Scale IQ of 129 on a test with an *SEM* of ±4 points. The examiner can be 68% confident that the next time the child is administered the same test, the child's score will fall somewhere within the range from 125 to 133. Therefore, if the criterion for placement into a gifted program is rigidly set at 130, this child will be denied services. However, if the child is later administered the same intelligence test and obtains a Full Scale IQ score of 131, the child will then be recommended for gifted services. A sounder approach would be to make a decision regarding eligibility and the test scores within the context of the child's history, academic progress, and behavior. Repeated assessments over time will truly differentiate the groups.

It also is important to note that many test manuals now report confidence intervals using the method of regression to the mean, instead of rigidly applying the ±1 *SEM*. Although many might suggest that in considering the *SEM*, all that is being proposed is to lower the cutoff score, in fact this is not what is being proposed. What is being suggested is to allow for flexibility in making identification decisions, even when cutoff scores are being used. Therefore, identification decisions should be made with a proper understanding of the underlying psychometric characteristics of standardized intelligence tests, and also with consideration of other performance variables (e.g., academic achievement).

Furthermore, it is important to recognize that children with an estimated IQ in the range of 131–134 may quite possibly obtain scores in the range of 128–131 if reassessed. The children would be less likely to obtain scores of 133–135, as these would be further from the mean.

Recent updates and versions of testing manuals also indicate that contemporary assessment tools may produce lower IQ estimates for gifted samples than previous test versions have produced. As part of the development phase for tests, many test publishers use gifted samples to help validate the cognitive measures. While measures such as the WISC-V, the SB5, the WJ IV, and the KABC-II all show significant differences between matched samples and gifted samples, the range of scores for previously identified gifted students may fall in the high average range (WJ-IV, WISC-V, KABC-II). The range of scores for the WISC-V also includes the traditional cut-off of 130 in the confidence interval for previously identified youth at the upper end (Wechsler, 2014b). It is important to recognize that the developers of these tests used different methods to identify students, including previous test results, history of services, or independent determination by a school. This pattern of results is consistent with the Flynn effect (Flynn, 1987) and suggests that high-ability students are not immune to this phenomenon. For example, the technical manual for the SB5 discusses the Flynn effect as one possible reason why previously identified gifted students displayed a mean SB5 Full Scale IQ of 123.7 (Roid, 2003). Essentially, it is more difficult for previously identified gifted individuals to retain scores of 130 or higher, due to the change in IQ values over time. Examiners identifying gifted students through the use of an IQ test are advised to use a new instrument in tandem with estimates from an instrument that has been available for 5 years or more and with which the examiners are well familiar.

The work of Ziegler and Ziegler (2009) adds a further wrinkle to the use of cutoff scores from a single test or even from multiple tests. An analysis of the fundamental basis of measurement error and estimation of the construct of intelligence led these authors to note that high levels of cognitive abilities (Full Scale IQs greater than 130) are likely to be underestimated by measures of intelligence. This prediction appears to be supported by the data from the previously discussed studies. What is advocated as a result is a low-threshold test that will catch all potentially gifted students, followed by an intelligence test that will underestimate but have a lower error rate as a result of a previous screen (Ziegler & Ziegler, 2009). One strategy that may help to reduce this possible problem would be the application of a Bayesian approach to gifted identification. Essentially, the essence of the idea would be to use the existing datasets regarding the predicted level of cognitive ability expected on a new version of a test, and to estimate the probability that an individual would fall into a gifted sample similar to the one used in the validation studies by the test publishers. Similar strategies have been advocated in other areas recently for helping to improve classification with high-stakes testing (Wagenmakers, Morey, & Lee, 2016).

Beyond the Composite IQ Score

Interpretation of intelligence test results beyond the full test's composite score is also a recommended practice in identifying gifted children. Depending on an intelligence test's theoretical model, it can provide a multiple-cluster (e.g., verbal ability, thinking ability) index (e.g., Verbal Comprehension Index, Visual Spatial Index) or composite scores beyond the global composite score. Ignoring a child's performance on these other indexes may preclude him or her from receiving gifted services. As an example, if a child attains a WISC-V Full Scale IQ of 127, a Verbal Comprehension Index of 142, a Visual Spatial Index of 117, a Fluid Reasoning Index of 117, a Working Memory Index of 121, and a Processing Speed Index of 100, the child may be overlooked for gifted services if the sole criterion is the Full Scale IQ. Here is a child who obviously displays verbal abilities within the gifted range, and the Full Scale IQ fails to account for these specific cognitive skills.

Moreover, it is important to consider the demands and skills required by specific subtests that contribute to index, cluster, or composite scores. In the aforementioned example, the child's lowest WISC-V index score is in Processing Speed. The subtests that contribute to the Processing Speed Index rely on speed, short-term visual memory, cognitive flexibility, and concentration. Although this child demonstrates an average level of processing speed (which is considerably lower than his or her Verbal Comprehension Index score), the score may be more a function of how the child has approached each specific subtest contributing to the Processing Speed Index.

Many gifted children have learned to sacrifice speed for accuracy and perform less well on speed-related tasks than on others. Kaufman (1992) has noted that the highly reflective and perfectionistic nature of many gifted children affects their performance on measures of intelligence where speed is rewarded. Also, variances between composite scores are fairly common among gifted individuals (Malone, Brock, Brounstein, & Shaywitz, 1991). Another theoretical interpretation of this discrepancy would argue that the Processing Speed Index is a much less *g*-loaded index of ability, and therefore less indicative of intelligence and more indicative of motoric speed (Reynolds & Kamphaus, 2003). The key issue here is not to rely solely on the overall composite score in understanding the cognitive skills of gifted children, but to encourage professionals to evaluate the clinical, emotional, and behavioral data leading to a performance estimate.

McGrew, Schrank, and Woodcock (2007) indicate that samples of gifted students tend to perform better on tasks of Gc and Gf than on tasks of long-term retrieval (Glr), working memory (Gsm), or visual–spatial thinking. Results from the KABC-II manual suggest that gifted students perform best on tasks designed to measure Gc (Kaufman & Kaufman, 2004).

The growing awareness that individuals who are gifted often show lower levels of performance on less *g*-loaded activities prompted the development of a Gifted Composite for the SB5 (McGowan et al., 2016). The composite removes working memory from the Full Scale IQ estimate. When independently examined with a sample of individuals referred for gifted evaluations, the Gifted Composite increased for 80% of the sample and by an average of 5 points (McGowan et al., 2016). This strategy to a large degree mirrors the strategy advocated by others who prefer to use the Wechsler tests' General Ability Index (GAI) or the EFI or VECI as opposed to the Full Scale IQ. The use of the GAI removes both Processing Speed and Working Memory subtests (Wechsler, 2014a).

Lack of Ceilings

With many measures of intelligence, there are not enough items at the upper end of subtests to fully discriminate the cognitive abilities of gifted individuals. Although individual items used within specific subtests are selected for their ability to discriminate between children at different levels of cognitive ability, for many subtests it is difficult to establish a ceiling, which makes it difficult to obtain an accurate estimate of cognitive ability with gifted children. When gifted children are assessed, it is common for them not to obtain a ceiling on several subtests of a specific cognitive measure. When this occurs, the overall test composite score is likely to be an underestimate of their true level of cognitive functioning. Many would suggest that this does not matter because their level of cognitive functioning is so high that they would qualify for gifted services anyway. Here the issue is not so much one of identification as of matching children with appropriate gifted programming. It is important to accurately assess the unique cognitive skills of even highly gifted students, to meet their educational needs and interests.

Recommendations on the Effective Use of Intelligence Tests

A few general recommendations on the use of intelligence tests in the identification of giftedness are warranted. First, it is recommended that school systems develop an operational definition of giftedness that incorporates the term *cognitively gifted.* The use of this term is suggested if a school system's primary criterion for placement in its gifted program is based on an individualized measure of intelligence. It is important to recognize that most current measures of cognitive abilities today are aligned with the CHC model of intelligence, and that this model can have important implications for the education of children in gifted programs beyond just entry (Warne, 2016). If other measures (e.g., rating scales, nominations, achievement tests) or characteristics (e.g., leadership skills, motivation) are considered along with results on an intelligence test, the definition should address the role of the intelligence test in relation to the other measures and characteristics tapped during the identification process. Second, it is recommended that the school system develop specific procedures related to the referral, screening, testing, and placement of gifted children. Again, if the school's primary identification criterion is based on an individualized measure of intelligence, and the goal is to identify cognitively gifted children, then the screening measure should be highly correlated with the selected intelligence test.

Third, it is recommended that school systems become thoroughly aware of the specific advantages and limitations of using standardized intelligence tests to identify giftedness. Coleman and Cross (2005) note that intelligence tests are highly reliable, are individually administered, allow an examiner to observe a child's behavior directly, and allow for a broader sampling of behavior than screening or group intelligence tests do. Other advantages of intelligence tests are their abilities to identify exceptionally gifted individuals with special educational needs (Gross, 1993); children who do not display the stereotypical high verbal ability, high achievement, and high motivation often associated with giftedness (Pyryt, 1996); and children who are "twice exceptional" (e.g., children identified as gifted and with learning disabilities). Children who are identified for gifted programs as a result of high *g* have improved life and health outcomes across the lifespan (Warne, 2016). As for limitations, this chapter has primarily focused on assisting schools in making informed decisions regarding the use and limitations of intelligence tests with gifted students.

Fourth, it is recommended that school systems use theory as a primary guide in selecting intelligence tests. As Flanagan and Ortiz (2002) astutely note, the use of a modern and valid theory of intelligence at the beginning of the assessment process is critical in facilitating accurate measurement and interpretation. Given the recent theoretical advances in intelligence testing, there is no excuse for ignoring theory and blindly selecting intelligence tests to identify giftedness. To be specific, understanding that one measure of intelligence assesses the constructs of verbal comprehension and perceptual organization, while another assesses verbal ability, working memory, and processing speed, is important to consider when evaluators are choosing intelligence measures for making identification decisions. Also, it is important to understand how these psychological constructs are measured. Do the specific constructs use speeded tasks, visual tasks, or verbal tasks? Are students penalized for less *g*-loaded constructs such as working memory (McGowan et al., 2016)? Without an understanding of the underlying theory behind the aforementioned constructs, it will be difficult to interpret an individual's results on an intellectual measure. Also, if a cognitive measure is found to assess primarily verbal ability, it is likely that only gifted children with strong verbal skills will be identified, while children with excellent perceptual organization skills, strong speed-of-information-processing skills, or excellent working memory skills will be missed during the identification process.

Last, it is recommended that school systems consider using a cross-battery approach when assessing for giftedness. Specifically, the CHC cross-battery approach (Flanagan et al., Chapter 27, this volume; Flanagan, Ortiz, Alfonso, & Mascolo, 2002; McGrew & Flanagan, 1998) should be considered. This approach is a method for utilizing separate batteries of tests and ensuring a broader range of theoretical constructs in the assessment of children. Although research is needed to support using the CHC cross-battery approach in the identification of gifted children, it does demonstrate how multiple batteries can be used to decrease the reliance on a single measure of cognitive ability.

SUMMARY

This chapter has explored some of the central issues related to using intelligence tests in the identification of giftedness. Although identification of giftedness is complex and has been richly debated, our goal has been to advocate for school systems' making informed decisions about the role of intelligence tests in the identification process. Although many strategies exist for identifying gifted and talented children for services, it appears that the use of a specific measure of cognitive ability dominates the identification process within the schools. It is important to design programs that begin with a definition of giftedness and build from there. The definition precedes and guides the identification process, and provides the rationale for what instruments to use in order to find and then to serve the appropriate students. This chapter has focused on the need for precision in choosing effective theory-driven intelligence tests for the identification process. Many programs for gifted students are focused on cognitive ability, and yet misuse test data in making critical decisions. The current availability of cognitive assessments for identifying superior cognitive ability is better now than ever before. It remains to be seen whether those who administer the programs will choose instruments wisely, in order to obtain the information needed to identify those students who are in need of a different type of program because of their demonstrated cognitive ability.

CHAPTER 22

Use of Ability Tests in the Identification of Specific Learning Disabilities within the Context of an Operational Definition

Dawn P. Flanagan
Vincent C. Alfonso
Michael Costa
Katherine Palma
Meghan A. Leahy

> There are no rules for converting concepts to operational definitions. Therefore, operational definitions are judged by *significance* (i.e., is it an authoritative marker of the concept?) and *meaningfulness* (i.e., is it a rational and logical marker of the concept?).
>
> —KAVALE, SPAULDING, AND BEAM (2009, p. 41)

Historically, identification of specific learning disabilities (SLD) has almost always included a consideration of an individual's overall cognitive ability, as well as his or her unique pattern of strengths and weaknesses (Sotelo-Dynega, Flanagan, & Alfonso, 2018). However, in recent years intelligence tests and tests of specific cognitive abilities and neuropsychological processes have come under harsh attack as useful tools in the identification of SLD (for a review, see Schneider & Kaufman, 2017). Although "IQ" tests have always had their critics, it was not until the reauthorization of the Individuals with Disabilities Education Improvement Act (IDEA, 2004) and the publication of its attendant regulations (U.S. Department of Education, 2006) that such criticism became more widespread (Fletcher-Janzen & Reynolds, 2008).

It is beyond the scope of this chapter to review all the issues surrounding the debate about the utility (or lack thereof) of cognitive and neuropsychological tests in the identification of SLD. The interested reader is referred to Alfonso and Flanagan (2018) for a comprehensive treatment of these issues. Based on our review of the literature and our clinical experience, we find inherent utility in cognitive and neuropsychological assessment for SLD identification and treatment. Therefore, the purposes of this chapter are to describe Flanagan, Ortiz, and Alfonso's (2013, 2017) operational definition of SLD, and to highlight the importance and utility of gathering data from cognitive and neuropsychological tests (among other quantitative and qualitative data sources) within this framework (see also Flanagan, Alfonso, Sy, et al., 2018).

This chapter was adapted from Flanagan, Alfonso, Sy, Mascolo, McDonough, and Ortiz (2018). Copyright © John Wiley & Sons, Inc. Adapted by permission All rights reserved.

A BRIEF PERSPECTIVE ON THE DEFINITION OF SLD

IDEA 2004 defines *SLD* as "a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, that may manifest itself in the imperfect ability to listen, think, speak, read, write, spell, or to do mathematical calculations. Such terms include such conditions as perceptual disabilities, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia," and SLD "does not include learning problems that are primarily the result of visual, hearing, or motor disabilities; of intellectual disability; of emotional disturbance; or of environmental, cultural, or economic disadvantage." Many researchers in the field (e.g., Kavale, Spaulding, & Beam, 2009) have argued that the federal definition of SLD in IDEA 2004 and its regulations do not reflect the best thinking about the SLD construct because it has not changed in well over 30 years. This fact is astonishing, as several decades of inquiry into the nature of SLD resulted in numerous (but unsuccessful) proposals over the years to modify the definition. If the field of SLD is to recapture its status as a reliable entity in special education and psychology, then more attention must be paid to the federal definition (Kavale & Forness, 2000). To bring clarity to the definition, Kavale and colleagues (2009) specified the boundaries of the term and the class of things to which it belongs. In addition, their definition delineates what SLD is and what it is not. Although their description is not a radical departure from the federal definition, it provides a more comprehensive description of the nature of SLD. The Kavale and colleagues definition is as follows:

> Specific learning disability refers to heterogeneous clusters of disorders that significantly impede the normal progress of academic achievement . . . The lack of progress is exhibited in school performance that remains below expectation for chronological and mental ages, even when [the student is] provided with high-quality instruction. The primary manifestation of the failure to progress is significant underachievement in a basic skill area (i.e., reading, math, writing) that is not associated with insufficient educational, cultural/familial, and/or sociolinguistic experiences. The primary severe ability–achievement discrepancy is coincident with deficits in linguistic competence (receptive and/or expressive), cognitive functioning (e.g., problem solving, thinking abilities, maturation), neuropsychological processes (e.g., perception, attention, memory), or any combination of such contributing deficits that are presumed to originate from central nervous system dysfunction. The specific learning disability is a discrete condition differentiated from generalized learning failure by average or above (>90) cognitive ability and a learning skill profile exhibiting significant scatter indicating areas of strength and weakness. The major specific learning disability may be accompanied by secondary learning difficulties that also may be considered when [educators are] planning the more intensive, individualized special education instruction directed at the primary problem. (p. 46)

Kavale and colleagues state that their richer description of SLD "can be readily translated into an operational definition providing more confidence in the validity of a diagnosis of SLD" (p. 46). In the following section, we describe an operational definition of SLD that captures the nature of SLD as reflected in the federal definition and in Kavale and colleagues' definition. In addition, the reasons why operational definitions are important and necessary for SLD identification are highlighted.

THE NEED FOR AN OPERATIONAL DEFINITION OF SLD

An operational definition of SLD is needed to provide more confidence in the validity of the SLD diagnosis (Flanagan, Fiorello, & Ortiz, 2010; Flanagan & Schneider, 2016; Kavale et al., 2009). An *operational definition* provides a process for the identification and classification of concepts that have been defined formally (see Sotelo-Dynega, Flanagan, & Alfonso, 2018, for a summary). With no change in the federal definition of SLD, the field has turned to articulating ways to operationalize SLD, with the intent of improving the clinical identification of this condition (Alfonso & Flanagan, 2018; Flanagan et al., 2013; Flanagan, Ortiz, Alfonso, & Mascolo, 2002, 2006; Kavale & Flanagan, 2007; Kavale & Forness, 2000; Kavale et al., 2009; Schneider & Kaufman, 2017; Swanson, 1991).

For more than three decades, the main operational definition of SLD was the so-called "discrepancy criterion." Discrepancy was first introduced in Bateman's (1965) definition of learning disabilities (LD) and later was formalized in federal regulations as follows:

> (1) The child does not achieve commensurate with his or her age and ability when provided with appropriate educational experiences, and (2) the child has

> a *severe discrepancy between achievement and intellectual ability* in one or more areas relating to communication skills and mathematics abilities. (U.S. Office of Education, 1977, p. 65083; emphasis added)

Several problems with the traditional ability–achievement discrepancy approach to SLD identification have been discussed extensively in the literature and are highlighted elsewhere (e.g., Hale, Wycoff, & Fiorello, 2011; see also Fiorello & Wycoff, Chapter 26, this volume); therefore, they are not repeated here.

With the reauthorization of IDEA in 2004, and the corresponding deemphasis on the traditional ability–achievement discrepancy criterion for SLD identification, there have been several attempts to operationalize the federal definition, many of which can be found in Alfonso and Flanagan (2018). Table 22.1 provides examples of how the 2004 federal definition of SLD has been operationalized.

One of the most comprehensive operational definitions of SLD was described nearly 20 years ago by Kavale and Forness (2000). These researchers critically reviewed the available definitions of learning disability and methods for their operationalization, and found them to be largely inadequate. Therefore, they proposed a modest, hierarchical operational definition that reflected current research (at the time) on the nature of SLD. Their operational definition is illustrated in Figure 22.1.

In their definition, Kavale and Forness (2000) attempted to incorporate the complex and multivariate nature of SLD. Figure 22.1 shows that SLD is determined through evaluation of performance at several "levels," each of which specifies particular diagnostic conditions. Furthermore, each level of the evaluation hierarchy depicted in Figure 22.1 represents a necessary, but not sufficient, condition for SLD determination. Kavale and Forness contended that it is only when the specified criteria are met at all five levels of their operational definition that SLD can be established as a "discrete and independent condition" (p. 251). Through their operational definition, Kavale and Forness provided a much more rational and defensible approach to the practice of SLD identification than that which had been offered previously. In short, their operationalization of SLD used "foundation principles in guiding the selection of elements that explicate the nature of LD" (p. 251); this represented both a departure from and an important new direction for current practice.

Flanagan and colleagues (2002) identified some aspects of Kavale and Forness's (2000) operational definition that they believed needed to be modified. For example, although Kavale and Forness's operational definition captured the complex and multivariate nature of SLD, it was not predicated on any particular theoretical model, and it did not specify what methods might be used to satisfy criteria at each level. In addition, the hierarchical structure depicted in Figure 22.1 seems to imply somewhat of a linear approach to SLD identification, whereas the process is typically more recursive and iterative. Consequently, Flanagan and colleagues proposed a similar operational definition of SLD, but based their definition primarily on the Cattell–Horn–Carroll (CHC) theory and its research base. In addition, these researchers provided greater specification of methods and criteria that may be used to identify SLD (e.g., Flanagan et al., 2013).

Because operational definitions represent only temporary assumptions about a concept, they are subject to change (Kavale et al., 2009). Flanagan and colleagues modify their operational definition routinely to ensure that it reflects the most current theory, research, and thinking with regard to (1) the nature of SLD; (2) the methods of evaluating various elements and concepts inherent in SLD definitions (viz., the federal definition); and

TABLE 22.1. Examples of How the IDEA 2004 Federal Definition of SLD Has Been Operationally Defined

- Absolute low achievement (for a discussion, see Burns, Maki, Warmbold-Brann, & Preast, 2018; Fletcher & Miciak, 2018; Lichtenstein & Klotz, 2007)
- Ability–achievement discrepancy (see Zirkel & Thomas, 2010, for a discussion)
- Failure to respond to scientifically based intervention (see Balu et al., 2015; Fletcher, Barth, & Stuebing, 2011; Fletcher, Lyon, Fuchs, & Barnes, 2007; Fletcher & Miciak, 2018; Fuchs & Fuchs, 1998; Hosp, Hosp, & Howell, 2007)
- Pattern of strengths and weaknesses (PSW; also called *alternative research-based approach* or *third-method* approach) (see Flanagan, Ortiz, & Alfonso, 2013, 2017; Hale, Flanagan, & Naglieri, 2008; Hale, Wycoff, & Fiorello, 2011; see also Alfonso & Flanagan, 2018, for a review of prominent PSW methods)

Note. All examples in this table include a consideration of exclusionary factors as specified in the federal definition of SLD.

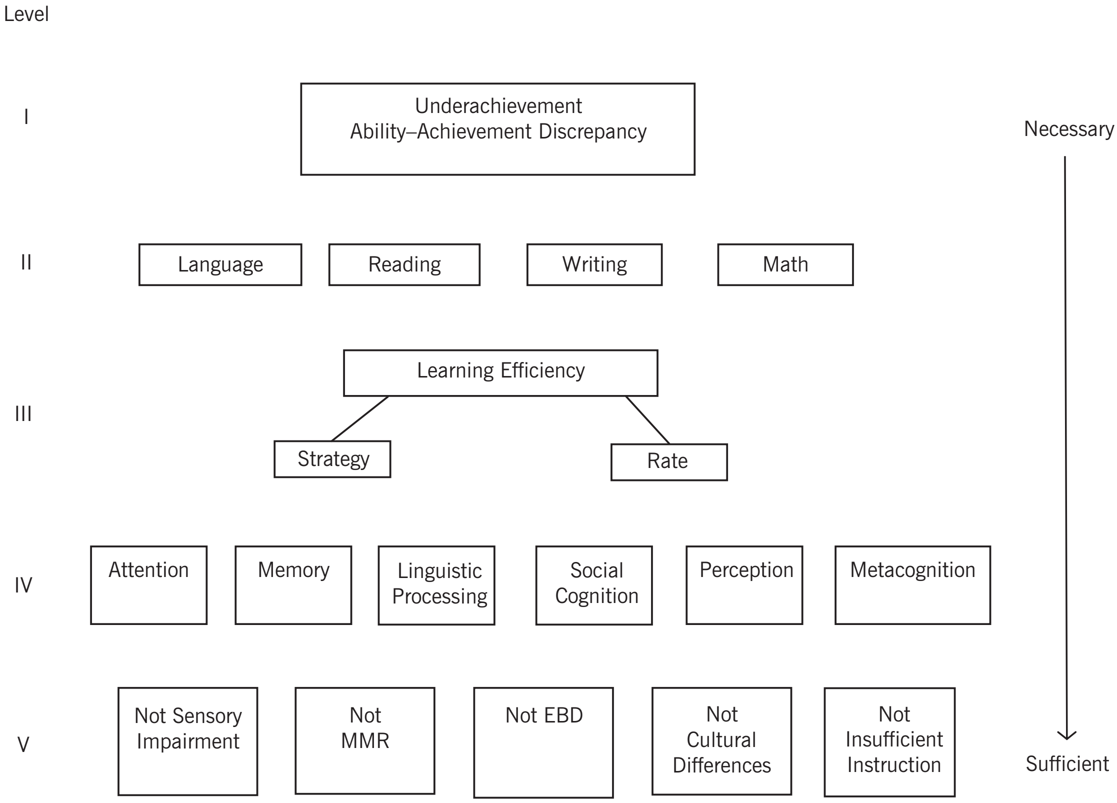

FIGURE 22.1. Kavale and Forness's operational definition of SLD. MMR, mild mental retardation (now called mild intellectual disability); EBD, emotional or behavioral disorder. From Kavale and Forness (2000). Copyright © by SAGE Publications, Inc. Reprinted by permission of SAGE Publications, Inc.

(3) criteria for establishing SLD as a discrete condition separate from undifferentiated low achievement and overall below-average ability to think and reason, particularly for the purpose of acquiring, developing, and applying academic skills (Flanagan et al., 2017; Flanagan, Alfonso, Sy, et al., 2018). Their operational definition of SLD is now referred to as the *dual-discrepancy/consistency* (DD/C) method (Flanagan et al., 2013, 2017; Flanagan, Alfonso, Sy, et al., 2018) and is presented in Figure 22.2. Flanagan and colleagues' approach to SLD identification encourages a continuum of data-gathering methods, beginning with curriculum-based measurement (CBM) and progress monitoring, and culminating in norm-referenced tests of cognitive abilities and neuropsychological processes for students who demonstrate an inadequate response to intervention.

Figure 22.2 shows that the DD/C operational definition of SLD is arranged according to levels, as is Kavale and Forness's (2000) definition. At each level, the definition includes (1) defining characteristics regarding the nature of SLD (e.g., an individual has difficulties in one or more areas of academic achievement); (2) the focus of evaluation for each characteristic (e.g., academic achievement, cognitive abilities/neuropsychological processes, exclusionary factors); (3) examples of evaluation methods and relevant data sources (e.g., standardized, norm-referenced tests and educational records, respectively); and (4) the criteria that need to be met to establish that an individual possesses a particular characteristic of SLD (e.g., below-average performance in an academic area, such as basic reading skill; cognitive processing weaknesses that are related to the academic skill weaknesses). As may be seen in Figure 22.2, the "Nature of SLD" column includes a description of what SLD is and what it is not. Overall, the levels represent adaptations and extensions of the recommendations offered by Kavale and colleagues (e.g., Kavale & For-

Level	Nature of SLD[a]	Focus of Evaluation	Examples of Evaluation Methods and Data Sources	Criteria for SLD	SLD Classification and Eligibility
I	Difficulties in one or more areas of academic achievement, including (but not limited to)[b] basic reading skill, reading comprehension, reading fluency, oral expression, listening comprehension, written expression, math calculation, and math problem solving.	**Academic Achievement:** Performance in specific academic skills (e.g., Grw [reading decoding, reading fluency, reading comprehension, spelling, written expression], Gq [math calculation, math problem solving], and Gc [communication ability, listening ability]).	Response to high-quality instruction and intervention via progress monitoring; performance on norm-referenced; standardized achievement tests; evaluation of work samples; observations of academic performance; teacher/parent/student interview; history of academic performance; and data from other members of the multidisciplinary team (MDT) (e.g., speech–language pathologist, interventionist, reading specialist).	Performance in one or more academic areas is *weak or deficient*[c] (despite attempts at delivering higher-quality instruction) as evidenced by converging data sources. Note that low scores are not sufficient to meet this condition. These scores must also represent *unexpected underachievement* (a condition determined by X-BASS, based on an individual's unique pattern of scores).	**Necessary**
II	SLD does not include a learning problem that is the result of visual, hearing, or motor disabilities; of intellectual disability; of social or emotional difficulty or disorder; or of environmental, educational, cultural, or economic disadvantage.	**Exclusionary Factors:** Identification of potential primary causes of academic skill weaknesses or deficits, including intellectual disability, cultural or linguistic difference, sensory impairment, insufficient instruction or opportunity to learn, organic or physical health factors, social-emotional or psychological difficulty or disorder.	Data from the methods and sources listed at levels I and III; behavior rating scales; medical records; prior evaluations; interviews with current or past professionals (counselors, psychiatrists, etc.)	Performance is not *primarily* attributed to these exclusionary factors, although one or more of them may contribute to learning difficulties. (Consider using the Exclusionary Factors form, which is included in this chapter as Figure 22.3.)	
III	A disorder in one or more of the basic psychological/neuropsychological processes involved in understanding or in using language, spoken or written; such disorders are presumed to originate from central nervous system dysfunction.	**Cognitive Abilities and Processes:** Performance in cognitive abilities and processes (e.g., Gv, Ga, Glr, Gsm, Gs), specific neuropsychological processes (e.g., attention, executive functioning, orthographic processing, rapid automatic naming), and learning efficiency (e.g., associative memory, free-recall memory, meaningful memory).	Performance on norm-referenced tests; evaluation of work samples; observations of cognitive performance; task analysis; testing limits; teacher/parent/student interview; history of academic performance; and records review.	Performance in one or more cognitive abilities and/or neuropsychological processes (related to academic skill deficiency) is *weak or deficient*[c] as evidenced by converging data sources. Note that low scores are not sufficient to meet this condition. The cognitive ability or process in question must also be *domain-specific* (a condition determined	

				by X-BASS, based on an individual's unique pattern of scores).	↓
IV	The SLD is a discrete condition differentiated from generalized learning deficiency by generally average or better ability to think and reason and a learning skill profile exhibiting significant variability, indicating a pattern of cognitive and academic strengths and weaknesses.	**Pattern of Strengths and Weaknesses (PSW) Marked by a Dual-Discrepancy/Consistency (DD/C) Situation:** Determination of whether academic skill weaknesses or deficits are *unexpected* and related to *domain-specific* cognitive weaknesses or deficits; pattern of data reflects a below-average aptitude–achievement *consistency* with at least *average ability* to think and reason.	Data gathered at all previous levels, as well as any additional data following a review of initial evaluation results (e.g., data gathered for hypothesis testing; data gathered via demand analysis and limits testing).	Circumscribed below-average aptitude–achievement *consistency*; circumscribed ability–achievement and ability–cognitive aptitude *discrepancies*, with at least average ability to think and reason; clinical judgment supports the impression that the student's overall ability to think and reason will enable him or her to benefit from tailored or specialized instruction/intervention, compensatory strategies, and accommodations, such that his or her performance rate and level will likely approximate those of more typically achieving, nondisabled peers. The DD/C PSW analysis is conducted by X-BASS, based on an individual's unique pattern of strengths and weaknesses.	**Sufficient for SLD Identification**
V	The SLD has an adverse impact on educational performance.	**Special Education Eligibility:**[d] Determination of least restrictive environment (LRE) for delivery of instruction and educational resources.	Data from all previous levels and MDT meetings.	Student demonstrates significant difficulties in daily academic activities that cannot be remediated, accommodated, or otherwise compensated for *without* the assistance of individualized special education services.	**Necessary for Special Education Eligibility**

[1] This column includes concepts inherent in the federal definition (IDEA, 2004), Kavale, Spaulding, and Beam's (2009) definition, Harrison and Holmes's (2012) consensus definition, and other prominent definitions of SLD (see Sotelo-Dynega, 2018). Thus, he most salient prominent SLD markers are included in this column.

[2] Poor spelling with adequate ability to express ideas in writing is often typical of dyslexia and/or dysgraphia. Even though IDEA 2004 includes only the broad category of written expression, poor spelling and handwriting are often symptomatic of a specific writing disability and should not be ignored (Wendling & Mather, 2009).

[3] Weak performance is typically associated with standard scores in the 85–89 range, whereas deficient performance is often associated with standard scores that are greater than 1 *SD* below the mean. Interpretations of weak or deficient performance based on standard scores that fall in the weak and deficient ranges are bolstered when they have ecological validity (e.g., when there is evidence that the abilities or processes identified as weak or deficient manifest in everyday classroom activities that require these abilities and processes).

[4] The major SLD may be accompanied by secondary learning difficulties that should be considered in planning the more intensive, individualized special education instruction directed at the primary problem. For information on linking assessment data to intervention, see Mascolo, Alfonso, and Flanagan (2014).

FIGURE 22.2. A CHC-based operational definition of SLD; this approach is now known as the DD/C method. X-BASS, Cross-Battery Assessment Software System (Flanagan, Ortiz, & Alfonso, 2017). Based on Flanagan and Alfonso (2017) and Flanagan, Ortiz, and Alfonso (2013).

ness, 2000; Kavale et al., 2009), but they also include concepts from various other researchers (e.g., Berninger, 2011; Decker, Bridges, & Vetter, 2018; Fletcher-Janzen & Reynolds, 2008; Geary, Hoard, & Bailey, 2011; Geary et al., 2017; Hale & Fiorello, 2004; Hale et al., 2010; Mazzocco & Vukovic, 2018; Nelson & Wiig, 2018; Reynolds & Shaywitz, 2009a, 2009b; Siegel, 1999; Stanovich, 1999; Vellutino, Scanlon, & Lyon, 2000).

The DD/C operational definition of SLD presented in Figure 22.2 differs from the one presented by Kavale and Forness (2000; see Figure 22.1) in four important ways. First, it is grounded in a well-validated contemporary theory on the structure of abilities (i.e., CHC theory; see Schneider & McGrew, Chapter 3, this volume, for a description). Second, in lieu of the traditional ability–achievement discrepancy method, a specific pattern of cognitive and academic ability and neuropsychological processing strengths and weaknesses is used as a defining characteristic or marker for SLD.[1] (It is important to understand that any pattern used for SLD determination should be supported by research on the relations among CHC abilities, processes, and academic outcomes—and, where possible, evidence on the neurobiological correlates of learning disorders in reading, math, and writing; see McDonough, Flanagan, Sy, & Alfonso, 2017.) Third, the evaluation of exclusionary factors occurs earlier in the SLD identification process in our operational definition, to prevent individuals from having to undergo additional testing. Fourth, we emphasize that SLD assessment is a recursive process rather than a linear one, and that information generated and evaluated at one level may inform decisions made at other levels. The recursive nature of the SLD identification process is reflected by the circular arrows in Figure 22.2. Each level of the CHC-based operational definition of SLD is described in more detail in the next section.

THE DD/C OPERATIONAL DEFINITION OF SLD

> A diagnosis identifies the nature of a specific learning disability and has implications for its probable etiology, instructional requirements, and prognosis. Ironically, in an era when educational practitioners are encouraged to use evidence-based instructional practices, they are not encouraged to use evidence-based differential diagnoses of specific learning disabilities.
>
> —BERNINGER (2011, p. 204)

According to the U.S. Department of Education (2006) regulations, there are three permissible methods for the identification of SLD: (1) traditional ability–achievement discrepancy, (2) response to intervention, and (3) alternative research-based approaches. The DD/C operational definition of SLD is consistent with the alternative research-based "third option" for SLD identification. The DD/C definition is grounded primarily in CHC theory, but has been extended to include important neuropsychological functions that are not explicit in CHC theory (e.g., executive functions, orthographic processing, cognitive efficiency). The essential elements in evaluation of SLD in the DD/C definition include (1) academic ability analysis, (2) evaluation of mitigating and exclusionary factors, (3) cognitive ability and processing analysis, (4) pattern of strengths and weaknesses (PSW) analysis, and (5) evaluation of interference with learning for purposes of special education eligibility.

It is assumed that the levels of evaluation depicted in Figure 22.2 are undertaken after it has been determined that the student is demonstrating an inadequate response to high-quality instruction and pre-referral interventions (consistent with tiers 1 and 2 of a response-to-intervention [RTI] approach or a multi-tiered system of support [MTSS]) have been conducted with little or no success, and therefore a focused evaluation of specific abilities and processes through standardized testing of cognitive and academic abilities is deemed necessary (Flanagan, Fiorello, et al., 2010; see also McCloskey, Slonim, & Rumohr, Chapter 39, this volume). Evaluation for the presence of an SLD assumes that an individual has been referred for testing specifically because of observed learning difficulties. Moreover, before a formal SLD assessment is begun, other data from multiple sources may have (and probably should have) already been uncovered within the context of intervention implementation. These data may include results from CBM, progress monitoring, informal testing, direct observation of behaviors, work samples, reports from people familiar with the child's difficulties (e.g., teachers, parents), and information provided by the child him- or herself. This type of systematic approach to understanding learning difficulties can emanate from any well-researched theory (e.g., Decker et al., 2018; Hale, Wycoff, & Fiorello, 2011; McCloskey, Whitaker, Murphy, & Rogers, 2012; McDonough & Flanagan, 2016). A summary of each level of the DD/C operational definition of SLD follows.

Level I: Difficulties in One or More Areas of Academic Achievement

SLD is marked by dysfunction in learning. That is, learning is somehow disrupted from its normal course by an underlying ability and processing deficits. Although the specific mechanism that inhibits learning is not directly observable, one can proceed on the assumption that it manifests in observable phenomena, particularly academic achievement. Thus level I of the operational definition involves documenting that some type of *learning* deficit exists. In the DD/C definition, the presence of a *weakness* or *normative weakness/deficit* (Table 22.2) —established through standardized testing of the major areas of academic achievement (e.g., reading, writing, math, oral language), and supported through other means, such as clinical observations of academic performance, work samples, and parent and teacher reports—is a necessary but insufficient condition for SLD determination. A finding of a weakness in academic achievement is not sufficient for SLD identification because this condition alone may be present for a variety of reasons, only one of which is SLD. Furthermore, the academic area of weakness must also meet criteria for *unexpected underachievement,* as discussed later in this chapter.

The academic areas that are generally assessed at level I in the DD/C operational definition include the eight areas of achievement specified in the federal definition of SLD (IDEA, 2004). These eight areas are basic reading skills, reading fluency, reading comprehension, math calculation, math problem solving, written expression, listening comprehension, and oral expression. Most of the skills and abilities measured at level I represent an individual's stores of acquired knowledge. These specific knowledge bases (e.g., quantitative knowledge [Gq], reading and writing ability [Grw], vocabulary knowledge [Gc]) develop largely as a function of formal instruction, schooling, and educationally related experiences (Carroll, 1993). Typically, the eight areas of academic achievement are measured via standardized, norm-referenced tests. In fact, many comprehensive achievement batteries, such as the Wechsler Individual Achievement Test—Third Edition (WIAT-III; Pearson, 2009), the Woodcock–Johnson IV Tests of Achievement (Schrank, Mather, & McGrew, 2014), and the Kaufman Test of Educational Achievement, Third Edition (KTEA-3; Kaufman & Kaufman, 2014), measure all eight areas (see Table 22.3). It is important to realize that data on academic performance should come from multiple sources (see Figure 22.2, level I, column 4).

If weaknesses or deficits in the child's academic achievement profile are not identified, then the issue of SLD may be moot because such weakness-

TABLE 22.2. Definition of Weakness and Normative Weakness or Deficit

Term or concept	Meaning within the context of DD/C	Comments
Weakness	Performance on standardized, norm-referenced tests that falls *below average* (where average is defined as standard scores between 90 and 110 [inclusive], based on a scale having a mean of 100 and standard deviation of 15). Thus a weakness is associated with standard scores of 85 to 89 (inclusive).	Interpreting scores in the very narrow range of 85–89 requires clinical judgment, as abilities associated with these scores may or may not pose significant difficulties for an individual. Interpretation of any cognitive construct as a weakness for the individual should include ecological validity (i.e., evidence of how the weakness manifests itself in real-world performances, such as classroom activities).
Normative weakness or deficit	Performance on standardized, norm-referenced tests that falls greater than one standard deviation below the mean (i.e., standard scores <85). This type of weakness is often referred to as *population-relative* or *interindividual.* The terms *normative weakness* and *deficit* are used interchangeably.	The range of 85–115, inclusive, is often referred to as the range of *normal limits* because it is the range in which nearly 70% of the population falls on standardized, norm-referenced tests. Therefore, scores within this range are sometimes classified as *within normal limits* (WNL). As such, any score that falls outside and below this range is a normative weakness *as compared to most people*. Notwithstanding, the meaning of any cognitive construct that emerges as a normative weakness is enhanced by ecological validity.

es are a necessary component of the definition. Nevertheless, some children who struggle academically may not demonstrate academic weaknesses or deficits on standardized, norm-referenced tests of achievement; this is particularly true of very bright students, for a variety of reasons. For example, some children may have figured out how to compensate for their processing deficits. Therefore, it is important not to assume that a child with a standard score in the upper 80s or low 90s on a "broad reading" composite is "OK," particularly when a parent, a teacher, or the student him- or herself expresses concern. Under these circumstances, a more focused assessment of the CHC and neuropsychological processes related to reading should be conducted. Conversely, the finding of low scores on norm-referenced achievement tests does not guarantee that there will be corresponding low scores on norm-referenced cognitive tests in areas that are related to the achievement area—*an important fact that was ignored in a relatively recent investigation of the DD/C method* (i.e., Kranzler, Floyd, Benson, Zaboski, & Thibodaux, 2016b). Below-average achievement may be the result of a host of factors, only one of which is weaknesses or deficits in related cognitive processes and abilities. Most practitioners know this to be true. See Flanagan and Schneider (2016) for a discussion. When weaknesses or deficits in academic performance are found, and are corroborated by other data sources, the process advances to level II.

Level II: Exclusionary Factors as Potential Primary or Contributory Reasons

Level II involves evaluating whether any documented weaknesses or deficits found through level I evaluation are or are not *primarily* the result of factors that may be, for example, largely external to the child, noncognitive in nature, or the result of a disorder other than SLD. Because there can be many reasons for weak or deficient academic performance, causal links to SLD should not be ascribed prematurely. Instead, reasonable hypotheses related to other potential causes for academic weaknesses should be developed. For example, cultural and linguistic differences are two common factors that can affect both test performance and academic skill acquisition adversely and can result in achievement data that appear to suggest SLD (see Ortiz, Melo, & Terzulli, 2018; Ortiz, Piazza, Ochoa, & Dynda, Chapter 25, this volume). In addition, lack of motivation, social-emotional disturbance, performance anxiety, psychiatric disorders, sensory impairments, and medical conditions (e.g., hearing or vision problems) also need to be ruled out as potential explanatory correlates to (or *primary* reasons for) any weaknesses or deficits identified at level I. Figure 22.3 provides an example of a form that may be used to document systematically and thoroughly that the exclusionary factors listed in the federal definition of SLD were evaluated.

Note that because the process of SLD determination does not necessarily occur in a strict linear fashion, evaluations at levels I and II often take place concurrently, as data from level II are often necessary to understand performance at level I. The circular arrows between levels I and II in Figure 22.2 are meant to illustrate the fact that interpretations and decisions that are based on data gathered at level I may need to be informed by data gathered at level II. Ultimately, at level II, the practitioner must judge the extent to which any factors other than cognitive impairment can be considered the *primary* reason for the academic performance difficulties. The form in Figure 22.3 provides space for documenting this judgment. If performance cannot be attributed primarily to other factors, then the second criterion necessary for establishing SLD according to the operational definition is met, and assessment may continue to the next level.

It is important to recognize that although factors such as having English as a second language may be present and may affect performance adversely, SLD can also be present. Certainly, children who have vision problems, chronic illnesses, limited English proficiency, and so forth, may also have SLD. Therefore, when these or other factors at level II are present, or even when they are determined to be *contributing* to poor performance, SLD should not be ruled out. Rather, only when such factors are determined to be *primarily* responsible for weaknesses in learning and academic performance—not merely contributing to them—should SLD be discounted as an explanation for dysfunction in academic performance. Examination of exclusionary factors is necessary to ensure fair and equitable interpretation of the data collected for SLD determination and, as such, is not intended to *rule in* SLD. Rather, careful examination of exclusionary factors is intended to rule out other possible explanations for deficient academic performance.

One of the major reasons for placing evaluation of exclusionary factors at this (early) point in the SLD assessment process is to provide a mechanism that is efficient in both time and effort, and that may prevent the unnecessary administration of additional tests. However, it may not be possible to rule out all the numerous potential exclusionary factors completely and convincingly at this stage in the assessment process. For example, the data gathered at levels I and II may be insufficient to draw conclusions about such conditions as developmental disabilities and intellectual disability (ID; see Farmer & Floyd, Chapter 23, this volume), which often requires more thorough and direct assessment (e.g., administration of an intelligence test and adaptive behavior scale). When exclusionary factors—at least those that can be evaluated at this level—have been examined carefully and eliminated as possible *primary* explanations for poor academic performance, the process may advance to the next level.

Level III: Performance in Cognitive Abilities and Neuropsychological Processes

The criterion at level III is like the one specified in level I, except that it is evaluated with data from an assessment of cognitive abilities and neuropsychological processes. Analysis of data generated from the administration of standardized tests represents the most common method available by which cognitive abilities and neuropsychological processes in children are evaluated. However, other types of information and data are relevant to

Evaluation and Consideration of Exclusionary Factors for SLD Identification

An evaluation for specific learning disabilities (SLD) requires an evaluation and consideration of factors *other* than a disorder in one or more basic psychological processes that may be the primary cause of a student's academic skill weaknesses and learning difficulties. These factors include (but are not limited to) vision/hearing[a] or motor disabilities, intellectual disability (ID), social-emotional or psychological disturbance, environmental or economic disadvantage, cultural and linguistic factors (e.g., limited English proficiency), insufficient instruction or opportunity to learn, and physical/health factors. These factors may be evaluated via behavior rating scales, parent and teacher interviews, classroom observations, attendance records, social/developmental history, family history, vision/hearing exams, medical records, prior evaluations, and interviews with current or past counselors, psychiatrists, and paraprofessionals who have worked with the student. Noteworthy is the fact that students with (and without) SLD often have one or more factors (listed below) that *contribute* to academic and learning difficulties. However, the practitioner must rule out any of these factors as being the *primary* reason for a student's academic and learning difficulties to maintain SLD as a viable classification/diagnosis.

Vision (check all that apply):

☐ Vision test recent (within 1 year)
☐ Vision test outdated (>1 year)
☐ Passed
☐ Failed
☐ Wears glasses

☐ History of visual disorder/disturbance
☐ Diagnosed visual disorder/disturbance
☐ Name of disorder: ______________________________
☐ Vision difficulties suspected or observed (e.g., difficulty with far- or near-point copying; misaligned numbers in written math work; squinting or rubbing eyes during visual tasks such as reading, computer use)

Notes: ____

____

____

____

____

Hearing (check all that apply):[b]

☐ Hearing test recent (within 1 year)
☐ Hearing test outdated (>1 year)
☐ Passed
☐ Failed
☐ Uses hearing aids

☐ History of auditory disorder/disturbance
☐ Diagnosed auditory disorder/disturbance
☐ Name of disorder: ____________________
☐ Hearing difficulties suggested in the referral (e.g., frequent requests for repetition of auditory information; misarticulated words; attempts to self-accommodate by moving closer to sound source; obvious attempts to read speech)

Notes: ____

Motor Functioning (check all that apply):

☐ Fine motor delay/difficulty

☐ Gross motor delay/difficulty

☐ Improper pencil grip (specify type: ________________)

☐ Assistive devices/aids used (e.g., weighted pens, pencil grip, slant board)

☐ History of motor disorder

☐ Diagnosed motor disorder

☐ Name of disorder: ________________________________

☐ Motor difficulties suggested in the referral (e.g., illegible writing; issues with letter or number formation, size, spacing; difficulty with fine motor tasks such as using scissors, folding paper)

Notes: ____

____

Cognitive and Adaptive Functioning (Check All That Apply):

☐ Significantly “subaverage intellectual functioning” (e.g., IQ score of 75 or below)

☐ Pervasive cognitive deficits (e.g., weaknesses or deficits in many cognitive areas, including Gf *and* Gc)

☐ Deficits in adaptive functioning (e.g., social skills, communication, self-care)

☐ Areas of significant adaptive skill weaknesses (check all that apply):

☐ Motor skills

☐ Daily living skills

☐ Communication

☐ Behavioral/emotional skills

☐ Socialization

☐ Other

Notes: ____

____

Social-Emotional/Psychological Factors (check all that apply):

☐ Diagnosed psychological disorder (specify: ________________________________)

☐ Date of diagnosis: ____

☐ Family history significant for psychological difficulties

☐ Disorder presently treated (specify treatment modality—e.g., counseling, medication): ____________

☐ Reported difficulties with social-emotional functioning (e.g., social phobia, anxiety, depression)

☐ Social-emotional/psychological issues suspected or suggested by referral

☐ Home–school adjustment difficulties

☐ Lack of motivation/effort

☐ Emotional stress

☐ Autism

☐ Present medications (type, dosage, frequency, duration):

☐ Prior medication use (type, dosage, frequency, duration):

☐ Hospitalization for psychological difficulties (date[s]: ________________________________)

☐ Deficits in social, emotional, or behavioral [SEB] functioning (e.g., as assessed by standardized rating scales) —significant scores from SEB measures:

FIGURE 22.3. *(continued)*

Environmental/Economic Factors (check all that apply):

☐ Limited access to educational materials in the home
☐ Caregivers unable to provide instructional support
☐ Economic considerations precluded treatment of identified issues (e.g., filling a prescription, replacing broken glasses, tutoring)
☐ Temporary crisis situation
☐ History of educational neglect
☐ Frequent transitions (e.g., shared custody)
☐ Environmental space issues (e.g., no space for studying, sleep disruptions due to shared sleeping space)

Notes: ____

____

Cultural/Linguistic Factors (check all that apply):[c]

☐ Limited number of years in U.S. (________)
☐ No history of early or developmental problems in primary language
☐ Current primary-language proficiency: (Date: ________ Scores: ________)
☐ Acculturative knowledge development (Circle one: High Moderate Low)
☐ Language(s) other than English spoken in home
☐ Lack of or limited instruction in primary language (# of years: ________)
☐ Current English-language proficiency: (Date: ________ Scores: ________)
☐ Parental educational and socioeconomic level (Circle one: High Moderate Low)

Notes: ____

____

Physical/Health Factors (check all that apply):

☐ Limited access to health care
☐ Minimal documentation of health history/status
☐ Chronic health condition (specify: ________________________________)
☐ Temporary health condition (date/duration: ________________________________)
☐ Hospitalization (dates: ________________________________)
☐ History of Medical Condition (date diagnosed: ________________________________)
☐ Medical treatments (specify:________________________________)
☐ Repeated visits to doctor/school nurse
☐ Medication (type, dosage, frequency, duration:________________________________)

Notes: ____

____

Instructional Factors (check all that apply):

☐ Interrupted schooling (e.g., midyear school move) Specify why: ________________
☐ New teacher (past 6 months)
☐ Nontraditional curriculum (e.g., home-schooled)
☐ Days absent/tardy: ____________
☐ Retained or advanced a grade or more
☐ Accelerated curriculum (e.g., AP classes)

Notes: ____

FIGURE 22.3. *(continued)*

Determination of Primary and Contributory Causes of Academic Weaknesses and Learning Difficulties (check one):

☐ Based on the available data, it is reasonable to conclude that one or more factors are *primarily* responsible for the student's observed learning difficulties. Specify: ____________________

☐ Based on the available data, it is reasonable to conclude that one or more factors *contribute* to the student's observed learning difficulties. Specify: ____________________

☐ *No* factors listed here appear to be the primary cause of the student's academic weaknesses and learning difficulties.

[a] For a vision or hearing disorder, it is important to understand the nature of the disorder, its expected impact on achievement, and the time of diagnosis. It is also important to understand what was happening instructionally at the time the disorder was suspected and/or diagnosed.

With regard to hearing, even mild loss can impact initial receptive and expressive skills as well as academic skill acquisition. When loss is suspected, the practitioner should consult professional literature to further understand the potential impact of a documented hearing issue (see the American Speech–Language–Hearing Association guidelines, *www.asha.org*).

With regard to vision, refractive error (i.e., hyperopia and anisometropia), accommodative and vergence dysfunctions, and eye movement disorders are associated with learning difficulties, whereas other vision problems (e.g., constant strabismus and amblyopia) are not. As such, when a vision disorder is documented or suspected, the practitioner should consult professional literature to further understand the impact of the visual disorder (e.g., see American Optometric Association, *www.aoa.org*).

[b] When there is a history of hearing difficulties and an SLD diagnosis is being considered, hearing testing should be recent (i.e., conducted within the past 6 months).

[c] When evaluating the impact of language and cultural factors on a student's functioning, the practitioner should consider whether and to what extent other individuals with similar linguistic and cultural backgrounds as the referred student are progressing and responding to instruction in the present curriculum. For example, if an LEP student with limited English proficiency is not demonstrating academic progress or is not performing as expected on a class- or districtwide assessment when compared to his or her peers who possess a similar level of English proficiency and acculturative knowledge, it is unlikely that cultural and linguistic differences are the sole or primary factors for the referred student's low performance. In addition, it is important to note that as the number of cultural and linguistic differences in a student's background increase, the likelihood becomes greater that poor academic performance is attributable primarily to such differences rather than to a disability.

Note. All 50 U.S. states specify eight exclusionary criteria. Namely, learning difficulties cannot be primarily attributed to (1) visual impairment; (2) hearing impairment; (3) motor impairment; (4) intellectual disability; (5) emotional disturbance; (6) environmental disadvantage; (7) economic disadvantage; and (8) cultural difference. Certain states have adopted additional exclusionary factors including autism (CA, MI, VT, and WI), emotional stress (LA and VT), home or school adjustment difficulties (LA and VT), lack of motivation (LA and TN), and temporary crisis situation (LA, TN, and VT). We have integrated these additional criteria under "Social-Emotional/Psychological Factors" and "Environmental/Economic Factors," and have added two further categories (namely, "Instructional Factors" and "Physical/Health Factors") to this form. This form may be reproduced and disseminated.

Note. Developed by Jennifer T. Mascolo and Dawn P. Flanagan. This form may be reproduced and disseminated.

FIGURE 22.3. *(continued)*

cognitive performance (see Figure 22.2, level III, column 4). Practitioners should seek out and gather data from other sources as a means of providing corroborating evidence for standardized test findings. For example, when test findings are found to be consistent with a child's performance in the classroom, more confidence may be placed on test performance because interpretations of cognitive deficiency have ecological validity—an important condition for any diagnostic process (Flanagan et al., 2013; Flanagan, Alfonso, Sy, et al., 2018; Hale & Fiorello, 2004). Table 22.4 provides an example of the cognitive abilities and neuropsychological processes measured by the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014), the Woodcock–Johnson IV Tests of Cognitive Abilities (Schrank, McGrew, & Mather, 2014), and the Kaufman Assessment Battery for Children, Second Edition Normative Update (Kaufman & Kaufman, 2018). For similar information on all major intelligence tests and neuropsychological instruments, see Flanagan and colleagues (2017).

A particularly salient aspect of the DD/C operational definition of SLD is the concept that a weakness or deficit in a cognitive ability or process underlies difficulties in academic performance or skill development. Because research demonstrates

Note. Gf, fluid intelligence; Gc, crystallized intelligence; Gsm, short-term memory; Gv, visual processing; Gs, processing speed. RQ, quantitative reasoning; MW, working memory; SR, spatial relations; Vz, visualization; P, perceptual speed; R9, rate of test taking; K0, general (verbal) knowledge; LD, language development; MS, memory span; I, induction; RG, general sequential reasoning; CF, flexibility of closure; VL, lexical knowledge. The following Cattell–Horn–Carroll (CHC) broad abilities are omitted from this table because none is a primary ability measured by the WISC-V: Glr (long-term storage and retrieval), Ga (auditory processing), Gt (decision/reaction time or speed), and Grw (reading and writing ability). Most CHC test classifications are from Flanagan, Ortiz, and Alfonso (2017). Classifications according to neuropsychological domains were based on our readings of neuropsychological texts (e.g., Fletcher-Janzen & Reynolds, 2008; Hale & Fiorello, 2004; Lezak, 1995; Miller, 2007, 2010) and are also found in Flanagan, Alfonso, and Mascolo (2011).

[a] E, expressive; R, receptive.

[b] Cognitive ability classifications for the Arithmetic subtest are based on analyses conducted by Keith, Fine, Taub, Reynolds, and Kranzler (2006; viz., Gf:RQ). It is important to note that the Keith et al. analyses did not include any other measures of math achievement; therefore, Gq was not represented adequately in their study. Arithmetic has been identified in many other studies as a measure of Gq, particularly math achievement (A3) (see, for discussions, Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009).

that the relationship between the cognitive dysfunction and the manifest learning problems is causal in nature[2] (e.g., Flanagan & Schneider, 2016; Fletcher, Lyon, Fuchs, & Barnes, 2007; Fletcher, Taylor, Levin, & Satz, 1995; Hale & Fiorello, 2004; Hale et al., 2010; Wagner & Torgesen, 1987), data analysis at this level should seek to ensure that identified weaknesses or deficits on cognitive and neuropsychological tests bear an empirical relationship to those weaknesses or deficits in achievement identified previously. It is this very notion that makes it necessary to draw upon cognitive and neuropsychological theory and research to inform operational definitions of SLD and increase the reliability and validity of the SLD identification process. Theory and its related research base not only specify the relevant constructs that ought to be measured at levels I and III, but predict the way they are related. Furthermore, application of current theory and research provides a substantive empirical foundation from which interpretations and conclusions may be drawn. Tables 22.5 through 22.7 provide summaries of the relations between CHC cognitive abilities and processes and reading, math, and writing achievement, respectively, based on findings from multiple literature reviews (Berninger, 2011; Flanagan, Ortiz, Alfonso, & Mascolo, 2006; Flanagan et al., 2013; McDonough et al., 2017; McGrew & Wendling, 2010; Niileksela, Reynolds, Keith, & McGrew, 2016). These tables also provide summaries of the literature on the etiology of academic difficulties (see McDonough et al., 2017, for a discussion).

The information contained in Tables 22.5 through 22.7 may be used to guide how practitioners organize their assessments at this level. That is, prior to selecting cognitive and neuropsychological tests, a practitioner should have knowledge of those cognitive abilities and processes that are most important for understanding a child's academic performance in the area(s) in question (i.e., the area[s] identified as weak or deficient at level I). Evaluation of cognitive performance should be comprehensive in the areas of suspected dysfunction. Because evidence of a cognitive weakness or deficit is a necessary condition for SLD determination, if no weaknesses or deficits in cognitive abilities or processes are found, then an essential criterion for SLD determination is not met. When the criterion at level III is not met, an evaluation of whether the obtained cognitive data represent an evaluation that was sufficient in breadth and depth vis-à-vis what is known about the relations between abilities, processes, and academic skill acquisition and development is warranted. Furthermore, a more in-depth exploration of exclusionary factors evaluated at level II may be warranted.

Also, because new data are gathered at level III, it is now possible to evaluate the exclusionary factors that could not be evaluated earlier (e.g., ID). The circular arrows between levels II and III in Figure 22.2 are meant to illustrate that interpretations and decisions based on data gathered at level III may need to be informed by data gathered at level II. Likewise, data gathered at level III are often necessary to rule out (or in) one or more factors listed at level II in Figure 22.2. Reliable and valid identification of SLD depends in part on being able to understand academic performance (level I), cognitive performance (level III), and the many factors that may facilitate or inhibit such performances (level II).

Level IV: Data Integration—The DD/C Pattern of Strengths and Weaknesses

The fourth level of evaluation involves an analysis of the individual's PSW. It revolves around a theory- and research-guided examination of performance across academic skills, cognitive abilities, and neuropsychological processes to determine whether the child's PSW is consistent with the SLD construct.

Figure 22.4 provides an illustration of three common components of the PSW method for identification of SLD. First, individuals with SLD have cognitive processing weaknesses or deficits. These weaknesses are depicted by the bottom left oval in the figure. Second, individuals with SLD have academic skill weaknesses or deficits. These weaknesses are depicted by the bottom right oval in the figure. Third, individuals with SLD have areas of cognitive strength. These strengths are depicted in the top center oval in the figure. In addition to these three components, the relationships between these ovals are important. The double-headed arrows between the top oval and the two bottom ovals in the figure indicate the presence of statistically significant discrepancies in measured performance between cognitive strengths and the areas of academic and cognitive weakness. These discrepancies denote that the differences are reliable and not due to chance. The double-headed arrow between the two bottom ovals reflects a consistency between the cognitive and academic areas of weakness. The consistency

TABLE 22.5. Summary of Relations among CHC Domains, Reading Achievement, and the Etiology of Reading Functions

CHC broad ability	Reading achievement	Etiology of reading functions
Gf	Inductive (I) and general sequential reasoning (RG) abilities play a moderate role in reading comprehension. Executive functions (EF), such as planning, organization, and self-monitoring, are also important.	Several cortical and subcortical structures are frequently implicated in basic reading skills and word-reading accuracy. Recent work appears to identify dysfunction in a left-hemispheric network that includes the occipito-temporal region, inferior frontal gyrus, and inferior parietal region of the brain (Fletcher, Simos, Papanicolaou, & Denton, 2004; Richlan, 2012; Richlan et al., 2009; Shaywitz et al., 2000; Silani et al., 2005). Numerous imaging studies have also found that dysfunctional responses in the left inferior frontal and temporo-parietal cortices play a significant role with regard to phonological deficits (Skeide et al., 2015). Similar brain regions are activated on tasks involving reading fluency, but additional activation is observed in areas involved in eye movement and attention (Jones, Ashby, & Branigan, 2013). Furthermore, there is also evidence for increased activation in the left occipito-temporal region, in particular the occipito-temporal sulcus, which is important for rapid processing of letter patterns (Dehaene & Cohen, 2011; Shaywitz et al., 2004).
Gc	Language development (LD), lexical knowledge (VL), and listening ability (LS) are important at all ages for reading acquisition and development. These abilities become increasingly important with age. Oral language, listening comprehension, and EF (planning, organization, self-monitoring) are also important for reading comprehension.	
Gwm	Memory span (MS) and working memory capacity (WM) or attentional control are important for overall reading success. Phonological memory or WM for verbal and sound-based information may also be important. WM is important for reading comprehension, which involves holding words and sentences in awareness, while integrating prior knowledge with incoming information.	
Gv	Orthographic processing (often measured by tests of perceptual speed that use orthographic units as stimuli) is related to reading rate and fluency. Orthographic processing involves the ability to process units of words based on visual long-term memory representations, which is critical for automatic word recognition.	Brain regions often associated with reading comprehension include the anterior temporal lobe, inferior temporal gyrus, inferior frontal gyrus, inferior frontal sulcus, and middle and superior frontal and temporal regions (Ferstl et al., 2008; Gernsbacher & Kaschak, 2003). More recent research has revealed a relationship between listening and reading comprehension and activation along the left superior temporal sulcus, which has referred to by some as the *comprehension cortex* (Berl et al., 2010). However, broader pathways are also activated in reading comprehension, reflecting increased cognitive demand compared to listening.
Ga	Phonetic coding (PC) or phonological awareness/processing is very important during the elementary school years for the development of basic reading skills and word-reading accuracy. Phonological memory or WM for verbal and sound-based information may also be important.	
Glr	Naming facility (NA) or rapid automatic naming (RAN; also called speed of lexical access) is very important during the elementary school years for reading rate and fluency or word recognition skills. Associative memory (MA) is also important.	Family and genetic factors have long been identified as crucial in reading achievement, with some researchers suggesting that a child with a parent with a reading disability is eight times more likely to have dyslexia than a child in the general population (Pennington & Olson, 2005).
Gs	Perceptual speed (P) abilities are important throughout school, but particularly during the elementary school years.	Shared environmental factors include language and literacy environment during childhood (Wadsworth et al., 2000) and quality of reading instruction.

Note. Information in this table was culled from the following sources: Flanagan, Ortiz, and Alfonso (2013); Flanagan, Ortiz, Alfonso, and Mascolo (2006); McDonough, Flanagan, Sy, and Alfonso (2017); McGrew and Wendling (2010); Niileksela, Reynolds, Keith, and McGrew, 2016. TABLE 22.6. Summary of Relations among CHC Domains, Math Achievement, and the Etiology of Math Functions

CHC broad ability	Math achievement	Etiology of math functions
Gf	Reasoning inductively (I) and deductively with numbers (RQ) is very important for math problem solving. Executive functions such as set shifting and cognitive inhibition are also important.	The intraparietal sulcus in both hemispheres is widely viewed as crucial in processing and representing numerical quantity (number sense), although there may be differences in activation as a function of age (Ansari & Dhital, 2006; Ansari, Garcia, Lucas, Hamon, & Dhital, 2005; Dehaene et al., 2004; Kaufmann et al., 2006; Kucian, von Aster, Loenneker, Dietrich, & Martin, 2008; Mussolin et al., 2010; Price & Ansari, 2013).
Gc	Language development (LD), lexical knowledge (VL), and listening ability (LS) are important at all ages for math problem solving. These abilities become increasingly important with age. Number representation (e.g., quantifying sets without counting, estimating relative magnitude of sets) and number comparisons are related to overall number sense.	Regions of the left fronto-parietal cortex, including the intraparietal sulcus, angular gyrus, and supramarginal gyrus, have been consistently associated with math calculation (Ansari, 2008; De Smedt, Holloway, & Ansari, 2011; Dehaene, Molko, Cohen, & Wilson, 2004; Dehaene et al., 2004). The dorsolateral prefrontal cortex has also been found to show increased activation during calculation, implying that executive functioning and working memory may be playing a role in the process (Davis et al., 2009).
Gwm	Memory span (MS) and working memory capacity (WM) or attentional control are important for math problem solving and overall success in math.	
Gv	Visualization (VZ), including mental rotation, is important primarily for higher-level math (e.g., geometry, calculus) and math problem solving.	A left-hemisphere network that includes the precentral gryus, inferior parietal cortex, and intraparietal sulcus is often implicated in math fact retrieval (Dehaene & Cohen, 1992, 1997; Dehaene et al., 1999). Furthermore, some researchers believe that rote math facts are retrieved from verbal memory, thereby requiring activation of the angular gyrus and other regions associated with linguistic processes (Dehaene, 1992; Dehaene & Cohen, 1995; Dehaene et al., 1999).
Ga		
Glr	Naming facility (NA; also called speed of lexical access) and associative memory (MA) are important for memorization and rapid retrieval of basic math facts and for accurate and fluent calculation.	
Gs	Perceptual speed (P) is important during all years, especially the elementary school years for math calculation fluency.	Prevalence of math disabilities is about 10 times higher in those with family members who had math disabilities than in the general population (Shalev et al., 2001).
		Environmental factors, including motivation, emotional functioning (e.g., math anxiety), and suboptimal or inadequate teaching, may also contribute to math difficulties (Szucs & Goswami, 2013; Vukovic et al., 2013). Furthermore, math achievement may be associated with cultural or gender-based attitudes that may be transmitted in the family environment (e.g., Chiu & Klassen, 2010; Gunderson et al., 2011).

Note. Information in this table was culled from the following sources: Flanagan, Ortiz, and Alfonso (2013); Flanagan, Ortiz, Alfonso, and Mascolo (2006); McDonough, Flanagan, Sy, and Alfonso (2017); McGrew and Wendling (2010); and McGrew et al. (2014). All references cited in the "Etiology . . ." column may be found in these sources.

TABLE 22.7. Summary of Relations between CHC Domains and Writing Achievement and the Etiology of Writing Functions

CHC broad ability	Writing achievement	Etiology of writing functions
Gf	Inductive (I) and general sequential reasoning (RG) are consistently related to written expression at all ages. Executive functions such as attention, planning, and self-monitoring are also important.	Neural correlates of writing are less understood, but some studies have suggested that the cerebellum and parietal cortex, particularly the left superior parietal lobe, may be involved (Katanoda et al., 2001; Magrassi et al., 2010). In addition, the frontal lobes have also been implicated and are considered crucial in planning, brainstorming, organizing, and goal setting, which are important for written expression (Shah et al., 2013). Functional neuroimaging studies have provided substantial evidence for the role of the ventral-temporal inferior frontal gyrus and the posterior inferior frontal gyrus in spelling (Rapp et al., 2015; van Hoorn et al., 2013). Other areas that have been identified include the left ventral cortex, bilateral lingual gyrus, and bilateral fusiform gyrus (Planton et al., 2013; Purcell et al., 2014; Richards et al., 2005, 2006). However, many of these regions have also been associated with reading and are not distinct to spelling/writing disorders. Although there is a significant genetic component involved in the development of writing skills, this etiology is often shared with a broad variety of reading and language skills (Olson et al., 2013).
Gc	Language development (LD), lexical knowledge (VL), and general information (K0) are important primarily after second grade and become increasingly important with age. Level of knowledge of syntax, morphology, semantics, and VL has a significant impact on clarity of written expression and text generation ability.	
Gwm	Memory span (MS) is important to writing, especially spelling skills, whereas working memory (WM) has shown relations with advanced writing skills (e.g., written expression, synthesizing multiple ideas, ongoing self-monitoring).	
Gv	Orthographic processing (often measured by tests of perceptual speed that use orthographic units as stimuli) is particularly important for spelling.	
Ga	Phonetic coding (PC) or phonological awareness/processing is very important during the elementary school years (primarily before fifth grade) for both basic writing skills and written expression.	
Glr	Naming facility (NA; also called speed of lexical access) has demonstrated relations with writing fluency. Storing and retrieving commonly occurring letter patterns in visual and motor memory are needed for spelling.	
Gs	Perceptual speed (P) is important during all school years for basic writing skills and is related to written expression at all ages.	

Note. Information in this table was culled from the following sources: Flanagan, Ortiz, and Alfonso (2013); Flanagan, Ortiz, Alfonso, and Mascolo (2006); McDonough, Flanagan, Sy, and Alfonso (2017); McGrew and Wendling (2010); and McGrew et al. (2014). All references cited in the "Etiology . . ." column may be found in these sources.

means that underlying cognitive processing weaknesses or deficits impede the typical development of basic academic skills in individuals with SLD. The cognitive and academic PSW represented in Figure 22.4 retains the component of unexpected underachievement that has historically been synonymous with the SLD construct (Kaufman, 2008; Kavale & Forness, 2000; Sotelo-Dynega et al., 2018), and adds an underlying cognitive processing component that was missing from traditional discrepancy approaches. The manner in which all components of the pattern are defined varies, sometimes quite substantially, between models. Figure 22.4 includes wording that is most consistent with the DD/C model, and each component of this PSW model is described next.

When the process of SLD identification has reached level IV, three *preliminary* criteria for SLD identification have been met: (1) one or more weaknesses or deficits in academic performance; (2) one or more weaknesses or deficits in cognitive abilities and/or neuropsychological processes; and (3) exclusionary factors determined not to be the primary causes of the academic and cognitive weaknesses or deficits. What has not been determined, however, is whether the pattern of results is marked by an empirical or ecologically valid relationship between the identified cognitive and academic weaknesses; whether the individual's cognitive weakness is *domain-specific*; whether the individual's academic weakness (underachievement) is *unexpected*; and whether the individual displays at least average ability to think and reason. These four conditions form a specific PSW that is marked by two discrepancies and a consistency (DD/C). Within the context of the DD/C operational definition, the nature of unexpected underachievement suggests that not only does a child have specific, circumscribed, and related academic and cognitive weaknesses or deficits—referred to as a *below-average cognitive aptitude–achievement consistency*—but that these weaknesses exist along with generally average or better ability to think and reason (i.e., overall average cognitive ability). These four conditions form a specific PSW that is marked by two discrepancies and a consistency (DD/C). The Cross-Battery Assessment Software System (X-BASS; Flanagan et al., 2017) is needed to determine whether the data demonstrate the DD/C pattern because specific formulae, regression equations, correction for false negatives, and so forth are necessary to make the determination (for explanations of how X-BASS conducts a PSW analysis, see Flanagan et al., Chapter 27, this volume; Flanagan, Alfonso, Sy, et al., 2018). Each of these four conditions is described below.

Consistency between Cognitive and Academic Weaknesses

A student with an SLD has specific cognitive and academic weaknesses or deficits. When these weaknesses are related empirically, or when there is an ecologically valid relationship between them, the relationship is referred to as a *below-average cognitive aptitude–achievement consistency* in the DD/C operational definition. This consistency is a necessary marker for SLD because SLD is caused in part by cognitive processing weaknesses or deficits. Thus there is a need to understand and identify the underlying cognitive ability or processing problems that contribute significantly to the individual's academic difficulties.

The term *cognitive aptitude* within the context of the DD/C operational definition represents the specific cognitive ability or neuropsychological processing weaknesses or deficits that are related empirically to the academic skill weaknesses or deficits. For example, if a child's basic reading skill deficit is related to cognitive deficits in phonological processing (a narrow Ga ability) and rapid automatic naming (a narrow Gr ability), then the combination of below-average Ga and Gr performances represents his or her *below-average cognitive aptitude for basic reading,* meaning that these below-average performances *raise the risk* of a weakness in basic reading skills (Flanagan & Schneider, 2016). Moreover, the finding of below-average performance on measures of phonological processing, rapid automatic naming, and basic reading skill represents a *below-average cognitive aptitude–achievement consistency* (or, more specifically, a below-average *reading* cognitive aptitude–*reading* achievement consistency). The concept of below-average cognitive aptitude–achievement consistency reflects the notion that there are documented relationships between specific cognitive abilities and processes and specific academic skills (see Tables 22.5–22.7). Therefore, the finding of below-average performance in related cognitive and academic areas is an important marker for SLD in the DD/C operational definition, and in other alternative research-based approaches (e.g., McCloskey et al., 2012; see Alfonso & Flanagan, 2018, for support of this SLD marker in other PSW models).

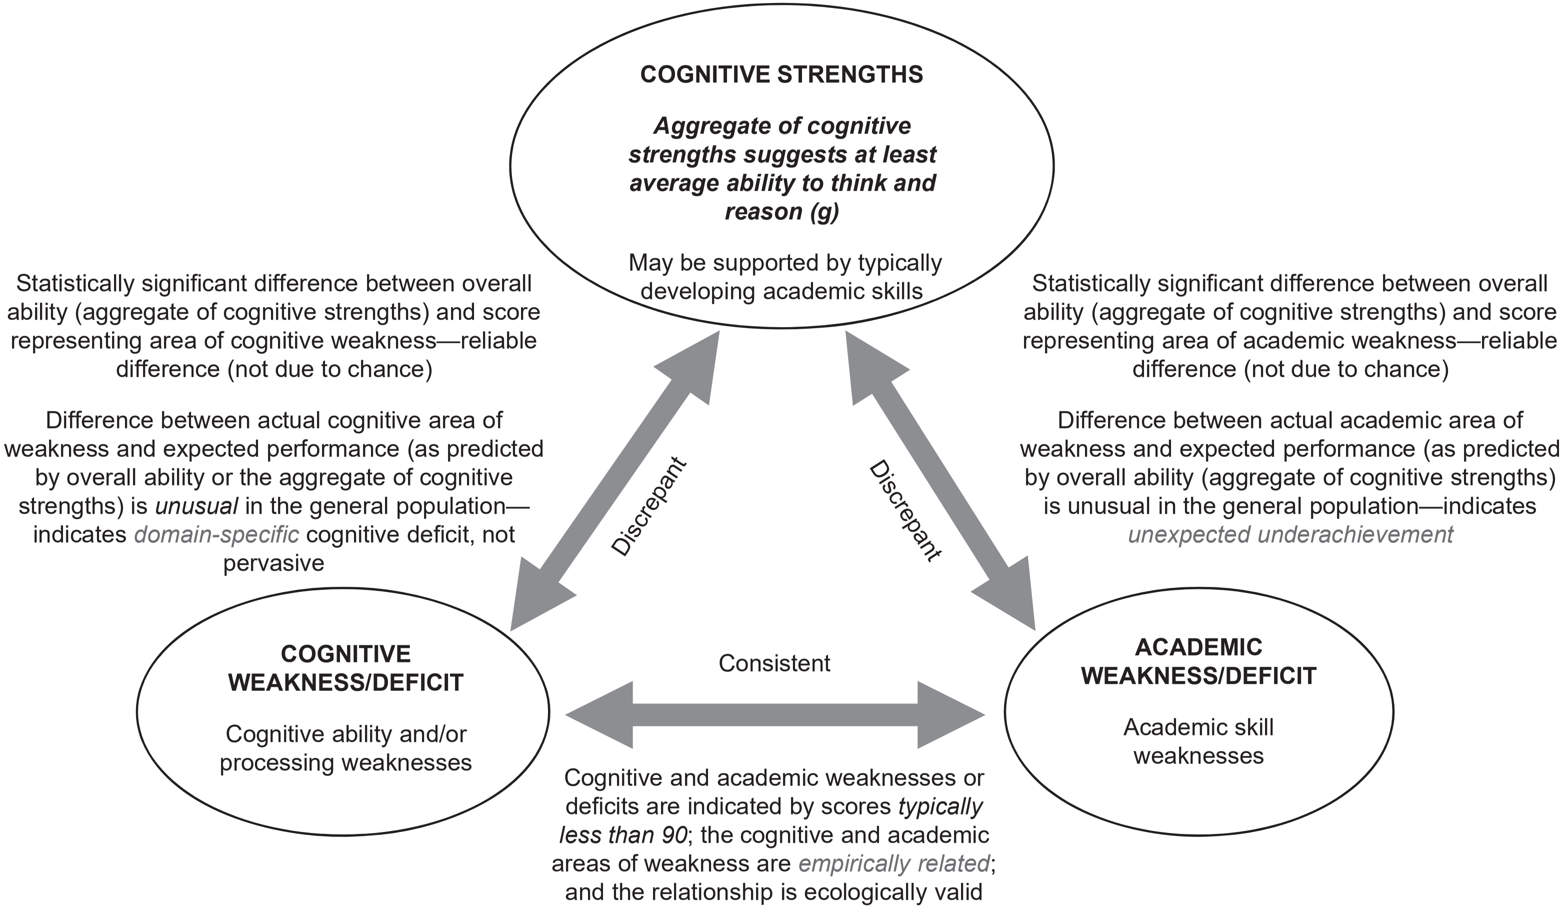

FIGURE 22.4. Conceptual understanding of the dual-discrepancy/consistency (DD/C) method. This figure is based on the work of Flanagan, Fiorello, and Ortiz (2010) and Hale, Flanagan, and Naglieri (2008). However, the wording in this figure is consistent wiht Flanagan, Ortiz, and Alfonso's (2013) DD/C model.

In the DD/C definition, the criteria for establishing a below-average cognitive aptitude–achievement *consistency* are as follows:

1. "Below-average" performance (i.e., scores of less than 90, and more typically at least a standard deviation or more below the mean) in the specific cognitive *and* academic areas that are considered weaknesses or deficits; and
2. Evidence of an empirical relationship between the specific cognitive and academic areas of weakness and/or an ecologically valid relationship between these areas. To validate the relationship between the cognitive and academic areas of weakness, practitioners can document the way each cognitive weakness or deficit manifests itself in real-world performances (see Mascolo, Alfonso, & Flanagan, 2014, for guidance).

It is important to understand that these criteria are operationalized further in X-BASS. Table 22.8 provides a more detailed explanation of how a consistency between cognitive and academic weaknesses is determined by X-BASS.

When the criteria for a below-average cognitive aptitude–achievement consistency are met, there may or may not be a nonsignificant difference between the scores that represent the cognitive and academic areas of weakness. That is, in the DD/C definition, *consistency* refers to the fact that an empirical or ecologically valid relationship exists between the areas of identified cognitive and academic weakness, but not necessarily a nonsignificant difference between these areas. While a nonsignificant difference between the areas of cognitive and academic weakness would be expected, it need not be an inclusionary criterion for SLD. Because many factors facilitate and inhibit performance, a student may perform better or worse academically than his or her cognitive weaknesses may suggest (for a discussion, see Flanagan & Schneider, 2016; Flanagan et al., 2013; Flanagan, Alfonso, Sy, et al., 2018).

Discovery of consistencies among cognitive abilities and/or processes and academic skills in the below-average (or lower) range could result from ID, developmental disabilities, or generally below-average cognitive ability (this would negate two important markers of SLD: that cognitive weaknesses are domain-specific and that underachievement is unexpected) (see Lovett & Kilpatrick, 2018). Therefore, identification of SLD cannot rest on below-average cognitive aptitude–achievement consistency alone. A child with SLD typically has many cognitive capabilities. Therefore, in the DD/C definition, the child must also demonstrate at least average ability to think and reason (i.e., standard scores generally ≥ 85), despite cognitive weaknesses or deficits. For example, in the case of a young child with reading decoding difficulties, it would be necessary to determine that performance in areas less related to this skill (e.g., Gf, math ability) are about average or better. Such a finding would suggest that the related weaknesses in cognitive and academic domains are not due to a more pervasive form of cognitive dysfunction, thus supporting the notion of *unexpected underachievement*—that the child would be likely to perform within normal limits (e.g., at or close to grade level) in whatever achievement skill he or she was found to be deficient in, if not for *specific* cognitive ability or processing weaknesses or deficits. Moreover, because the child has generally average or better ability to think and reason, the academic skill deficiency is indeed unexpected. In sum, the finding of a pattern of circumscribed and related weaknesses (i.e., below-average cognitive aptitude–achievement consistency), despite at least average ability to think and reason (or a pattern of strengths) is convincing evidence of SLD—particularly when the student who demonstrates this pattern did not respond well to high-quality instruction, and when exclusionary factors were ruled out as the primary causes of the deficits.

At Least Average Ability to Think and Reason

An SLD is just what its full name indicates: *specific*. It is not general. As such, the below-average cognitive aptitude–achievement consistency ought to be circumscribed and represent a level of functioning significantly different from the student's cognitive capabilities or strengths in other areas. Indeed, the notion that students with SLD are of generally average or better overall cognitive ability is well known and has been written about for decades (e.g., Hinshelwood, 1917; Orton, 1937). In fact, the earliest recorded definitions of learning disability were developed by clinicians, based on their observations of individuals who experienced considerable difficulties with the acquisition of basic academic skills, despite their average or above-average general intelligence. According to Monroe (1932), "The children of superior mental capacity who fail to learn to read are, of course, spectacular examples of specific reading difficulty since they have such

TABLE 22.8. Description of the Below-Average Aptitude–Achievement Consistency of the DD/C Model and How It Is Determined by Using X-BASS

DD/C	X-BASS	Comments
Areas of cognitive and academic weakness are below average, and there is an empirical and/or ecologically valid relationship between them.	For this component of the PSW analysis, X-BASS answers two specific questions and based on the answers to those questions, provides a statement about the presence of below-average aptitude–achievement consistency. The first question is “Are the scores that represent the cognitive and academic areas of weakness actually weaknesses as compared to these areas in most people (i.e., below average or lower compared to same-age peers from the general population)?” The program parses the cognitive and academic weakness scores into three levels: < 85, 85–89 inclusive, and ≥ 90. Scores less than 85 are considered *normative* weaknesses; scores between 85 and 89 (inclusive) are considered weaknesses because they are below average; and scores of 90 or higher are not considered to be weaknesses. Next, the two scores (academic and cognitive) are examined relative to each other. When both scores are less than 85, the program will report a “Yes,” meaning that both scores are normative weaknesses. If one score is less than 85 and the other is between 85 and 89, the program will report “Likely.” If both scores are between 85 and 89 (inclusive), the program reports “Possibly” (because the scores are within normal limits, despite being classified as below average). The program will also report “Possibly” when one score is less than 85 and one is 90 or higher. If one score is between 85 and 89 (inclusive) and the other is 90 or higher, the program reports “Unlikely” and when both scores are 90 or higher, the program reports “No,” indicating that the scores cannot be considered weaknesses as compared to most people. The second question is “Are the areas of cognitive and academic weakness related empirically?” The strength of the relationship between the cognitive and academic areas of weakness is reported automatically by X-BASS as either LOW (median intercorrelation $< .30$), MODERATE or MOD) (median intercorrelation between .30 and .50), or HIGH (median intercorrelation $> .50$), based on a review of the literature (see Flanagan, Ortiz, & Alfonso, 2013; McGrew & Wendling, 2010) and the technical manuals of cognitive and intelligence batteries (e.g., WJ IV, WISC-V). Information regarding where the cognitive and academic weakness scores fall as compared to those for most people, and the strength of the relationship between the two areas, is used to answer the question “Is there a below-average aptitude–achievement consistency?” The answer automatically generated by X-BASS will be either “Yes, Consistent,” “No, Not Consistent,” or “Possibly, Use Clinical Judgment.” For example, if the cognitive and academic areas selected by the evaluator as weaknesses are associated with scores that fall below 85 and if the strength of the relationship between the areas of cognitive and academic weakness is moderate or high, then the program will report “Yes, Consistent.”	In some cases, the answer to the question of whether or not an individual’s PSW is marked by a below-average aptitude–achievement consistency may not be clear from the quantitative data alone. As such, it is always important to interpret an individual’s PSW within the context of all available data sources (e.g., exclusionary factors, behavioral observations, work samples) and render a judgment about SLD based on the totality of the data.

obvious abilities in other fields" (p. 23; cf. Mather, 2011). Indeed, "all historical approaches to SLD *emphasize the spared or intact abilities* that stand in stark contrast to the deficient abilities" (Kaufman, 2008, pp. 7–8; emphasis added).

Current definitions of SLD also recognize the importance of generally average or better overall ability as a characteristic of individuals with SLD. For example, the official definition of learning disability of the Learning Disabilities Association of Canada states in part, "Learning Disabilities refer to a number of disorders which may affect the acquisition, organization, retention, understanding or use of verbal or nonverbal information. These disorders affect learning in individuals who *otherwise demonstrate at least average abilities essential for thinking and/or reasoning*" (*www.ldac-acta.ca/learn-more/ld-defined*, emphasis added; see also Harrison & Holmes, 2012).

Unlike some definitions of SLD, such as Canada's, the IDEA 2004 definition does not refer to overall cognitive ability level. However, the 2006 federal regulations contain the following phrasing: "(ii) The child exhibits a pattern of strengths and weaknesses in performance, achievement, or both, relative to age, State-approved grade-level standards, or intellectual development, that is determined by the group to be relevant to the identification of a specific learning disability" (U.S. Department of Education, 2006). Given the vagueness of the wording in the federal regulations, one could certainly infer that this phrase means that the cognitive and academic areas of concern are significantly lower than what is expected, relative to those of same-age peers or relative to otherwise average intellectual development. Indeed, there continues to be considerable agreement that a student who meets criteria for SLD has *some* cognitive capabilities that are at least average in relation to those of most people (e.g., Alfonso & Flanagan, 2018; Berninger, 2011; Feifer, 2012; Fiorello, Flanagan, & Hale, 2014; Flanagan & Alfonso, 2017; Geary et al., 2011; Hale & Fiorello, 2004; Hale et al., 2011; Harrison & Holmes, 2012; Kaufman, 2008; Kavale & Flanagan, 2007; Kavale & Forness, 2000; Kavale et al., 2009; Mather & Wendling, 2011 and Chapter 28, this volume; McCloskey et al., 2012; Naglieri & Feifer, 2018; Shaywitz, 2003). Moreover, the criterion of overall average or better cognitive ability (despite specific cognitive processing weaknesses) is necessary for differential diagnosis (see Lovett & Kilpatrick, 2018).

When a student does not meet criteria specified in the DD/C operational definition of SLD, it is possible that the student exhibits *slow learning* (SL; i.e., below-average ability to learn and achieve). However, by failing to differentially diagnose SLD from SL or other conditions that impede learning (such as ID or pervasive developmental disorders), the SLD construct loses its meaning, and there is a tendency (albeit well intentioned) to accept anyone under the SLD category who has learning difficulties for reasons other than specific cognitive dysfunction (e.g., Kavale & Flanagan, 2007; Kavale, Kauffman, Bachmeier, & LeFever, 2008; Lovett & Kilpatrick, 2018; Mather & Kaufman, 2006; Reynolds & Shaywitz, 2009a, 2009b). According to Kavale and colleagues (2008, p. 145), "About 14% of the school population may be deemed SL, but this group does not demonstrate unexpected learning failure, but rather an achievement level consonant with IQ level . . . slow learn[ing] has never been a special education category, and 'What should not happen is that a designation of SLD be given to a [child with] slow learning' (Kavale, 2005, p. 555)." Although the underlying and varied causes of the learning difficulties of all students who struggle academically *should be investigated and addressed,* an accurate SLD diagnosis is necessary because it informs instruction (e.g., Hale et al., 2010). As such, it seems prudent for practitioners to adhere closely to the DD/C operational definition of SLD (or other alternative research-based models), so that SLD can be differentiated from other disorders that also manifest themselves in academic difficulty (Berninger, 2011; Della Toffalo, 2010; Lovett & Kilpatrick, 2018).

Although it may be some time before consensus is reached on what constitutes "at least average overall cognitive ability" or "at least average ability to think and reason" for SLD identification, a child who has SLD, *generally speaking,* ought to be able to perform academically at a level approximating that of his or her more typically achieving peers *when provided with individualized instruction as well as appropriate accommodations, and instructional and curricular modifications alongside remedial interventions.* In addition, for a child with SLD to reach performances (in terms of both rate of learning and level of achievement) approximating those of his or her nondisabled peers, the child must possess the ability to learn compensatory strategies and apply them independently; this often requires higher-level thinking and reasoning, including intact executive processes (see Maricle & Avirett, Chapter 36, this volume; McCloskey, Perkins, & Van Divner, 2009). Individuals with SLD can minimize the effects of cognitive processing weaknesses on their ability to access instruction and the curriculum under certain circumstances (Mascolo et al., 2014). Special education provides the mechanism to assist a child with SLD in minimizing or bypassing his or her processing deficits through individualized instruction and intervention and through the provision of appropriate adaptations, accommodations, remediation, and compensatory strategies. However, to succeed in minimizing the effects of an individual's cognitive processing weaknesses in the educational setting to the point of achieving at or close to grade level, at least average overall ability to think and reason is very likely to be requisite, especially in upper elementary school and beyond (see Fuchs & Young, 2006, for a discussion of the mediating effects of IQ on response to intervention). Of course, it is important to understand that while at least average overall ability to think and reason is probably necessary for a child with SLD to be successful at minimizing his or her cognitive processing deficits, many other factors may facilitate or inhibit academic performance, including motivation, determination, perseverance, familial support, quality of individualized instruction, student–teacher relationships, and existence of comorbid conditions (see Flanagan et al., 2012, for a discussion; see also Flanagan & Schneider, 2016).

Determining at least average ability to think and reason for a child who has a below-average cognitive aptitude–achievement consistency is not a straightforward task, and there is no agreed-upon method for determining this condition or even requiring this condition as part of a state's or district's SLD identification guidelines (i.e., it is part of some methods of SLD identification, but not all methods). The main difficulty in determining whether an individual with *specific* cognitive weaknesses has at least average ability to think and reason (as determined by an estimate of *g*)[3] is that the global ability score or scores available on a cognitive or intelligence battery may be attenuated by the cognitive processing weakness(es). Most batteries have a total test score that is an aggregate of *all* (or nearly all) abilities and processes measured by the instrument. As such, in many instances, an individual's specific cognitive weaknesses or deficits attenuate the total test score on these instruments. This problem with ability tests was noted as far back as the 1920s, when Orton stated, "It seems probably that psychometric tests as ordinarily employed give an entirely erroneous and unfair estimate of the intellectual capacity of these [learning disabled] children" (1925, p. 582; cf. Mather, 2011). Perhaps for this reason, intelligence and cognitive ability batteries have become more differentiated, offering a variety of specific cognitive ability composites and options for global ability estimates. Nevertheless, there is increasing agreement that a child who meets criteria for SLD has at least some cognitive capabilities that are indeed average or better (e.g., Berninger, 2011; Flanagan et al., 2008, 2017; Geary et al., 2011; Hale & Fiorello, 2004; Hale et al., 2010; Kaufman, 2008; Kavale & Flanagan, 2007; Kavale & Forness, 2000; Kavale et al., 2009; Naglieri & Feifer, 2018).

To determine whether a child who demonstrates a below-average cognitive aptitude–achievement consistency also has at least average ability to think and reason, consistent with the DD/C model, X-BASS is used (see Flanagan et al., Chapter 27, this volume). The X-BASS provides a means of parceling out cognitive deficits from global functioning and judging the robustness of the spared abilities or cognitive strengths. This program is not meant to replace clinical judgment, but rather to inform it. Others have also developed methods and suggested formulas for determining whether individuals have cognitive strengths that are in stark contrast to their cognitive weaknesses (Naglieri, 2011; see also Fiorello & Wycoff, Chapter 26, this volume). Ultimately, the determination regarding whether a child with a below-average cognitive aptitude–achievement consistency has an SLD (and not SL or ID, for example), or exhibits unexpected (not expected) underachievement, must rely to some extent on clinical judgment.[4] Such judgment, however, is bolstered by converging data from multiple sources that were gathered via multiple methods and clinical tools (Alfonso & Flanagan, 2018; Flanagan & Alfonso, 2011).

Even when it is determined that a student has overall average ability to think and reason, along with a below-average cognitive aptitude–achievement consistency, these findings alone do not satisfy the criteria for a PSW consistent with the SLD construct in the DD/C operational definition. This is because it is not yet clear whether the differences between the score representing overall ability and those representing specific cognitive and academic weaknesses or deficits are statistically significant, meaning that such differences are reliable differences (i.e., not due to chance). Moreover, it is not yet clear whether the cognitive area or areas of weakness are domain-specific, and whether the academic area or areas of weakness (or underachievement) are unexpected.

Domain-Specific Cognitive Weaknesses or Deficits: The First Discrepancy

SLD has been described as a condition that is *domain-specific*. In other words, areas of cognitive weakness or deficit are circumscribed, meaning that while they interfere with learning and achievement, they are not pervasive and do not affect all or nearly all areas of cognition. According to Stanovich (1993), "The key deficit must be a vertical faculty rather than a horizontal faculty—a domain-specific process rather than a process that operates across a variety of domains" (p. 279). It is rare to find an operational definition that specifies a criterion for determining that the condition is "domain-specific." Some suggest that this condition is supported by a statistically significant difference between a student's overall cognitive ability and a score representing the individual's cognitive area of weakness (e.g., Hale & Fiorello, 2004; Naglieri, 2011).

However, a statistically significant difference between two scores means only that the difference is not due to chance; it does not provide information about the *rarity* or infrequency of the difference in the general population. Some statistically significant differences are common in the general population; others are not. Therefore, to determine whether the cognitive area that was identified as a weakness by the evaluator is domain-specific, the difference between the individual's actual and expected performance in this area should be uncommon in the general population.

X-BASS is needed to conduct the calculations necessary (1) to determine if a proxy for *g* can be derived, based on the cognitive areas designated as strengths; and (2) to arrive at an overall ability (*g*) estimate. X-BASS then uses the individual's unique pattern of strengths (proxy for *g*) to predict where the individual was expected to perform in the cognitive domain that is weak, and reports whether the difference between predicted and actual cognitive performance is rare relative to same-age peers (i.e., occurs in about 10% or less of the general population). A rare difference is considered a *domain-specific weakness* (see Flanagan et al., Chapter 27, this volume, for more detail).

Unexpected Underachievement: The Second Discrepancy

Traditionally, ability–achievement discrepancy analysis was used to determine whether an individual's underachievement (e.g., reading difficulty) was unexpected (i.e., the individual's achievement was not at a level commensurate with his or her overall cognitive ability). A particularly salient problem with the ability–achievement discrepancy approach is that a total test score from a cognitive or intelligence test (e.g., Full Scale IQ or FSIQ) is often used as the estimate of overall ability. However, for an individual with SLD, the total test score is often attenuated by one or more specific cognitive weaknesses or deficits, and therefore may provide an unfair or biased estimate of the individual's overall intellectual capacity. Furthermore, when the total test score is attenuated by specific cognitive weaknesses or deficits, the ability–achievement discrepancy is often not statistically significant, which frequently results in denying the student much-needed academic interventions and special education services (e.g., Aaron, 1995; Hale et al., 2011). For this reason, the WISC-V includes the General Ability Index (GAI) as an alternative to the FSIQ and the WJ IV includes the Gf-Gc composite for use in comparison (discrepancy) procedures—an alternative that Flanagan and her colleagues have advocated for many years (e.g., see Appendix H in Flanagan, McGrew, & Ortiz, 2000; Appendix H in Flanagan et al., 2013).

The DD/C operational definition circumvents the problem that plagued traditional ability–achievement discrepancy methods by determining whether the individual has at least average ability to think and reason, *despite one or more cognitive areas of weakness*. As stated above, X-BASS calculates a proxy for *g* when an individual's designated areas of strength are sufficient for this purpose. X-BASS then uses this value to predict where the individual was expected to perform in the academic domain that is weak, and reports whether the difference between predicted and actual academic performance is rare relative to same-age peers (i.e., occurs in about 10% or less of the general population). A rare difference is considered *unexpected underachievement* (see Flanagan et al., Chapter 27, this volume, for more detail).

Level V: SLD's Adverse Impact on Educational Performance

When a child meets criteria for an SLD diagnosis (i.e., when criteria for levels I through IV are met), it is typically obvious that the child has difficulties in daily academic activities that need to be addressed. The purpose of the fifth and final level of evaluation is to determine whether the identified condition (i.e., SLD) impairs academic functioning to such an extent that special education services are warranted.

The legal and diagnostic specifications of SLD necessitate that practitioners review the whole of the collected data and make a professional judgment about the extent of the adverse impact that any measured deficit has on an individual's performance in one or more areas of learning or academic achievement. Essentially, level V analysis serves as a kind of quality control feature designed to prevent the application of an SLD diagnosis in cases in which "real-world" functioning is not in fact impaired or substantially limited, compared to that of same-age peers in the general population—regardless of the patterns seen in the data.

This final criterion requires practitioners to take a very broad survey not only of the entire array of data collected during the assessment, but also of the real-world manifestations and practical implications of any presumed disability. In general, if the criteria at levels I through IV have been met, it is likely that in the majority of cases, level V analysis serves only to support conclusions that have already been drawn. However, in cases where data may be equivocal, level V analysis is an important safety valve, ensuring that any representations of SLD suggested by the data are indeed manifested in observable impairments in one or more areas of functioning in real-life settings.

Children with SLD require individualized instruction, accommodations, and curricular modifications to varying degrees, based on such factors as the nature of the academic setting, the severity of the SLD, the developmental level of each child, the extent to which each child can compensate for specific weaknesses, the way instruction is delivered, the content being taught, and so forth. As such, some children with SLD may not require special education services, such as when their academic needs can be met through classroom-based accommodations (e.g., use of a word bank during writing tasks, extended time on tests) and/or differentiated instruction (e.g., allowing a student with a writing deficit to record reflections on a reading passage and transcribe them outside the classroom prior to submitting a written product). Other children with SLD may require both classroom-based accommodations *and* special education services. And in a case where a child with SLD is substantially impaired in the general education or inclusive setting, a self-contained special education classroom may be required to meet his or her academic needs adequately.

There are two possible questions at Level V that must be answered by the multidisciplinary team (MDT). First, can the child's academic difficulties be remediated, accommodated, or otherwise compensated for without the assistance of individualized special education services? If the answer is yes, then services (e.g., accommodations, curricular modifications) may be provided, and their effectiveness monitored, in the general education setting. If the answer is no, then the MDT must answer the second question: What are the nature and extent of special education services that will be provided to the child? In answering this question, the MDT must ensure that individualized instruction and educational resources are tailored to the child in the least restrictive environment. Furthermore, such interventions should be linked to assessment (i.e., the identified cognitive and academic weaknesses) and should be evidence based.

Summary of the DD/C Operational Definition of SLD

In the preceding paragraphs, we have provided a summary of the DD/C operational definition of SLD. This definition provides a research-based framework for the practice of SLD identification and is likely to be most effective when it is informed by advances in cognitive and neuropsychological theory and research that support (1) the identification and measurement of constructs associated with SLD; (2) the relationships between cognitive abilities and processes and academic skills; and (3) a defensible method of interpreting results. Among the many important components of the definition, we have focused primarily on specifying criteria at the various levels of evaluation to establish the presence of SLD in a manner consistent with IDEA 2004 and its attendant regulations. These criteria include identification of empirically related academic and cognitive abilities and processes in the below-average range, compared to those of same-age peers from the general population; determination that exclusionary factors are not the primary cause of the identified academic and cognitive deficits; and identification of a pattern of performance reflecting domain-specific cognitive weaknesses, unexpected underachievement, and at least average ability to think and reason.

When the quantitative criteria specified at each level of the operational definition are met, as determined by X-BASS, and exclusionary factors have been ruled out as the primary cause of learning difficulties, it may be concluded that the data gathered are sufficient to support a diagnosis or classification of SLD. Because the conditions outlined in Figure 22.2 are based on current SLD research, and the calculations carried out by X-BASS are psychometrically sound, the DD/C operational definition represents progress toward a more complete and defensible approach to the process of evaluating SLD than previous (and many competing) methods (see Flanagan et al., Chapter 27, this volume; Miller, Maricle, & Jones, 2016).

The PSW Approach in Perspective

Given its increasing popularity, research on the PSW approach is emerging. One emerging body of research indicates that there is a lack of agreement among PSW models. This research also suggests that PSW models are effective at determining *who does not have SLD,* but they are not as effective at determining *who does have SLD.* Valid points are made about potential weaknesses of PSW models in this literature (e.g., Kranzler, Floyd, Benson, Zaboski, & Thibodaux, 2016a, 2016b; Miciak, Fletcher, Stuebing, Vaughn, & Tolar, 2014; Stuebing, Fletcher, Branum-Martin, & Francis, 2012). However, it is important to understand that among the studies that have been conducted thus far, there are misrepresentations of PSW models, faulty assumptions about PSW models, and questions about the appropriateness of the methodology used to evaluate the assumptions underlying these models (see Flanagan & Schneider, 2016). Nevertheless, those engaged in PSW research should be commended for their work and for getting the conversation going. The current research has already sparked new ideas on how to evaluate the accuracy of the PSW approach more effectively (see Schneider's contribution in Flanagan, Alfonso, & Schneider, 2018; see also Miller et al., 2016).

Another emerging body of research provides support for a neuropsychological PSW approach (Hale et al., 2010, 2016). Specifically, this research shows the relevance of PSW methods for differential diagnosis of SLD in reading (e.g., Feifer, Nader, Flanagan, Fitzer, & Hicks, 2014), math (e.g., Kubas et al., 2014), and written expression (e.g., Fenwick et al., 2016). Valid points are made about the potential strengths of PSW models in this literature. Although valid points are made both for and against the use of PSW models, the results of the studies that have been published to date are affected by methodological preferences used to analyze the data, as well as the accuracy (and inaccuracy) of the assumptions made about each PSW model (for brief discussions, see Alfonso & Flanagan, 2018; Fiorello & Wycoff, Chapter 26, this volume; Flanagan & Schneider, 2016).

NOTES

1. Most individuals have statistically significant strengths and weaknesses in their cognitive ability and processing profiles. Intraindividual differences in cognitive abilities and processes are commonplace in the general population (McGrew & Knopik, 1996; Oakley, 2006). Therefore, statistically significant variation in cognitive and neuropsychological functioning in and of itself must not be used as de facto evidence of SLD. Instead, the pattern must reflect what is known about the nature of SLD (see Figure 22.2).

2. The term *causal* as used within the context of the DD/C model has been misconstrued to mean *deterministic*. That is, if we know the causal inputs, we can predict the outcome perfectly (Kranzler et al., 2016b). However, just because the causal inputs may be known, the outcomes clearly and obviously cannot be predicted perfectly. Cognitive abilities are indeed causally related to academic abilities, but the relationship is *probabilistic,* not deterministic, and is of moderate size (Flanagan & Schneider, 2016). The finding of cognitive weaknesses raises the risk of academic weaknesses; it does not guarantee academic weaknesses (Flanagan & Schneider), as assumed by Kranzler and colleagues. Likewise, it should not be assumed that the finding of academic weaknesses means that there are related cognitive weaknesses (again, a faulty assumption made by Kranzler et al.). As most practitioners know, in many cases there are no cognitive correlates to academic underachievement. This is because academic weaknesses may be related to numerous factors, only one of which is a cognitive weakness.

3. Many scholars use the term *overall cognitive/intellectual ability* interchangeably with the first factor that emerges in a factor analysis of cognitive tests—that is, Spearman's *g.* The estimates of overall cognitive or intellectual ability (or ability to think and reason) referred to in this chapter are consistent with this conceptualization.

4. Overall average (or better) cognitive ability or at least average ability to think and reason is difficult to

determine in students with SLD because their specific cognitive deficits often attenuate their total test scores (e.g., IQ). Therefore, such decisions should be based on multiple data sources and data-gathering methods. For example, a student with an SLD in mathematics may have a below-average WISC-V Full Scale IQ, due to deficits in processing speed and working memory (Flanagan & Alfonso, 2017; Geary et al., 2011). However, if the student has an average or better WISC-V GAI and average or better reading and writing ability, for example, then it is reasonable to assume that this student has at least average ability to think and reason. Of course, the more converging data sources that are available to support this conclusion, the more confidence one can place in such a judgment. The X-BASS calculates a value called the *facilitating cognitive composite (FCC)* that summarizes the individual's cognitive integrities or strengths when such a value is considered a good proxy of *g* given its constituents. The FCC is used in the PSW analysis conducted by X-BASS.

CHAPTER 23

Use of Intelligence Tests in the Identification of Children and Adolescents with Intellectual Disability

Ryan L. Farmer
Randy G. Floyd

Intellectual disability (ID)—previously called *mental retardation* (see Rosa's Law, 2010)—is characterized by significant deficits in intellectual and adaptive functioning, with onset during the developmental period (American Association on Intellectual and Developmental Disabilities [AAIDD], 2010; American Psychiatric Association [APA], 2013). *Intellectual functioning* is broadly defined by hierarchical composites (most typically IQs) that assess abstract thinking, judgment, learning, planning, problem solving, and reasoning. *Adaptive functioning*, or adaptive behavior, is defined by conceptual, practical, and social domains of behavior. Deficits in both intellectual and adaptive functioning need to be present and have an impact on the individual prior to age 18 in order for these deficits to be considered ID. While broad, this definition is commensurate with all clinical diagnostic (AAIDD, 2010; APA, 2013; World Health Organization [WHO], 2010, 2016) and governmental classification (Individuals with Disabilities Education Improvement Act of 2004 [IDEA, 2004]; McNicholas et al., 2018; Social Security Administration [SSA], n.d.) procedures for ID. The impact of ID on an individual can be significant. To better understand ID, it is beneficial to consider the presentation of individuals with ID, causal factors, prevalence and incidence rates, and comprehensive assessment of ID for the purposes of diagnosis and treatment.

PRESENTATION, EPIDEMIOLOGY, AND ETIOLOGY

Individuals with ID will present with a variety of intellectual and adaptive limitations, ranging from impairments in developmental repertoires (e.g., gross motor skills) to academic and social difficulties (APA, 2013; National Academies of Sciences, Engineering, and Medicine, 2015). Behavioral excess may also manifest partially as a result of reduced functional communication (McClintock, Hall, & Oliver, 2003). For instance, Cooper and colleagues (Cooper, Smiley, Allan, et al., 2009; Cooper, Smiley, Jackson, et al, 2009) determined prevalence rates of 6.3% for physical aggression, 4.9% for self-injurious behavior, and 3.0% for destructive behavior for children with ID. In addition to behavioral excess, behavioral deficits may warrant clinical or educational supports.

The international prevalence rate of ID—that is, the proportion of the population affected by ID—is highly variable across studies, but it is estimated to be 10.37 per 1000 in the population, or 1%, with a higher prevalence rate in males (McKenzie, Milton, Smith, & Oullette-Kuntz, 2016). Historically, IQ-only approaches to the diagnosis of ID would result in a prevalence rate of approximately 2–3%, based on a Gaussian curve. Within the clinical population, approximately 85%, 10%, 3.5%, and 1.5% of cases are classified at mild, moderate, severe, and profound levels of severity, respectively (National Academies, 2015). Furthermore, in the United States between 2008 and 2013, students with ID accounted for approximately 2% of children served via special educational programs (U.S. Department of Education, 2016). In terms of identification, individuals with dysmorphic features, documented microcephaly, or significant impairment, such as deficits in gross and fine motor skills or marked language delays, are more likely to be identified with ID within the first 2 years of life (APA, 2013).

The etiology of ID varies as significantly as its presentation. Prenatal influences include all known genetic and metabolic anomalies; malformations during brain development; *in utero* exposure to toxins, teratogens, drugs, and alcohol; and exposure to maternal or placental infection. Included within this broad category of prenatal influences, genetic disorders account for a significant proportion of ID cases, with estimates between 15 and 20% (see Kaufman, Ayub, & Vincent, 2010). For this reason, genetic counseling is frequently recommended if the etiology of ID is unclear (American Academy of Pediatrics & American College of Medical Genetics and Genomics, 2013). Perinatal influences are those that occur immediately before, during, or after birth, and include a variety of childbirth-related traumas. Finally, postnatal influences are those that occur after childbirth and include infection; neurocognitive disorders, including both open and closed head injuries, as well as congenital and degenerative conditions; exposure to toxins; and sustained social deprivation. A comprehensive review of the epidemiology and etiology of ID is outside the scope of this chapter (see Walker & Johnson, 2006).

DEFINITION OF ID

ID has been defined by various diagnostic and classification criteria (see Table 23.1). Fortunately, the diagnostic criteria for ID are largely similar across organizations and have been relatively stable since 1958 (AAIDD, 2010). However, updates and minor inconsistencies may affect the assessment process and identification rate. For example, Papazoglou, Jacobson, McCabe, Kaufmann, and Zabel (2014) found that changes to the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5; APA, 2013) criteria may result in as much as a 9% reduction in diagnosis rates when compared to diagnosis rates based on the previous version of the DSM (APA, 2000).

A number of sources have outlined the differences among the various sets of criteria for ID (e.g., Floyd, Woods, Singh, & Hawkins, 2016), but few have included comparisons with (1) the *International Statistical Classification of Diseases and Related Health Problems*, 10th revision, second edition (ICD-10; WHO, 2004); (2) its probable successor, the beta draft of ICD-11 (WHO, 2016); (3) IDEA (2004) eligibility criteria; and (4) SSA (n.d.) criteria. For the most part, all agencies utilize three classification elements: deficits in (1) intellectual functioning, (2) adaptive functioning, and (3) onset during the developmental period. As with any operational definition, diagnostic criteria should be judged on the basis of their objectivity, clarity, and completeness (Hawkins & Dobes, 1977). In this case, the classification elements of the definition can be deemed present or absent in a systematic, measurable manner; are clear, without need for further interpretation; and are accompanied by boundary conditions that are delineated so that one can be included or excluded on the basis of objective data. Accordingly, the definition provided by the AAIDD (2010) is the most precise one available.

Intellectual Deficits

The AAIDD (2010), APA (2013), SSA (n.d.), and WHO (2004, 2016) define deficient intellectual functioning as an IQ at approximately two standard deviations or below (see the second column in Table 23.1). The language of these guidelines specifying that an IQ “equal to or below” two standard deviations below the mean is fairly consistent between organizations, and this criterion translates into a standard score equal to or below 70 on most intelligence tests. Only ICD-10 (WHO, 2004) requires a standard score below 70, with no provision for a diagnosis when an IQ is equal to 70. The outlier, IDEA (2004), specifies that intellectual functioning must be “significantly subaverage” with no quantifiable definition of subaverage. In response to the lack of specificity offered by the federal definition, many states have specified cutoff scores for IQ (McNicholas et al., 2018).

Adaptive Behavior Deficits

Historically, the focus in evaluating ID has been on intellectual functioning, but the most recent versions of the AAIDD (2010) and APA (2013)

TABLE 23.1. Intellectual Disability (ID) Criteria by Agency or Group

Agency or group	Intellectual deficit	Adaptive deficit	Onset	Level of impairment
AAIDD (2010)	IQ: ~ ≤2 *SD*	Overall or domain score; ≤2 *SD*	<18 years of age	Adaptive functioning and level of ongoing supports
DSM-5 (APA, 2013)	IQ: ~ ≤2 *SD*	At least one domain; sufficient impairment requiring ongoing support	Developmental period, often with early manifestation	Adaptive functioning and level of ongoing supports
ICD-10 (WHO, 2004)	IQ: <2 *SD*	Supplemental only	Developmental period implied	Intellectual impairment
ICD-11 beta draft (WHO, 2016)	IQ: ≤2 *SD*	Adaptive functioning; ≤2 *SD*	Developmental period	Adaptive and intellectual impairment
IDEA (2004)	Significantly subaverage general intellectual functioning	Adaptive behavior deficits	Developmental period	Level of impairment not delineated; impairment must impede educational performance
SSA (n.d.)	Significantly subaverage general intellectual functioning: A full-scale IQ of 70 or below, *or* a full-scale IQ of 71–75 and part score of 70 or below	Significant deficits in adaptive functioning in two broad areas	<18 years of age	Not delineated in definition

Note. IQ is used in this table to indicate composites representing psychometric *g*; such composites may not utilize the term *IQ*. AAIDD, American Association on Intellectual and Developmental Disabilities; APA, American Psychiatric Association; DSM-5, *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition; ICD-10, *International Statistical Classification of Diseases and Related Health Problems,* 10th revision, second edition; ICD-11 beta draft, *International Statistical Classification of Diseases and Related Health Problems,* 11th revision, beta draft; IDEA, Individuals with Disabilities Education Improvement Act of 2004; *SD,* standard deviation; SSA, Social Security Administration; WHO, World Health Organization.

definitions, and upcoming iterations of the WHO (2016) definition, are emphasizing adaptive functioning and the intensity of necessary supports in the home, school, and community. The SSA (n.d.) requires evidence of adaptive deficits across domains, but does not specify the type of evidence required. Overall, more variability is noted regarding the adaptive deficits category than the intellectual deficits category. These criteria are presented in the third column of Table 23.1. The AAIDD (2010), DSM-5 (APA, 2013), ICD-11 beta draft (WHO, 2016), IDEA (2004), and SSA (n.d.) require that adaptive deficits be documented. Only ICD-10 (WHO, 2004) considers adaptive behavior deficits to be supplementary information. However, even within those that require the documentation of adaptive deficits, the AAIDD and APA criteria permit clinicians to diagnose ID when a deficit is noted in only one domain of adaptive behavior (practical, social, or conceptual). The AAIDD also permits consideration of a composite adaptive score, whereas the ICD-11 beta draft (WHO, 2016) seemingly requires a composite adaptive score. Again, IDEA (2004) utilizes the least specific language, in that it only requires that deficits in adaptive behavior be present. Only about half of states specify the type of adaptive scores that should be considered; most do not specify cutoff criteria (McNicholas et al., 2018).

Age of Onset

Age of onset serves as the third functional component of the diagnostic criteria. Although there is minor variability in the terminology used across criteria, it is largely agreed that age of onset should be prior to age 18 (AAIDD, 2010). In the fourth column of Table 23.1, the onset criteria are specified. Only ICD-10 (WHO, 2004) does not specify the developmental period, which is only heavily implied in its description of ID. DSM-5 (APA, 2013) specifies that identification typically occurs during the early developmental period, and defines this period of time as prior to entering first grade.

CONSIDERATIONS IN MAKING A DIAGNOSIS

When a clinician is considering ID as a diagnosis, a number of factors may confound the assessment process. These factors fit into two broad categories: (1) competing hypotheses regarding the appropriate diagnosis, and (2) construct-irrelevant influences that reduce the validity of the assessment results. In addition to considering competing hypotheses and construct-irrelevant influences, clinicians should consider the influence of culture and language.

Differential Diagnosis

When a clinician is presented with a referral concern that warrants a comprehensive assessment for ID, common competing hypotheses that should be ruled out or considered for children include autism spectrum disorder (ASD), assorted communication disorders (CD), global developmental delay (GDD), neurodevelopmental disorders (NDD), and neurocognitive disorders (NCD). The process of addressing, considering, and accepting or ruling out competing diagnostic hypotheses is *differential diagnosis* (APA, 2013). Although these issues must be considered, it is of note that ASD, CD, and NCD can all be comorbid with ID if a comprehensive assessment reveals that the child or adolescent meets all relevant criteria. DSM-5 (APA, 2013) specifies that a diagnosis “should be made” (p. 39) when all three elements of the operational definition are met; however, clinicians should not diagnose ID solely on the presence of genetic or other primary medical conditions (e.g., Down syndrome). In general, clinicians should be knowledgeable about related diagnoses as well as appropriate procedures for ruling out competing hypotheses. Brief descriptions of major confounding diagnoses and their relation to ID are provided below; for the sake of brevity, DSM-5 nomenclature is employed throughout.

ASD is a pervasive developmental disorder that affects social-emotional functioning and is perhaps the most challenging co-occurring diagnosis to disentangle from ID, due to significant behavioral similarities between the two clinical populations (Matson & Shoemaker, 2009). The most salient factors in discriminating between ASD and ID are language development and social skills. A comprehensive assessment should be conducted by an interdisciplinary team of clinicians with sufficient expertise to determine whether the child or adolescent warrants a single diagnosis (i.e., ASD or ID) or dual diagnoses (i.e., both ASD and ID). Clinicians are strongly encouraged to engage in continuing education, due to the rapid progress of research in this area and advancement of best practices (see Volkmar et al., 2014). Of note, children with ASD may present with challenging behavioral topographies that further reduce the validity of standardized testing. Test examiners should have expertise with the types of behavior that may be present or should consult an expert in the area.

CD is a broad term encompassing language delays, disorders, and related language impairment, and has an estimated prevalence of 6–18% (American Speech–Language–Hearing Association, n.d.). As many as 4% of children with ID also present with comorbid CD (Pinborough-Zimmerman al., 2007). Children with CD may perform poorly on language-laden components of intelligence tests and may receive lower adaptive ratings in areas such as communication, preacademic skills, and social skills (American Speech–Language–Hearing Association, n.d.; Fujiki, Brinton, & Todd, 1996; Harrison & Oakland, 2015). When CD is suspected, consultation with a speech–language pathologist is strongly encouraged, and a comprehensive, interdisciplinary evaluation is necessary to make a differential diagnosis.

GDD is defined as deficits in a variety of developmental domains, such as intellectual functioning, adaptive functioning, or gross motor skills (Shevell, 2008). Pragmatically, DSM-5 (APA, 2013) has maintained this definition, which has also included children who cannot undergo diagnostic assessment for any number of reasons or who are too young to undergo such testing. That is, children ages 4 years, 11 months and younger may be diagnosed with GDD when a pattern of developmental deficits is present, but data regarding intellectual functioning or “clinical severity”

(APA, 2013, p. 41) is absent or unreliable. Similarly, for individuals older than 5 years of age, a diagnosis of unspecified intellectual disability (intellectual developmental disorder) may be provided in extenuating circumstances, such as when physical impairments or severe problem behaviors interfere with assessment (APA, 2013). GDD and unspecified ID are unique among the other disorders listed in this section, as they are exclusionary of a diagnosis of ID. These diagnostic classifications are only utilized in the event that relevant information is unavailable, but the preponderance of evidence supports a diagnosis.

Additionally, some children do not meet criteria to satisfy all classification elements of ID or other specific developmental disorders (e.g., GDD), but still have significant impairment in social, occupational, or other domains that warrants clinical services. Such children may be diagnosed with NDD. Clinicians may choose to specify the etiology of that disorder (e.g., NDD associated with prenatal alcohol exposure) or not (i.e., unspecified NDD). Differentiating GDD and unspecified ID from NDD may be challenging, but it should be based on a thorough review of all relevant criteria. NDD is, by default, a broader category than GDD or unspecified ID, but it does not include those situations described previously where valid results are unavailable. Similar to GDD and unspecified ID, NDD is exclusionary of a diagnosis of ID (APA, 2013). Uniquely, ICD-10 (WHO, 2004) also includes borderline intellectual functioning (BIF), which has the sole classification element that an individual's IQ is between 71 and 84. It is clear upon review that this version of BIF overlaps with NDD, but it does not require functional impairment in any domains. DSM-5 (APA, 2013) defines BIF similarly, but does not recognize it as a mental disorder; rather, it is considered a condition or problem that may justify assessment (e.g., cognitive testing) or treatment (e.g., discrete-trial training) procedures when the primary diagnosis does not solely warrant such procedures. It is recommended that clinicians use BIF solely as a modifier or to justify initial assessment (e.g., rule-out of ID) and not as a stand-alone diagnosis.

The group of disorders known as NCD, including traumatic brain injury, is characterized by regression in both cognitive and adaptive domains. The rate of acquired NCD (i.e., traumatic brain injury) requiring hospitalization is of significant concern among child and adolescent populations, with incidence rates as high as 74 in 100,000. Of those, the estimated prevalence of disability is as high as 20% (Thurman, 2014). The criteria for major NCD echo the first two elements of the criteria for ID: deficits in (1) intellectual functioning and (2) adaptive functioning (APA, 2013). One primary distinction between ID and NCD is that ID requires that onset of the deficits occur during the developmental period. Furthermore, the criteria for NCD only specify that the impacted domain demonstrates a noticeable decline from previous levels of functioning. When NCD results in stable cognitive and adaptive deficits that would otherwise meet the criteria for ID and the individual is within the developmental period, the child or adolescent is said to have met all of the classification elements of ID and could receive both diagnoses (APA, 2013).

Construct-Irrelevant Influences

The accurate assessment of ID is of utmost importance, and thus clinicians should act purposefully to ensure that their test results are valid (Bracken, 2000). A number of individual variables may result in *construct-irrelevant* influences, which introduce error and reduce the validity of assessment results. Stable construct-irrelevant influences include sensory (e.g., visual or auditory) impairments, physical (e.g., fine or gross motor) impairments, and speech and language impairments. Transient construct-irrelevant influences include fatigue, interfering behavioral topographies (e.g., impulsivity and noncompliance), illness, motivation, and mood lability (Bracken, 2000; Kranzler & Floyd, 2013). Identifying construct-irrelevant influences prior to assessment provides an opportunity for the clinician to consider modifying the assessment battery and to consider the use of testing accommodations. Any number of strategies and accommodations may be warranted to minimize construct-irrelevant influences or to elucidate results in light of a competing diagnostic hypothesis (see Herschell, Greco, Filcheck, & McNeil, 2002; Wechsler, 2014).

Culture and Language

Culture is a constellation of learned behaviors that are transferred between people within a given group. Culture shapes one's experiences through complex, culture-specific contingencies (Glenn, 2004). According to this logic, it is clear that all behavior is directly or indirectly shaped by cultural experiences. Based on the understanding that psychometric instruments measure samples of behavior, it is also logical that the assessment results obtained through the use of such measures are culturally shaped (Valencia & Lopez, 1992). In order to understand assessment results fully, clinicians must be familiar with the cultural backgrounds of their clients, as well as the cultures of the local community and of the local student population (Rhodes, Ochoa, & Ortiz, 2005).

As with culture, language proficiency and linguistic background can have a significant impact on the assessment results of children and adolescents from diverse backgrounds. Mather and Wendling (2014) posited that "the most important accommodation for students who are English language learners (ELL) is having an examiner who is knowledgeable about important issues relevant to second language acquisition, the assessment process, and the interpretation of test results for students" (p. 43). Clinical judgment in relation to how cultural and linguistic factors may influence assessment is paramount when a clinician is interpreting the many pieces of data obtained during the assessment process. Luckasson and Schalock (2015) provide an excellent review of the standards of clinical judgment within the field of ID, and a commentary about the necessity for considering cultural and linguistic factors.

BEST PRACTICES IN THE ASSESSMENT OF ID

A comprehensive, multidimensional assessment of ID goes beyond classification and must consider the individual from an ecological, reciprocal perspective (see Figure 23.1). The AAIDD (2010) provides a multidimensional framework of human functioning encompassing five domains: (1) intellectual abilities, (2) adaptive behavior, (3) health, (4) participation, and (5) context of the individual. Information pertaining to each domain is necessary for understanding assessment results and for

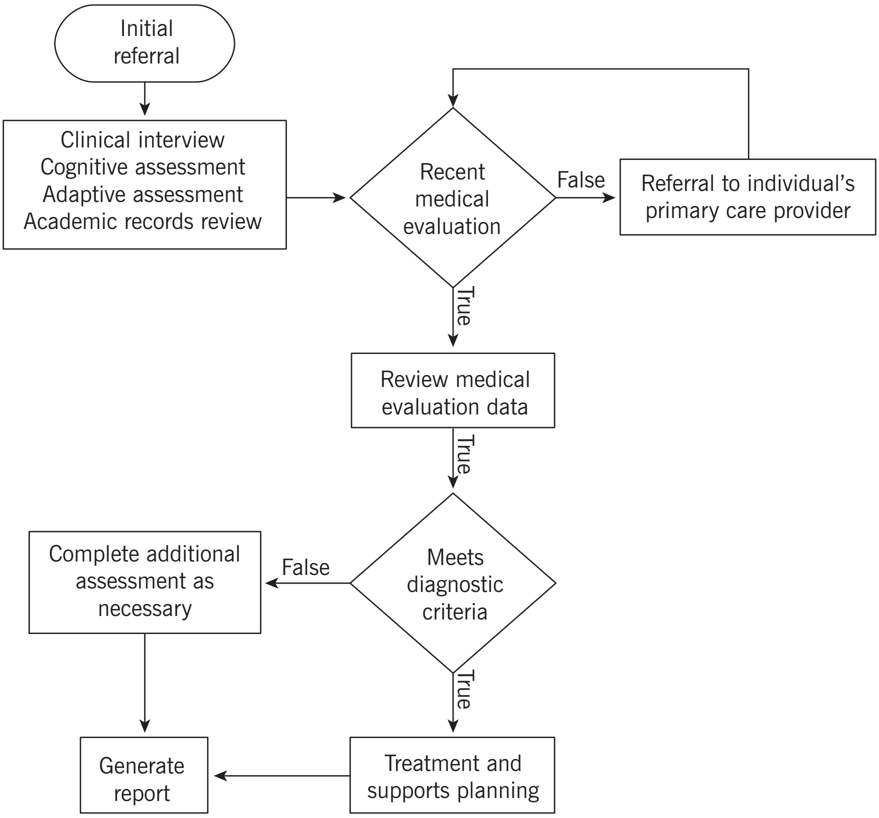

FIGURE 23.1. Process map for the assessment of ID.

successful treatment planning. In order to develop best practices in regard to ID assessment, it is necessary to consider how a clinician might go about evaluating each of the five domains. In general, a comprehensive and focused clinical interview is the foundation of the assessment process, and it should provide guidance for continued assessment across the five dimensions of human functioning.

Dimension 1: Intellectual Functioning

Intellectual functioning is typically assessed based on results from an individual, norm-referenced cognitive ability test battery like those described extensively elsewhere in this book, but we do not review such batteries in this chapter. Instead, we describe the importance of the scores these batteries yield during the assessment process. Generally speaking, best practices in the assessment of intellectual functioning include interpreting global composite scores, considering confidence intervals surrounding those scores, ensuring that the assessment instruments used are appropriate for the individual and are psychometrically sound, and completing accurate and standardized test administrations. The final section of this chapter also addresses controversial practices associated with the assessment of intellectual functioning.

Dimension 2: Adaptive Behavior

Adaptive functioning is an assortment of conceptual, practical, and social skills that an individual uses on a day-to-day basis. Adaptive behaviors make up an important dimension of human functioning as defined by the *International Classification of Functioning, Disability and Health* (ICF; WHO, 2001), and understanding an individual's adaptive skills not only constitutes the second classification element for a diagnosis of ID, but also informs treatment planning and supports. To determine whether an individual meets the criteria for a diagnosis of ID, norm-referenced instruments should be used with multiple, informed stakeholders (e.g., parent and teacher) to obtain cross-setting ratings of the individual's everyday performance. For more information on available instruments and recommendations for practice, see Floyd and colleagues (2015).

In addition to norm-referenced instruments, we encourage clinicians to consider criterion-referenced instruments (Partington, 2010), direct observations of adaptive behavior (Mannix, 2009), semistructured interviews with the client and stakeholders related to specific adaptive behavior strengths and weaknesses (Thompson et al., 2004), and combinations thereof, in order to facilitate treatment and supports planning. For young children and adolescents, we encourage clinicians to include instruments such as the Assessment of Basic Language and Learning Skills—Revised (Partington, 2010); the Verbal Behavior Milestones Assessment and Placement Program (Sundberg, 2008); and the Supports Intensity Scale (Thompson et al., 2004). These instruments, more so than others, can help to identify key areas for intervention development.

Dimension 3: Health

The AAIDD (2010), in alignment with the WHO (2001), defines *health* broadly as a client's physical health, mental health, and social well-being. Reviewing medical history, developmental history, and current medical status during a clinical interview is a key component, while consultation with the client's primary care provider provides continuity of care and ensures that an updated medical examination has been completed for the individual. Consultation with a pediatrician may yield significant information that directly affects primary and secondary diagnoses and the development of treatment goals and supports. Furthermore, engaging in multidisciplinary or interdisciplinary practice with the child or adolescent's primary care provider facilitates referrals and client care. Whenever possible, continuing communication between providers is recommended.

Dimension 4: Participation

A significant component of human functioning is the ability to engage with others socially; to take part in activities; and to assume roles in the home, school, workplace, and community. *Participation* is broadly defined as an individual's engagement in these activities in a manner typical of the person's culture and age group (AAIDD, 2010; WHO, 2001). Clinicians should consider participation during their broad screening of adaptive and intellectual functioning, and should consider how the child or adolescent's functioning affects his or her level of participation across domains. Additionally, clinicians should weigh the benefits of engaging in direct observation of behavior across settings, in an effort to better understand barriers to participation and to determine how supports may facilitate engagement.

Dimension 5: Context

An individual's context should be considered from an ecological perspective (Bronfenbrenner, 1979), wherein interactions with the individual's immediate environment, his or her community, and the encompassing culture and society are considered. These systems may affect an individual's various opportunities, expectations, resources, and social interactions. Broadly, clinicians should consider (1) personal factors, such as characteristics of the individual and family, specific strengths and weaknesses, and familial support; and (2) environmental factors, such as societal attitudes, accessibility, and community supports. Clinicians should also consider advantages and barriers across settings and within the community, the possible impact of the individual's health status on his or her functioning, and the person's level of social supports.

It is beyond the scope of this chapter to review each of these dimensions fully, but we encourage the reader to consider how the distinct components converge to provide a comprehensive perspective of the individual, his or her personal strengths and limitations, and the strengths and limitations of the environment. Not only is consideration of these five dimensions useful for the purpose of diagnosis, but it is also critical to developing appropriate and sufficient treatment and support plans.

ASSESSMENT OF INTELLECTUAL FUNCTIONING

What IQs Measure

As evident in Table 23.1, there is a historical and general consensus that intellectual deficits are best measured by global ability composites from cognitive ability test batteries that are broad in scope and multidimensional in their measurement. Although these global ability composites are no longer based on a ratio of mental age and chronological age that produces a true quotient, the term *intelligence quotient* (IQ) is often used to encapsulate a diversity of specific score labels. Throughout the remainder of this chapter, we use this term.

IQs from individually administered cognitive ability test batteries are typically derived from summing norm-referenced scores corresponding to component parts (i.e., subtests), which are often tasks containing similar items scaled in increasing difficulty. When these scores are aggregated, the effects of shared cognitive abilities are magnified, and the effects of cognitive abilities unique to each task are minimized. The product is a more general measure of intellectual abilities than any task could represent alone. In the same vein, this process of aggregation also increases the reliability of IQs; reliability is a much-valued property, especially when clinicians are making high-stakes diagnostic decisions based on these scores. IQs very frequently demonstrate reliability estimates of .95 and higher (Kranzler & Floyd, 2013), which is a very high standard not typically met by other measures in psychology. Reliability is discussed later in this chapter.

The AAIDD (2010) makes explicit references to *general mental ability* (a.k.a. psychometric *g*) as the focal point in assessment of intellectual functioning. Some of our research with various colleagues in recent years has investigated how well IQs from cognitive ability test batteries measure this psychological construct. This research used two methods to examine the "*g* saturation" of IQs derived from some of the most prominent test batteries available for children and adolescents. First, Reynolds, Floyd, and Niileksela (2013) employed confirmatory factor analysis methods applied to norming sample data from subtests from three batteries. These analyses produced a statistic called *hierarchical omega*, which represented the percentage of variance in the IQs that could be attributed to psychometric *g*. Results showed that 82–83% of this variance could be attributed to this construct. Clearly, these IQs are highly *g*-saturated.

In addition, we (Farmer, Floyd, Reynolds, & Kranzler, 2014) drew data from three validity studies, in each of which two test batteries were administered to the same sample of children and adolescents. Confirmatory factor analysis was used to create a latent variable representing the construct of psychometric *g* from one test battery. Then this latent variable was correlated with the IQ from the other test battery (administered concurrently). Results revealed very strong correlations and substantial *g* saturation across five IQs. Similar to the Reynolds and colleagues (2013) results, 77– 90% (M = 85%) of variance in the IQs could be attributed to psychometric *g*. Based on both measurement theory and psychometric analyses, the IQs yielded by these cognitive ability test batteries appear to be good representations of the construct they target. These values do not by any means indicate perfect measurement accuracy, but they do reflect remarkably high relations between a score used in the practice of psychology and the psychological entity it targets.

Reynolds and colleagues (2013) employed complete norming sample datasets, and we (Farmer et al., 2014) employed much smaller validity study samples including typically developing students. These samples were not "clinical samples," selected on the basis of some condition or diagnosis. As a result, it is unclear whether these results would generalize to those who are not typically developing—especially students with ID. Research by Detterman and Daniel (1989), Reynolds, Keith, and Beretvas (2010), and Reynolds (2013) focused on *Spearman's law of diminishing returns* (SLODR), providing keen insights into the *g* saturation of IQs with children and adolescents with (or suspected of having) ID. Sometimes called *ability differentiation,* SLODR reflects the finding that individual tasks included in cognitive ability test batteries correlate more strongly as general mental ability levels decrease across samples (and vice versa). Following SLODR, one can reason that IQs (as reflections of common variance across correlated tasks) are better measures of psychometric *g* for those who have ID than those at higher general ability levels—those with IQs in the average range and those with intellectual giftedness.

Using data from the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007) norming sample, and calculating hierarchical omega coefficients as mentioned previously, Reynolds (2013) demonstrated that the *g* saturation of a global composite formed from five DAS-II composite scores ranged from 89 to 92% across age groups for those with IQs of 70 and below. The *g* saturation was much weaker for other ability groups, as it ranged from 83 to 86% for those with IQs of approximately 100, and 54 to 66% for those with IQs of 130 or higher. (Recall that similar values from Reynolds et al., 2013, using the full ability range, spanned 82–83%.) Although these findings bring into question the validity of using IQs to represent psychometric *g* when those with high IQs are assessed, they strengthen the support for using IQs as the key measure reflecting intellectual functioning during the assessment of ID. Thus, consistent with SLODR, IQs are likely to be better measures of their targeted construct with those most likely to complete assessments targeting ID symptoms (all things being equal) than with those at higher general ability levels.

Preconditions for Testing

As noted previously, in order to be confident that IQs from the most well-developed cognitive ability test batteries measure psychometric *g* with integrity for each individual being tested, it is necessary that those engaged in assessment identify potential confounds that may surface during testing and make efforts to eliminate or accommodate them. In contrast to an assessment model that highlights understanding of the construct-relevant and construct-irrelevant reasons for score variation after testing has been completed (e.g., National Research Council, 2002; Sattler, 2008), a model that reduces or eliminates the effects of construct-irrelevant influences prior to testing would be ideal (Bracken, 2000). As many children and adolescents with ID display concomitant sensory impairments, physical disabilities, or behavioral excesses, this population may be at particular risk for underperformance during testing. In other words, because of these construct-irrelevant influences, the truest estimates of intellectual functioning may be underestimates. For example, children experiencing fine motor problems will likely perform more slowly than expected when asked to construct patterns with blocks and complete puzzles when given puzzle pieces, regardless of their "visual processing" abilities. As a result, these children may not be awarded time bonuses that are sometimes available, and they may fail items they otherwise would have completed if they had been provided more time.

To address these construct-irrelevant influences, we (along with our colleagues) developed parent and teacher ratings scales, an interview, and direct screening measures to better identify such problems before testing begins. Published in part in Kranzler and Floyd (2013), the Screening Tool for Assessment (STA) targets vision problems, color blindness, hearing problems, articulation problems, fine motor problems, and behavioral excesses that might interfere with the accurate measurement of intellectual abilities during testing. The STA parent and teacher rating scales each include 32 items that might indicate problems in these areas. The STA Direct Screening Form includes a nine-item semistructured interview that addresses readiness for testing; the prior night's sleep; and sensory, speech, and motor problems. It is followed by informal direct screening measures in which examinees are asked to identify letters that decrease in size (vision screening), label color (color blindness screening), complete simple commands to point to body parts (hearing screening), repeat words comprising letter patterns associated with common articulation problems (articulation screening), and trace lines and write a short sentence with a pencil (fine motor screening). Since the publication of the STA in 2013, a vision screening form that includes line drawings versus letters has been developed for those who have not yet learned the names of letters, but can name what is depicted in simple drawings. (The vision screener can be obtained by contacting either of us chapter authors.) Although, to our knowledge, they have not been extensively used and evaluated by experts in the field and with large numbers of students with ID, these screening forms may assist examiners in identifying construct-irrelevant influences before testing. Some modifications may be needed, however, with lower-functioning and younger students with ID.

Psychometric Considerations in Test Selection and Interpretation

Those engaged in assessment of ID should be aware of psychometric considerations when they are selecting and completing cognitive ability test batteries. Kranzler and Floyd (2013) have offered a checklist designed to guide assessors through consideration of these key features, which include the quality of the test battery's norming; subtest, test, and IQ scaling; reliability; and validity evidence. In the sections that follow, we highlight these key features and standards for evaluating scores from cognitive ability test batteries and adaptive behavior instruments.

Norming

It is important that those engaged in assessment of ID draw upon cognitive ability test batteries that are supported by the largest, most expansive, and most recent norming sample data (National Research Council, 2002). Of course, larger norming samples are likely to produce more accurate indications of the relative discrepancy between one individual's measured intellectual ability and that of their age-based peers. Like survey poll results, smaller samples are likely to be less accurate in their results than larger samples. In the case of cognitive ability test batteries, the size of the total norming sample matters less than the size of the norm group to which the individual is compared because those comparisons are uniformly age-based. Some standards suggest that 1-year norm intervals should include at least 100 individuals to be considered adequate (e.g., Hammill, Brown, & Bryant, 1992). More recently, attention has been paid to evaluating the size of norm intervals associated with more narrow segments of the norming sample (e.g., 1-month to 6-month intervals) associated with norm tables provided by the test publishers. According to Norfolk and colleagues (2015), the following evaluation scheme can be employed in evaluating norming sample size: *good* when at least 100 children and adolescents are included per norm interval, *adequate* when 30–99 children and adolescents are included, and *inadequate* when fewer than 30 children and adolescents are included. In addition to being large, the norming sample should be representative of the targeted population. Thus it is desirable that it represent the demographic characteristics of that population and be considered nationally representative. Floyd and colleagues (2015) have suggested that similar criteria can be applied in examining sampling across states: *good* with sampling across at least 35 states, *adequate* with sampling across 25–35 states, and *inadequate* with sampling across less than 25 states.

A more systematic influence on test scores that is highly relevant to ID assessment is the recency of the norming data. In accordance with the Flynn effect (Flynn, 1984; Trahan, Stuebing, Hiscock, & Fletcher, 2014), norming data collected more recently will produce lower scores than those collected decades before on contemporaneous assessments. As such, older norming sample data will inflate the estimate of an individual's intellectual functioning and potentially lead to failure to identify ID in cases in which it exists (McGrew, 2015b). Following extensive research focused on the Flynn effect, one might generally expect that IQs will be inflated 3 points for every decade between the collection of the norming data and testing, so that a test normed in 2006 could be expected to produce an IQ 3 points higher than a test that was normed in 2016 if both were administered to the same individual in 2017. Across the span of 15 years, this inflation would approximate 5 IQ points. This predicable influence due to the Flynn effect might tip the scales in undermining an otherwise accurate assessment of intellectual functioning; thus, it should be acknowledged and controlled. Following Alfonso and Flanagan (2009) and Floyd and colleagues (2015), Floyd and colleagues (2016) have offered these standards for evaluating the recency of norming samples: "*good* when at least some of the norming data (when a range of data collection was reported) were collected within the past 10 years, *adequate* when data were collected within the past 15 years, and *inadequate* when all data were collected more than 15 years ago" (p. 275).

Scaling

The range of scores produced by cognitive ability test batteries should also be considered. During the assessment of ID, it is important that the IQs be able to measure intellectual functioning at its lowest levels. Across recently published test batteries, IQs most frequently range from about 40 to about 160, and relatively few produce IQs that fall below 40 (Kranzler & Floyd, 2013). This range is generally satisfactory for identifying most cases of ID (based on the criteria of IQs of appropriately 70 or lower evident in Table 23.1); an IQ of 40 is more than two standard deviations below 70. Limitations in test batteries producing problems in measuring intellectual functioning at the lowest levels of ability are called *floor violations*, and they are typically evident at the task (e.g., subtest or test) level. Floor violations reflect the fact that there are not enough easy items associated with each subtest or test, so that some children or adolescents cannot answer at least one item correctly. According to a traditional standard (Bracken, 1987), a floor violation occurs when a subtest or test raw score of 1 does not produce a norm-referenced score at least two standard deviations below the mean. This means that a raw score of 1 should be equal to a scaled score of 4 or lower, a *T* score of 30 or lower, and a deviation IQ of 70 or lower. It is wise to examine this information (often apparent in norm tables) before testing begins, while considering the age of the examinee. Floor violations are most evident at the young age levels of test batteries, and test batteries with multiple floor violations are likely to overestimate intellectual functioning and fail to correctly identify true cases of ID.

Reliability and Confidence Intervals

Reliability refers to consistency in measurement across replications, and it is a very important characteristic to consider in the assessment of ID. The reliability of IQs is typically reported in the form of internal-consistency reliability estimates and test–retest reliability coefficients. Internal-consistency reliability estimates for composites scores like IQs are typically calculated by considering the internal consistency of the tasks (subtests or tests) contributing to the IQs (e.g., coefficient alpha values), as well as the correlations between those task scores. The resulting internal-consistency reliability estimates for IQs are, as noted previously, often .95 or higher (Kranzler & Floyd, 2013). Test–retest reliability coefficients represent (on a relative scale) consistency across time. Test–retest reliability is typically examined by administering a test battery to the same group twice across a month or two; resultant scores from each administration are correlated with one another. Due to the nature of the correlation typically employed (a Pearson product–moment correlation), differences in the absolute level of scores across administrations (which may be due to practice effects and the like) will not contribute to higher or lower correlations. Thus the resulting coefficient represents relative relations (and not absolute differences) across time.

Kranzler and Floyd (2013) have suggested that the standard for internal-consistency reliability coefficients be .95 and the standard for test–retest reliability coefficients be .90 (especially across a month or less and employing correlations corrected for restriction of range). These standards, however, may be too high when scores other than IQs are considered. Reynolds and Livingston (2014) and Floyd and colleagues (2015) have offered a more forgiving scale for both types of reliability, which holds them to a standard of .90. Regardless of the standard that is selected, a more reliable measure is usually better.

As both the AAIDD (2010) and APA (2013) reference consideration of the *standard error of measurement* (*SEM*), a general term used to describe the distribution of hypothetical true scores an examinee is likely to obtain with repeated measurement (all things being equal), the reliability of measures has real-world effects. An IQ with high reliability will produce *SEM* values (±2 points) that are far smaller than those IQs with inadequate reliability (±5 points). As a result, the confidence interval, which stems from extension of the *SEM* value, will be relatively narrow. A score with inadequate reliability can produce a band of error that easily spans more than 15 points—more than a standard deviation—which would make it incredibly difficult to determine whether (1) intellectual functioning is actually below a stated cutoff or (2) a low score is due to inaccuracy in measurement for the student being assessed.

Reliability (typically, internal-consistency reliability) is also important, as its values are used to calculate *estimated true scores* and *standard error of estimated true score* values, which form the foundation for confidence intervals offered by most cognitive ability test batteries. To our surprise, most batteries of this type do not equip users to employ *SEM* values per se (Kranzler & Floyd, 2013), as the standard error of estimated true score is usually employed instead. With individuals with low IQs relative to their peers, the estimated true score for IQs will be slightly closer to the mean than their associated obtained IQs, and the standard error of estimated true score for IQs will be slightly smaller than the traditional *SEM* for the same variable. These appropriate but slight adjustments to the confidence intervals for IQs may be substantial enough to alter the decisions made by professionals considering these scores (as discussed in the section on cutoff scores and clinical judgment that follows). Reliability clearly matters.

Validity

It behooves clinicians to consider all the evidence addressing a test's integrity in measuring its targeted constructs as well as its intended interpretations. As such, *validity* refers to "the degree to which evidence and theory support the interpretations of test scores by proposed uses of tests" (American Educational Research Association [AERA], American Psychological Association, & National Council on Measurement in Education, 2014, p. 11). In the most recent conceptions of this measurement property, validity evidence is categorized into five types. *Evidence based on content* refers to developing and employing test items that appear to measure the targeted construct, and then examining item-level information to evaluate whether the items achieve these goals. For example, items from intelligence tests should be developed on the basis of a theoretical understanding of cognitive abilities, and item scores should be substantially correlated and be able to be scaled in terms of their difficulty. *Evidence based on response processes* refers to evaluating the behavioral and cognitive steps that those taking tests would complete to solve its items. Both intelligence tests that require advanced fine motor skills and memory tests that unduly involve mathematics knowledge could be said to require construct-irrelevant processes, indicating invalidity in assessment. In our experience, publishers of cognitive ability test batteries do not provide evidence based on test content or responses processes derived from only ID samples. This information typically applies to all test takers, and examiners need to determine whether the test's content and response processes would undermine the conclusions they draw for the students they assess, considering the students' unique characteristics.

Evidence based on internal structure reflects the correlations between parts of a test. Evidence may appear as relations between and among individual tasks (subtests and tests) within a battery, and analyses often include correlations and more sophisticated exploratory and confirmatory factor analyses. In contrast, *evidence based on relations with other variables* reflects the relations between scores from a test battery and variables not derived from that test battery. Researchers examining this source of validity evidence often refer to *criterion-related validity, concurrent validity,* and *predictive validity*. Other variables correlated with test scores in question may include demographic characteristics, such as age, gender, race, or ethnicity, as well as scores from other assessment instruments. For example, a study examining the correlations between IQs and adaptive behavior domain scores obtained from a parent interview, and a clinical group comparison study employing students with ID, provide such evidence. Although there appears to be an increase in clinical group comparison studies involving children with ID reported in test battery manuals, it is extremely uncommon to see validity studies addressing evidence based on internal relations and evidence based on relations with other variables that employ only samples with ID. These studies are not typically conducted, in part because correlational studies with samples associated with a restricted range of scores (vs. scores varying like those across the population) tend to produce weaker correlations (due to an artifact) than those found when a broad sample is targeted. Thus, rather than strengthening the body of validity evidence, studies like these (e.g., with students with ID, who display such range restriction) are associated with artifacts that appear to weaken the validity argument. As a result, few test publishers, authors, and researchers endeavor to complete them.

Evidence based on consequences is the least understood and evaluated type of validity evidence; this term refers to evidence associated with intended positive effects of testing and unintended detrimental effects of testing. For example, evidence indicating invalidity in assessment might be indicated if a new cognitive ability test battery classified only students who were from a minority ethnic background as having ID, and classified students with similar characteristics who were from the majority ethnic background as not having ID. In sum, test users should carefully review validity evidence summarized in test manuals, available online, and published in chapters, books, and peer-reviewed journals, to ensure that it supports trustworthy data representative of targeted constructs.

Controversial Practices in the Assessment of Intellectual Functioning

In this section, we briefly review five controversies associated with ID assessment and offer our informed opinions to guide the application of research to practice. Readers should refer to chapters by McGrew for discussion of score adjustments addressing the Flynn effect (McGrew, 2015b) and use of multidimensional cognitive ability test batteries (McGrew, 2015a).

Using Fixed Cutoffs versus Flexible Cutoffs

As noted previously, diagnostic systems designed to identify ID have increasingly focused on clinical judgment (AAIDD, 2010; Luckasson & Schalock, 2015) and recognition of measurement error during assessment (evident in use of confidence intervals). Thus, there is less emphasis on *fixed cutoffs* (sometimes called *bright-line cutoffs*) associated with absolute score markers than in the past. For example, with fixed cutoffs, a child or adolescent who is one or two points above a score threshold (e.g., an IQ of 70) would not meet the symptom criterion for the disorder. This practice is clearly problematic. Instead, *flexible cutoffs* associated with interpretation of standard error terms and associated confidence intervals and application of clinical judgment when determining if symptom criteria are met offer much greater sensitivity in identifying cases of ID. Although Table 23.1 indicates this trend toward flexible cutoffs, only about half of states in the United States refer to these considerations (McNicholas et al., 2018). We view flexible cutoffs as necessary and discourage use of fixed cutoffs in the assessment of ID.

Obtaining and Averaging Multiple IQs

For a variety of reasons, cognitive ability test batteries produce different IQs for many individuals (AAIDD, 2010; McGrew, 2015a). In fact, research has demonstrated that a quarter of those completing different test batteries concurrently may obtain IQs that are discrepant by 10 or more points (Floyd, Clark, & Shadish, 2008). Throughout our careers, we have heard others recommend administering two or more test batteries in sequence when it is suspected that a child or adolescent has ID, and we have engaged in this practice ourselves. It seems wise to employ at least two indicators of a deficit in intellectual functioning when ID is being considered. This strategy is particularly wise when a student's performance during initial testing indicates that a confounding variable is in play, lowering the student's score. But what should be done if the IQs from valid administrations are discrepant, and one indicates a deficit in intellectual functioning and the other does not? On a descriptive level, the statistical significance of IQ differences can be tested (see McGrew, 2015a); sizeable score differences might not be unexpected when measurement error is considered. It is likely that the average of two or more valid IQs would be a more accurate estimate of intellectual functioning than any one alone. Based on Schneider and McGrew's (2011) work, Schneider (2013) has provided the most defensible means of averaging these scores. We view this method as promising and psychometrically defensible, yet recognize that it is understudied.

Interpreting Part Scores

The National Research Council (2002) offered a number of important insights and new research findings to the discussion of ID assessment and identification. One was consideration of *part scores,* which are variables targeting more specific abilities than the IQ. As a contrast to the IQ (a total test score), part scores refer to subtest and subscale scores more generally and to factor index, clusters, and broad ability composite scores more specifically. The National Research Council (2002) first asserted that variation across part scores contributing to an IQ might be problematic by stating:

> There are occasions when a total test score may not be the best indicator of an individual's overall intellectual functioning, and the examiner must resort to interpreting one of the instrument's part scores as the best indicator of overall intellectual functioning. . . . In such cases, the instrument's total test score may offer little more than an awkward and artefactual "average" of a number of relatively disparate subtest or subscales (i.e., part scores). (p. 109)

After addressing methods to evaluate the integrity of the IQ, such as testing the statistical significance, determining the base rate of differences between part scores, and selecting subtests contributing to the IQ (e.g., based on their *g* saturation), the National Research Council (2002) explained how IQs should be considered in relation to part scores.

First, the council outlined the upper limit of the IQ range that would indicate deficits in intellectual functioning by stating that

> when a scale score discrepancy meets the previously mentioned criteria of significance and meaningfulness, the total test score may simply be too high to support a diagnosis of mental retardation. . . . The final criterion for deciding whether or not to use part scores in place of the total test score . . . is that, no matter how great the discrepancy between relevant subscales, individuals with total test scores greater than 75 should not be diagnosed. (pp. 113–114)

Next, after advocating for consideration of IQs except in instances when their validity is in question, the council stated, "In such cases, appropriate part scores may better represent the individual's true overall level of cognitive functioning" (p. 114), but added two caveats. It stated that "only part scores derived from scales that demonstrate high *g*-loadings . . . should be used in place of the composite IQ score when its validity is in doubt" (p. 115), and that "if a part score is used in place of the composite IQ score . . . the part score should not exceed 70" (p. 115). As reported in Table 23.1, these recommendations still form the foundation for diagnosis according to the SSA (n.d.).

Following the National Research Council (2002) recommendations, Bergeron and Floyd (2006, 2013) examined part score profiles of students with ID. Bergeron and Floyd (2006) targeted part score profiles of 30 students with ID receiving special education services. Seven part scores were obtained from the Woodcock–Johnson III (WJ III) Tests of Cognitive Abilities (Woodcock, McGrew, & Mather, 2001). Although the average IQ (the WJ III General Intellectual Ability—Extended score) was in the very low range (*M* = 54.8, *SD* = 12.5), and almost every student demonstrated an IQ of 70 or below, part scores were much more varied. In fact, 37% of the students scored in the average range (90–110) or higher on at least one part score, and 77% of students scored in the low average range (80–89) or higher on at least one part score. In a follow-up study, Bergeron and Floyd (2013) employed datasets offered as clinical validity studies of students with ID supporting the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV; Wechsler, 2003), the Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004), and the DAS-II (Elliott, 2007). They also found that part scores were likely to indicate higher levels of functioning than the tests' IQs did. Despite the fact that the group-level WISC-IV, KABC-II, and DAS-II profiles were generally "flat," with all mean values less than 70 and the associated IQs routinely less than 70 for individuals, they found that a third or more of cases produced a part score in the low average range or higher for the WISC-IV (45%), KABC-II (52%), and DAS-II (33%).

These findings indicate two phenomena at play: *regression toward the mean* and *combinatorial probabilities*. (We highly recommend the excellent instructional video focusing on these phenomena by Schneider, 2011.) According to Kranzler and Floyd (2013), regression toward the mean refers to

> the general statistical phenomenon by which repeated measurement produces scores that are less extreme and closer to average due to chance occurrence alone. . . . Because of regression toward the mean, we would expect (1) that children and adolescents with very low IQs will exhibit some subtest or composite scores that are closer to the population mean than their IQs and (2) that the subtests and composite scores demonstrating the lowest correlations with the others will be most affected. (p. 188)

In contrast, combinatorial probabilities explain how the IQs (stemming in part from the same tasks producing the part scores) are likely to be lower than most part scores—and consistently so. Combinatorial probabilities can be explained the following way:

> Just as it is increasingly improbable that a person will roll a 5 on each consecutive roll of a die, it is increasingly improbable that an examinee will score consistently lower than his or her peers across subtests and composite scores. As a result of combinatorial probabilities, IQs will be more deviant (i.e., further away from the mean) than the average of the scores that contribute to them, representing this increasing improbability. . . . Accordingly, for individuals with very low IQs, subtest scores and composite scores will be higher than expected from their IQs. (Kranzler & Floyd, 2013, p. 188)

Consideration of part scores (especially under the assumption of a valid administration, not confounded by construct-irrelevant influences) clearly complicates consideration of deficits in intellectual functioning. It appears improbable that professionals are likely to enact the recommendation that an IQ of 75 or lower, accompanied by a part score of 70 or lower, be indicative of a deficit in intellectual functioning—especially when flexible cutoffs are increasingly applied. Consideration of part scores, however, also introduces other complications, discussed next.

Invalidating IQs When Their Components Are Discrepant

It is sometimes stated that large discrepancies between the part scores contributing to an IQ undermine its meaningfulness in representing psychometric *g*. Recommendations from test authors appearing in guidelines for interpretation included in test kits (Wechsler, 2014), and the widespread proliferation of recommendations for clinical interpretation (Sattler, 2008), reinforce this practice. It is assumed that this same practice should be applied to students with ID; in fact, the National Research Council (2002) addressed the statistical significance and base rate of part score discrepancies when it discussed identification of ID.

In a series of studies designed to evaluate the validity of this practice, Watkins and colleagues (Freberg, Vandiver, Watkins, & Canivez, 2008; Kotz, Watkins, & McDermott, 2008; Watkins, Glutting, & Lei, 2007) employed intelligence test norming sample data to examine differential prediction of IQs on achievement outcomes when children and adolescents were distinguished by whether they displayed substantial variation in part scores (variable profiles) or not (flat profiles). Watkins and colleagues (2007) demonstrated, using data from two large-scale validity studies and data obtained from practitioners, no differences between groups formed based on the extent of variation in part score profiles (yet matched on IQs) when the relations between IQs and reading and mathematics scores were compared. Freberg and colleagues (2008) replicated these findings, using data obtained from practitioners that included IQs obtained at one point in time and achievement test scores obtained later in time. All data were from students with disabilities (including ID). Prior findings were extended through the analysis of subsamples of students with larger discrepancies in their part score profiles. Finally, Kotz and colleagues (2008) completed similar analyses, using data from the original Differential Ability Scales (Elliott, 1990) and two co-normed achievement subtests. Again, as in Freberg and colleagues' study, prior findings were extended through the analysis of subsamples with larger discrepancies in their part score profiles and through examining subtypes of part score discrepant profiles (e.g., those with relative strengths evident in one part score vs. another).

More recently, McGill (2016) supported the results of these studies by Watkins and colleagues through an analysis of the KABC-II (Kaufman & Kaufman, 2004), which includes a greater number of part scores (five) than the standard batteries employed by Watkins and colleagues do. McGill formed groups based on part score profile variation (as Watkins and colleagues did), and selected data from only the group with at least one discrepant part score in the profile for further analysis. McGill demonstrated through exploratory factor analysis that the KABC-II factor structure was not undermined by such discrepancies, and showed that indices of integrity in measurement (omega coefficients) remained sound when data from groups with discrepant part score profiles were considered. In addition, predictions employing the IQ from the KABC-II (the Fluid–Crystallized Index) revealed that it remained a strong predictor of achievement outcomes when data from individuals with discrepant part score profiles were used. Most constituent part scores offered small and negligible incremental validity in prediction of achievement outcomes. Findings were replicated across two age groups (ages 7–12 and 13–18).

When we consider the results from Bergeron and Floyd (2006, 2013), it seems likely that students with ID would be just as likely—and perhaps even more likely, due to the effects of regression toward the mean on part scores—to demonstrate sizeable discrepancies between part scores, which have been claimed to undermine the meaningfulness of IQs. In addition to this evidence from Watkins and colleagues (Freberg et al., 2008; Kotz et al., 2008; Watkins et al., 2007) and McGill (2016) supporting the integrity of the measurement of the construct of psychometric *g* amidst cases with significant variation in part scores, as well as the maintenance of the predictive properties of IQs in explaining variation in achievement, we see the practice of invalidating IQs when their components are discrepant as particularly problematic when applied to cases of ID.

More generally, if global composites like IQs are cast aside due to variability in their constituents, clinicians are left with scores that possess inferior psychometric properties—especially reliability. Following this successive-levels approach (Sattler, 2008), if the part scores contributing to an IQ are discrepant, one would disregard the IQ and interpret the part scores, which typically possess lower reliability and weaker bodies of validity evidence. Then, if subtests contributing to part scores are discrepant, one would disregard the part scores and interpret subtest scores, which almost always possess lower reliability (and sometimes inadequate reliability) and usually are supported by even weaker bodies of validity evidence than part scores are. Following this logic, if there is variation in performance across items scaled in terms of difficulty, one might even disregard the subtest scores and interpret item-level scores, which almost certainly possess terribly low reliability and inadequate validity evidence.

Identifying Infants and Preschool-Age Children with ID

All diagnostic models included in Table 23.1 require onset of ID during the developmental period, which usually implies "during the first 18 years of life." Professionals tasked with identifying the reasons for developmental delays in young children face many challenges, and some of these professionals may be called upon to determine if children with severe impairments have ID. They are faced with several problems associated with measurement accuracy, as assessment of infants, toddlers, and other preschool-age children are not always responsive to individual testing (Bracken, 2000); their behaviors may range from unresponsive to aggressive. As suggested earlier in this chapter, these behaviors may be more extreme or more likely to be multitudinous in cases of children referred for ID. In addition, growth in language skills, cognitive abilities, motor skills, and attention is rapid during this period; thus changes across short periods of time should be expected. As a result, research has demonstrated that many estimates of intellectual functioning obtained during this period are not sufficiently reliable across time or maximally predictive of long-term outcomes (Jenni et al., 2015). In the same vein, many developmental screeners commonly employed during this period (especially with children under the age of 3) do not yield IQs or other scores designed to represent intellectual functioning per se. As a result, scores that only roughly reflect intellectual functioning may need to be employed.

Due to these complications in identifying ID (and other conditions) during early childhood and to the stigma associated with the diagnosis, classification systems have been extended to address developmental delays similar to ID without employing the ID label. As noted previously, DSM-5 (APA, 2013) refers to GDD when referencing a condition associated with deficits in intellectual functioning, adaptive functioning, and gross motor skills in early childhood. In addition, IDEA (2004) allows for students ages 3–9 to be identified with a developmental delay if they display delays in physical, communication, social-emotional, cognitive, or adaptive behavior development. On the basis of references to cognitive and adaptive behavior development, a child within this range with the characteristics of ID could be identified as having a developmental delay. Considering psychometric standards guiding testing practices, the effects of social labeling, and the effectiveness of early interventions to address a variety of areas of developmental delays, delaying identification of ID for young children with mild cases of the condition seems appropriate in many cases.

CONCLUSION

ID is a disabling condition associated with deficits in intellectual functioning and adaptive behavior. Those involved in the assessment of children and adolescents with ID should consider recent changes in diagnostic criteria for the condition, as well as best practices in assessment. They should carefully review the resources provided by the AAIDD (2010) and should stay abreast of research informing score interpretation and test battery selection. This chapter has been written to assist them in achieving these goals.

CHAPTER 24

Intellectual and Neuropsychological Assessment of Individuals with Sensory and Physical Disabilities and Traumatic Brain Injury

Scott L. Decker
Julia Englund Strait
Alycia M. Roberts
Joseph Ferraracci

This chapter outlines the neuropsychological basis and assessment of sensory and physical deficits, as well as traumatic brain injury (TBI), in children. These disabilities are discussed together and addressed within a neuropsychological framework because behavioral deficits resulting from these disabilities clearly originate in biological functioning. The goal of the chapter is to provide a better understanding of the clinical manifestations of these disabilities for enhancing assessment procedures, interventions, and services for children with such conditions.

Assessments of sensory and physical functioning have long been part of standard neuropsychological evaluations (S. Finger, 1994). Although basic sensory abilities are often viewed as orthogonal to higher-level abilities, sensory measures have been correlated not only with academic measures (Decker, 2004), but also with measures of intellectual functioning (Decker, 2002; Roberts, Pallier, & Goff, 1999; Stankov, Seizova-Cajic, & Roberts, 2001), and this relationship between sensory processing and cognition increases as individuals age (Humes, Busey, Craig, & Kewley-Port, 2013). Regarding physical functioning, there is a longstanding history of literature linking motor functioning (including physical activity) and cognition (Haapala, 2013; Sibley & Etnier, 2003; Tomporowski, Davis, Miller, & Naglieri, 2008). More recently, research has begun to investigate the importance of early fine motor development as a predictor of cognitive functioning (Kim, Carlson, Curby, & Winsler, 2016; Stöckel & Hughes, 2016). As such, both sensory and physical abilities are prerequisites for the input and output mechanisms of cognitive faculties and provide indicators of the cognitive system's integrity.

There are shared areas of the brain that participate in sensory–motor behaviors as well as higher cognitive abilities. For example, lesions in the left frontal area of the brain may result in contralateral motor impairment (i.e., right-sided hemiparesis) as well as language deficits (i.e., expressive aphasia), due to localized proximity of both functions in a spatially similar area of the brain (Kolb & Whishaw, 2003). The benefit of neuropsychological theory is that it provides a framework for explaining the connections between sensory deficits and intellectual deficits, as well as between sensory functions and higher cognitive faculties like language or executive functions (e.g., working memory, inhibition, motor planning). The benefits of a neuropsychological framework extend beyond assessment to intervention planning and establishing rehabilitation expectations.

In the sections that follow, we focus specifically on sensory, physical, and TBI-related disabilities. Each section provides both practical and legal definitions for each type of disability. In addition, assessment and intervention issues are addressed. Both individual child factors and test-related factors important to consider when clinicians are selecting, administering, and interpreting neuropsychological and cognitive tests are included.

SENSORY DISABILITIES

According to the U.S. Census Bureau (2010), approximately 8.1 million people in the United States, or about 3.3% of the general population, had difficulty seeing, and approximately 7.6 million people, or about 3.1% of the general population, had difficulty hearing. The *Standards for Educational and Psychological Testing* volume (American Educational Research Association [AERA], American Psychological Association, & National Council on Measurement in Education, 2014) emphasizes fairness in testing for individuals with such disabilities and suggests common accommodations for these individuals, including modifying presentation or response format, timing, or setting; using only portions of a test; or substituting assessment instruments/using alternative tests (see also Montgomery, Torres, & Eiseman, Chapter 30, this volume). Individual factors may affect which tests are given and what modifications are made, as well as how accurately the resultant test scores reflect a child's cognitive and neuropsychological functioning. It is therefore the clinician's responsibility to ensure selection of appropriate instruments, nonbiased test administration and interpretation of results, and application and consideration of necessary modifications for each child.

In a school setting, children with visual impairment or blindness (VI/B) are served mainly under the Individuals with Disabilities Education Improvement Act of 2004 (IDEA, 2004) category of *visual impairment,* defined in federal regulations (U.S. Department of Education, 2006) as follows:

> *Visual impairment including blindness* means an impairment in vision that, even with correction, adversely affects a child's educational performance. The term includes both partial sight and blindness. (p. 46757)

According to the U.S. Department of Education (n.d.), in the 2014–2015 school year, U.S. public schools in the 50 states, outlying areas, and freely associated states served 2,959 children ages 3–5 (of 753,697 total preschool students served under all categories) and 25,567 children and youth ages 6–21 (of 5,944,241 total) under the IDEA 2004 category of visual impairment. Slightly more children and youth (9,042 ages 3–5 and 67,884 ages 6–21 in 2014–2015) were served under the combined *deafness* and *hearing impairment* IDEA categories, defined, respectively, as follows:

> *Deafness* means a hearing impairment that is so severe that the child is impaired in processing linguistic information through hearing, with or without amplification that adversely affects a child's educational performance. . . . *Hearing impairment* means an impairment in hearing, whether permanent or fluctuating, that adversely affects a child's educational performance but that is not included under the definition of deafness in this section. (U.S. Department of Education, 2006, p. 46756)

And, lastly, in 2014–2015, 165 children ages 3–5 and 1,243 children and youth ages 6–21 were served under the IDEA *deaf-blindness* definition:

> *Deaf-blindness* means concomitant hearing and visual impairments, the combination of which causes such severe communication and other developmental and educational needs that [the children] cannot be accommodated in special education programs solely for children with deafness or children with blindness. (U.S. Department of Education, 2006, p. 46756)

Few studies focus specifically on the cognitive and neuropsychological assessment of children with deaf-blindness, which involves multiple disabilities that may or may not be interrelated, and so the populations with VI/B and deafness/hearing impairment (D/HI) are our main focus in this portion of the chapter. Briefly, however, in a recent review of individual variables for examiners to consider when evaluating children and individuals with deaf-blindness, Dalby and colleagues (2009) specified etiology as a major factor. According to Dalby and colleagues, individuals with congenital deaf-blindness are more likely to experience cognitive, adaptive, and social impairments than those whose deaf-blindness is acquired. Those with acquired deaf-blindness are more likely to use speech as their primary mode of communication. The American Association of the Deaf-Blind's website (*www.aadb.org*) offers educational resources to address the needs of children with multiple disabilities, such as listings of state organizations, service providers, and support groups; frequently asked questions and fact sheets; newsletters and magazines; and information about assistive technology. *Best Practices in School Psychology V* (Thomas & Grimes, 2008) offers broad-based information helpful for designing instruction and intervention for individuals with multiple disabilities like deafblindness. In particular, Powell-Smith, Stoner, Bilter, and Sansosti (2008) emphasize the importance of systemic collaboration, considering each child's optimal learning environment and mode of communication, and encouraging family involvement.

Etiologies: A Brief Overview

In a typically developing child, vision begins with the eye detecting light in the environment and transducing the stimulus energy into neurological impulses. These impulses are sent from the eye (retina) to the occipital lobes of the brain via the optic nerve, which travels through the lateral geniculate nucleus in the midbrain before transferring information to the primary visual cortex for basic visual processing; then information such as orientation, contrast, color, location in space, and identity is saved for higher-level processing in either the occipito-parietal dorsal visual stream or the temporo-parietal ventral visual stream, depending on information type. In some children with VI/B, abnormal pigment production in the eye (albinism, a congenital condition; Bradley-Johnson & Morgan, 2008) disrupts this process early in the stream. Other congenital causes include retinitis pigmentosa, which involves degeneration of light-sensitive retinal cells, or various forms of prenatal damage to the visual system. If the damage occurs during or after birth, the vision loss is considered acquired. Bradley-Johnson and Morgan (2008) list the following possible diseases and accidents that may result in acquired vision loss: head injury, anoxia at birth, central nervous system infections (e.g., meningitis), and medication reactions. Damage to any part of the visual pathway can lead to observable difficulties with visual tasks, but most children's vision loss can be traced to the eye or optic nerve early in the pathway. One exception is cortical visual impairment, sometimes called cortical blindness, which occurs with damage to the brain's visual system from head injuries, infections, and other accidents or diseases. Children with this condition experience problems not only with basic visual processing, but also with attention and other cognitive functions (Bradley-Johnson & Morgan, 2008). Understanding the etiology of a child's vision loss can aid in individualized and sensitive psychoeducational assessment and planning.

Children without hearing impairments first receive sound information as sound waves, or vibrations, entering the outer, middle, and then inner ear. The vibrations travel from the eardrum to three tiny bones in the middle ear, and then one of those bones, called the stirrup, sends the vibrations along the coiled cochlea in the inner ear. When the cochlea vibrates, tiny hairs called cilia move, and the sound information passes through the auditory nerve to the auditory cortex in the temporal lobes of the brain for processing. The auditory cortex organizes information from different sound frequencies in higher cortical areas, which individuals "hear" as different sounds.

According to the American Speech–Language–Hearing Association (ASHA; 2010), sensorineural hearing loss—which occurs when the cochlea or auditory nerve is damaged, is permanent, and often cannot be corrected with surgery or other medical procedures—can result from disease (e.g., viruses or tumors); exposure to toxins (e.g., drugs) or high noise levels; head injuries; inherited genetic syndromes; or perinatal injury. These children not only have trouble hearing low-level sound, but also experience difficulty understanding speech and hearing sounds clearly (ASHA, 2010). Conductive hearing loss, on the other hand, results primarily in an inability to hear faint sounds or a reduction in sound level that is often medically correctable. Conductive hearing loss can be caused by middle ear pathology (e.g., otitis media or ear infection), impacted earwax, ear canal infection, irritation from a foreign body in the ear, or malformation or absence of any physical part of the outer or middle ear (ASHA, 2010). If there is damage to or malfunction of both the outer or middle ear and the inner ear or auditory nerve, mixed (sensorineural and conductive) hearing loss can occur. In addition, hearing loss can be unilateral (occurring only in one ear) or bilateral. According to ASHA, about 1 in 1,000 children is born with unilateral hearing loss, and approximately 3% of all school-age children have it. Children with both unilateral and bilateral hearing loss are at risk for academic, speech–language, and social-emotional difficulties (ASHA, 2010).

Special Considerations for Assessment: Child Factors

A variety of individual factors can influence the test performance of children with sensory disabilities and can affect the interpretation of results. Selected chapters in the Thomas and Grimes (2008) volume offer helpful educational programming information for students with VI/B (Bradley-Johnson & Morgan, 2008) and students with D/HI (Lukomski, 2008), highlighting the diversity of these populations and the lack of a "one-size-fits-all" solution for their psychoeducational planning. For both populations, early intervention and family collaboration, as well as a multidisciplinary approach to assessment, placement, and intervention, are imperative for appropriate data-based decision making in the schools. The school psychologist must cooperate with a team of specialists and other professionals—such as speech–hearing therapists and educators, medical personnel, and VI/B educators—to develop a comprehensive, interdisciplinary educational plan for each child that addresses child–environment fit, considers preferred modes of communication, and includes objectives and strategies for improving social interaction and communication skills. Figure 24.1 summarizes additional broad guidelines for selecting, administering, and interpreting intellectual assessment measures for students with sensory disabilities.

For a child with D/HI, Lukomski (2008) stresses including the following specific elements in the child's plan: strategies for handling communication breakdowns, handling the child's fatigue, school staff training in communication strategies, and American Sign Language (ASL) parent training. In addition, decision-making and planning teams must keep in mind that most children with hearing problems have average IQs, but exhibit lags in literacy and academic achievement because of developmental differences in the acquisition and internalization of language. For children with VI/B, having a basic understanding of the variety and availability of adaptive technologies and materials—such as raised-line paper, computer programs with speech or Braille output, and closed-circuit television that electronically magnifies text for children with low vision—is crucial (Bradley-Johnson & Morgan, 2008). Since many visual cues in the environment are unavailable to these children, the school psychologist must also include strategies targeted at improving organizational skills and social communication. For children with either D/HI or VI/B, evaluation should include systematic observation of the children in a variety of settings, since social interactions, communication modes, and behavior may vary among contexts.

Next, we consider specific areas of heterogeneity in the populations with VI/B and D/HI that may affect test selection, administration, and interpretation, including the following: age at onset; quantitative and qualitative nature of the vision or hearing loss; etiology; comorbidity; and (for children with D/HI) reading and language ability, preferred mode of communication, and parental hearing status.

Individual Factors to Consider in Assessment of Children with VI/B

One major individual factor to consider in the assessment of children with VI/B is age at onset of the sensory impairment, which contributes to the heterogeneity of this population. For example, in the standardization sample for the Comprehensive Vocational Evaluation System (CVES; Dial, Chan, Mezger, et al., 1991)—an empirically developed, VI/B-specific neuropsychological battery—56% of cases were considered "congenital," with onset of vision impairment occurring from birth to 1 year of age; 8% were "early blind" (2 years to 5 years, 11 months); 9% were "school-age" (6 years to 17 years, 11 months); and the rest were adult-onset cases (Hill-Briggs, Dial, Morere, & Joyce, 2007). Joyce, Isom, Dial, and Sandel (2004) found that adults with early-onset VI outperformed those with adult-onset VI in shape and texture discrimination on tests from the Haptic Sensory Discrimination Test (HSDT) and McCarron Assessment of Neuromuscular Development, VI/B Version (MAND-VI), providing evidence that age at onset of VI substantially impacts neuropsychological test results. Conversely, adult-onset participants excelled at persistent motor control, and the school-onset group performed significantly better than early-onset individuals in bimanual dexterity (Joyce et al., 2004). On the other hand, MacCluskie, Tunick, Dial, and Paul (1998) compared Wechsler Adult Intelligence Scale—Revised (WAIS-R) and Cognitive Test for the Blind (CTB) performance for groups of adults ($N = 60$) with early-onset (before age 2) versus late-onset (after age 5) VI and found no significant differences. However, years of education significantly contributed to variance in cognitive ability scores. The authors tested a small sample of adults and did not control for degree of residual vision, so these results should be interpreted with caution. Notwithstanding, one implication for professionals assessing persons with VI/B is that while age of onset itself may not contribute to variability in cognitive test scores, number of

Selection	Administration	Interpretation
Consider results of appropriate screening and sensory assessment measures already administered (e.g., functional vision assessment [FVA] and learning media assessment [LMA] for students with VI/B).	Plan administration in collaboration with other professionals as appropriate (e.g., VI professionals, speech–language pathologists).	Include multiple sources of information, from different informants and in a variety of formats, in any interpretations and conclusions (e.g., direct observation, teacher and parent report, record review).
Be clear about, and clearly state in the report, reasons for evaluation and how results will be used (e.g., diagnosis, disability determination, intervention planning, etc.).	Ensure that examiner has appropriate training in test theory, standardized assessment, child development, and unique needs and characteristics of children with sensory impairments.	Provide clear rationale for using the selected tests, and clearly identify which subtests were included and excluded (if any) and why.
Evaluate appropriateness of educational programming, including placement and any interventions, up to the current point in time (i.e., has the student received evidence-based, appropriate core instruction?).	Plan adaptations and accommodations in collaboration with other professionals knowledgeable about sensory disabilities before administering the test.	Report IQ and factor scores as ranges or confidence intervals, rather than point estimates.
Consider medical history and current conditions, possible comorbid disability conditions, and the child's strengths.	Provide standardized administration whenever possible. Consider which tasks will require adaptations (which do not change the content or difficult level of test materials), which tasks will need significant modification, and which tasks are wholly inappropriate.	Include qualitative information about behavior and performance when available, particularly when test administration deviates from standardized conditions (e.g., testing-of-limits procedures, alternative response modalities).
Consider both individual (e.g., level of impairment or communication mode) and test factors (e.g., norm sample, language requirements).	Follow appropriate best practice and ethical guidelines, and provide appropriate documentation in the report, for all adaptations and accommodations to test materials and administration or response methods (e.g., use of interpreters, Braille or orally administered test versions).	Clearly note limitations of the currently available data, and of standardized test scores, in drawing firm conclusions about performance and level of functioning.
Consider most appropriate subtests within each test battery, given task demands (input, processing, and output) and test-author-provided suggestions.	Follow test manual recommended accommodations, if available.	Involve professionals knowledgeable about sensory disabilities (e.g., rehabilitation professionals) in generating appropriate recommendations.

FIGURE 24.1. Guidelines for assessing children with sensory disabilities. These guidelines are based on information and conclusions presented in Goodman, Evans, and Loftin (2011); Lund, Miller, and Ganz (2014); Reesman et al. (2014); and the Texas School for the Blind and Visually Impaired (2016).

years of education seems to matter. Thus it is important to consider how each examinee's current age and grade level may influence scores in individuals with both congenital and late-onset VI/B.

Another variable that can affect test performance and interpretation of results is level of blindness or amount of vision loss. For instance, an individual with congenital (onset prior to 18 months of age) blindness and no vision—a Braille or tactile learner—is at the most severe end of the spectrum, and will require the most modifications both to testing and to educational content and delivery methods; a print learner with low vision will require fewer testing and educational modifications. Consider the illustrative case of the CVES standardization sample, in which 71% of cases were considered "legally blind," 18% "visually impaired," and 11% "totally blind." It is also worth noting that even two individuals with the same optical refraction score (e.g., 20/100) may have different functional levels of vision (Hill-Briggs et al., 2007). In the Joyce and colleagues (2004) study, participants who had some residual functional vision performed significantly better on various subtests of the HSDT and MAND-VI (included in the CVES battery) than those who were "totally blind"; again, this demonstrates the importance of considering level of vision loss in assessing individuals with VI/B.

Clinicians should keep in mind that VI/B has different etiologies in different people, and that multiple etiologies may even be present within the same individual. Studies have found differences in cognitive and neuropsychological performance based on these different etiologies. For example, participants whose blindness was caused by early birth (retinopathy of prematurity, or ROP) performed significantly worse on spatial and auditory analysis (verbal–spatial cognitive abilities) and hand strength (perceptual–motor functions) tests from the CVES battery than participants with either retinitis pigmentosa or congenital cataracts as etiologies (Nelson, O'Brien, Dial, & Joyce, 2001). It was concluded that ROP caused more cognitive impairment than other common etiologies of VI/B. Similarly, McGee (1994) found that those with diabetes-related blindness performed worse on tasks measuring left-lateralized perceptual–motor functions, as well as on nonverbal cognitive tasks.

Many individuals with VI/B have comorbid disabilities or conditions that may or may not be related to their vision loss, including neuropsychological conditions (such as head injuries, cerebral palsy, and tumors) and other disabilities commonly seen in school settings (e.g., learning, hearing, or physical disabilities). In fact, throughout the CVES standardization process, only 25% of the individuals who presented with vision loss did *not* have profiles consistent with another such disorder (Hill-Briggs et al., 2007), and standardization was based only on this 25%. However, since the majority of individuals with VI/B seem to have comorbid disorders, it is debatable whether or not a group without comorbidity is truly representative of the population with VI/B in the United States. In fact, according to Miller (2007), almost all children with sensory impairments have additional impairments in academic, social, cognitive, adaptive, and/or behavioral domains. It is vital for the evaluator to keep in mind that the cognitive and neuropsychological profile observed during evaluation of an individual with VI/B and a comorbid condition may be the effect of the VI/B, of the other neuropsychological disorder, of the additive combination of both independent conditions, or of the multiplicative effects of both conditions acting together.

Individual Factors to Consider in Assessment of Children with D/HI

Age at onset should also be considered in assessing children with D/HI. Because hearing, verbal communication, and language development are linked, children with early-onset (prior to 18 months old) hearing loss and those whose hearing loss occurred after significant language development exhibit significantly different profiles of linguistic and communicative functioning (Braden, 1994; Marschark & Clark, 1993; Meadow, 1980). Although severe and profound hearing loss will have the most significant impact on test administration, any level of hearing loss can have some effect on standardized test performance (Braden, 1994). In addition, examiners should consider whether the hearing loss is progressive, as an examinee's current level of hearing loss may not be the same as it was earlier in development or will be later in life (Hill-Briggs et al., 2007). Finally, as in the evaluation of children with VI/B, clinicians must also consider the additive and interactive influences of any comorbid disability or medical condition. A learning disability, for example, may be overlooked if diagnostic overshadowing causes the examiner to erroneously attribute all verbal reasoning deficits to hearing loss. According to several recent surveys of students with D/HI in special education, about half have additional disabilities (Gallaudet Research Institute, 2007; Mitchell, 2006; Szymanski, Brice, Lam, & Hotto, 2012).

One relatively unique factor in assessing individuals with D/HI is their level of reading and language ability. According to the Gallaudet Research Institute (Holt, 2005), 18-year-olds with severe hearing loss usually perform on tests of reading comprehension at a grade 4.5 level, and those with profound hearing loss at a grade 3.8 level. Competency with reading and writing tasks may also be negatively affected by the different grammatical structures of traditional spoken English and many signing systems, such as ASL. Therefore, asking children with D/HI to read the directions for a test is not an appropriate modification. Variability in reading and language levels should also be considered when examiners are selecting tests that include high verbal loadings or rely substantially on reading instructions and/or stimuli.

A further consideration for evaluators in testing an individual with D/HI is the examinee's primary or preferred mode of communication—both current and during development. Current communication mode has implications for communication methods during testing; for example, this affects the decision of whether to use an interpreter, to seek an examiner fluent in ASL or another visual communication system, or to modify the test administration in some other way so as to accommodate the individual child's hearing loss level and preferred communication style. Several studies have also shown that mode of communication during development—for example, cued speech, oral communication, combined methods, or sign language (ASL or another signing system)—affects cognitive functioning and performance, and even lateralization of neuropsychological tasks (e.g., Bosworth & Dobkins, 1999; Cattani & Clibbens, 2005; Charlier & Leybaert, 2000; LaSasso, Crain, & Leybaert, 2003).

Parental hearing status (i.e., whether the parents also have D/HI) can also affect a child's development of language and communication (Anderson, 2006), as well as achievement and psychosocial adjustment (Polat, 2003). It can also affect cultural and identity development, as the child decides whether to identify primarily with deaf culture or to assimilate him- or herself into the hearing world (Leigh, Marcus, Dobosh, & Allen, 1998). Clinicians should not only be sensitive to these cultural issues, but remember that the hearing status of a child's parents will affect the child's cognitive functioning (Braden, 1994; Vernon, 2005) and his or her preferred or primary communication mode in adolescence and adulthood. Although debates continue regarding this issue, it has been shown that deaf children born to hearing parents function at a lower cognitive level than those born to deaf parents (Braden, 1994; Vernon, 2005).

Special Considerations for Assessment: Test Factors

In addition to addressing individual child factors, clinicians should consider the inadequacies of the assessment instruments themselves—from instructions, to stimuli, to norms and norming samples—for use with special populations, as such inadequacies have historically plagued both research and application of evaluation methods for individuals with VI/B and D/HI.

For individuals with VI/B, some tests can be administered without vision requirements, such as subtests from the Halstead–Reitan Battery (HRB), including the Tactual Performance Test, Grip Strength, and Finger Oscillation, as well as the haptic version of Raven's Progressive Matrices (Rich & Anderson, 1965). However, tests for general cognition and memory that lack vision requirements are more difficult to find. Furthermore, the appropriateness of these tests for the population with VI/B is debatable, considering inadequate norms for special populations and the need to control for examinees' varying levels of residual vision (Hill-Briggs et al., 2007). Although traditional IQ tests (e.g., the Stanford–Binet and Wechsler scales) have been adapted for individuals with VI/B, the norming samples for this group have historically been very small and included children with comorbid disabilities (Gutterman, Ward, & Genshaft, 1985). For example, in the original norming sample for the CVES battery created specifically for examinees with VI/B, 44% of those tested displayed profiles indicative of some kind of neuropsychological disorder (Dial, Chan, Tunick, Gray, & Marme, 1991). As noted earlier, the CVES norms were ultimately based on the final 25% of tested cases that had no other disability or medical condition besides VI/B (Hill-Briggs et al., 2007); therefore, practitioners should be wary of the inherent problems faced by test creators in finding and selecting appropriate norming samples. If much of the normative sample already exhibits the very class of disorders the test is designed to detect, sensitivity for doing so is severely limited.

Examiners testing children with D/HI must consider that these individuals' need for basic communication accommodations during the test automatically breaks standard administration. Oral administration without a sign language interpreter, therefore, is often impossible and is always inappropriate with individuals who do not primarily use oral communication outside the testing situation (Hill-Briggs et al., 2007). Reesman and colleagues (2014) specifically note that "when and if a hearing psychologist with limited proficiency in ASL is assessing the cognitive skills of an ASL-using child who is deaf or hard of hearing, the inclusion of measures requiring interpretation and evaluation of a child's language may be viewed as wholly inappropriate" (p. 104). Additionally, individuals who typically use sign language or other visual communication strategies may seem to have adequate oral expression abilities, but may have difficulty processing incoming auditory information. Informal communication abilities can be similarly deceiving, but the testing situation is a formal communication context with different demands and a higher imperative to ensure that each individual sound and word is being expressed and received precisely as it is intended. These individuals need to spend extra time processing auditory information, and when interpreters are used, time delays and inconsistencies in wording and meaning can have a negative impact on test performance.

Use of interpreters also makes it difficult to adhere closely to standardized administration. This is because ASL and spoken English have different syntactical rules and grammatical structure, which render verbatim or direct translation impossible. Because of these difficulties, test instructions should be given in the examinee's preferred communication mode—such as ASL, if possible—and the examiner should allow extra practice trials and modeling when necessary (Hill-Briggs et al., 2007). If the examiner is not fluent in the examinee's primary communication mode, an experienced interpreter who is familiar with the examinee's dialect or signing approaches, as well as with mental health interpreting idiosyncrasies (Miller & Vernon, 2001), should be sought. Moreover, sensory distractions—both visual and auditory—should be carefully minimized. Hill-Briggs and colleagues (2007) also caution against asking examinees with D/HI to cover their eyes or wear a blindfold during perceptual and motor tasks (since this eliminates their sole mode of communication), and recommend using visual barriers instead.

The question of which tests to use in assessing individuals with D/HI is as important as deciding how to modify them, and is further discussed below. Although the Wechsler scales have been used with such individuals in the past (Braden, 1994), "adapting" a Wechsler test by only considering the nonverbal half of the test (Performance IQ, in older editions) is problematic, as excluding the other half of the test may lead to under- or overestimation of overall cognitive ability. Furthermore, as a general rule, tests with high verbal loading should be avoided. Testing considerations for individuals with D/HI may seem complex, but with appropriate evaluation of materials and methods employed, accurate measures of functioning are possible.

Instruments for Assessing Individuals with VI/B

Clinicians might consider using a cognitive measure developed specifically for individuals with VI/B, such as the Cognitive Test for the Blind (CTB), which was standardized on and designed for such individuals. The CTB is one of several tests included in the CVES for assessing individuals with VI/B (Hill-Briggs et al., 2007), and it covers three primary neuropsychological factors: verbal–spatial cognitive abilities, perceptual–motor functions, and emotional–coping concerns. Although the CTB has acceptable reliability and validity (Nelson, Dial, & Joyce, 2002), it can only be used with individuals age 14 and older. Despite the positive results from test development of the CVES showing its utility for populations with VI/B (Chan, Lynch, Dial, Wong, & Kates, 1993; Dial, Chan, Mezger, et al., 1991; Kaskel, Dial, Chan, & Roldan, 1991), the test was developed for adults; although some measures suggested in the battery (e.g., the Wechsler Intelligence Scale for Children [WISC]) are well suited for children, the battery as a whole is not.

Although there have been attempts to create and disseminate child-friendly cognitive tests specifically for individuals with VI/B, most of these tests are no longer commercially available due to problems with test reliability and validity, as well as inadequately made comparisons between samples of children with VI/B and typically developing children. Creators of the Bielefeld Developmental Test for Blind Infants and Preschoolers, for example, attempted to create "blind-neutral" items for young children but were not successful, and the test was removed from circulation (Brambring &

Tröster, 1994). The best option remaining for practitioners working with children who have VI/B is to try to select, from the available children's standardized cognitive and neuropsychological tests, those that most easily lend themselves to modification. Select subtests from widely available batteries such as the WISC-V, for example, are appropriate for a pediatric population and can be used with these children if interpreted with caution.

The Texas School for the Blind and Visually Impaired (2010) previously suggested using only the verbal subtests from the various Wechsler scales or the Woodcock–Johnson Tests of Cognitive Abilities (WJ COG), but they stressed that clinical judgment is needed for interpreting results from only half of the entire test. Because the WJ COG, however, includes tests that are designed to be used selectively, interpretation of only verbal subtests on this measure may be preferable to using those from the Wechsler scales, in which subtests are designed to contribute to an interpretable composite. Also, minimizing the inclusion of subtests that are heavily nonverbally loaded or that comprise several tasks dependent on visual–spatial information is essential. Examiners' manuals for several popular tests like the WJ IV COG provide tables listing appropriate subtests for populations with VI/B and suggested accommodations specifically for these examinees (Mather & Wendling, 2014). According to a test manual search we conducted, however, neither the WISC-V nor the WJ IV COG manual offers VI/B norms. Table 24.1 displays commonly used cognitive tests that provide suggested accommodations and/or lists of appropriate subtests for individuals with VI/B (and other disabilities).

Flanagan, Ortiz, and Alfonso (2013) have revised their recommendations for the cross-battery assessment (XBA) approach to cognitive evaluation of children. This approach is based on the Cattell–Horn–Carroll (CHC) model of intelligence (see Schneider & McGrew, Chapter 3, this volume), which purports that general intelligence, or *g*, comprises a number of broad-stratum abilities, such as fluid reasoning (Gf), crystallized knowledge (Gc), quantitative reasoning (Gq), visual–spatial processing (Gv), and short-term memory (Gsm). Instead of administering only one cognitive test battery to children, examiners using this approach systematically select tests from more than one battery, to ensure that the abilities and processes most germane to the referral are assessed comprehensively. The XBA approach often results in a more psychometrically stable and complete picture of cognitive abilities than that which can be obtained by a single battery. This approach may aid examiners of children with VI/B in selecting test instruments, as subtests from different batteries can be administered according to both their contributions to the CHC broad abilities and their level of appropriateness for these children. If one Gf subtest, as an illustration, involves visual stimulus material—as does the WJ IV COG Analysis–Synthesis test—then Gf tests that are less dependent

on visual information can be selected. Evaluators applying the XBA approach, however, must note that some broad-ability cluster scores (such as Gv) may be difficult or impossible to obtain or interpret, depending on the individual child and his or her level of vision loss.

Various tests from the HRB or Luria–Nebraska Battery (LNB) can be used for individuals with VI/B if careful attention is paid to the examinee's need for modifications and if these modifications are considered in interpreting results. The NEPSY-II, which may be more appropriate for school-age children, does not offer VI/B norms or suggested accommodations, but includes subtests similar to those found in the HRB and LNB and may be administered with similar accommodations. Ultimately, test selection should be a collaborative decision between a clinician and a specialist or vision teacher knowledgeable about and experienced in working with children who have VI/B. In addition, formal evaluation methods should be supplemented by informal, often more subjective methods (e.g., student work samples, personal interactions with the child, and interviews with parents and teachers), in order to gain a more complete picture of the child's neuropsychological strengths and weaknesses than may not be obtainable from test scores alone. According to the Texas School for the Blind and Visually Impaired (2016), intellectual assessment of these students should also include direct observations of the child.

Instruments for Assessing Individuals with D/HI

Although the earlier-discussed issues of mode of communication, use of interpreters, and other standardized test problems still make cognitive and neuropsychological assessment of individuals with D/HI complex, there is considerably more research on this topic (for overviews, see Braden, 2001; Maller, 2003; Reesman et al., 2014) than is available for the population with VI/B. Braden (1994) reviewed over 300 studies on IQ and deafness, and found that IQ distributions for deaf people without comorbid conditions and for hearing people are nearly identical; this has also helped to raise awareness of the intellectual potential of students with D/HI. Again, test selection and interpretation should include awareness of individual variables—and, as noted above for individuals with VI/B, it should be a multidisciplinary team effort involving hearing teachers and other special professionals.

Reesman and colleagues (2014) reviewed 13 cognitive assessment measures available at that time for available information on using the tests with students who have D/HI. Many measures offered guidance in their test manuals regarding administration accommodations, including the Stanford–Binet Intelligence Scales, Fifth Edition (SB5); the Leiter International Performance Scale—Revised (Leiter-R) and Leiter-3; the WJ III COG; the Differential Ability Scales—Second Edition (DAS-II); the Kaufman Assessment Battery for Children—Second Edition (KABC-II); the Wechsler Nonverbal Scale of Ability (WNV); the WISC-IV; the Comprehensive Test of Nonverbal Intelligence—Second Edition (CTONI-2); and the Universal Nonverbal Intelligence Test (UNIT). The authors noted that the DAS-II offered particularly specific information regarding translation and back-translation (for fidelity) of administration instructions to and from ASL. Additionally, the ASL translation of the DAS-II instructions is available on DVD. Outside of a reliable ASL test translation, Reesman and colleagues pointed out that tests that rely solely on gesture for instruction presentation and response minimize translation issues for individuals who use different communication modalities from those of the examiner. For example, Maller (2000) examined the UNIT and concluded that no items in the four subtests studied showed differential item functioning across typically developing and D/HI samples.

In terms of test interpretation, although some measures included a small D/HI clinical norm sample, no test manual offered an adequate description of the sample in terms of communication modality, use of assistive listening devices, degree of hearing loss, etc. to allow for confident comparison (Reesman et al., 2014). Furthermore, the test manuals offered little guidance in appropriate interpretation of scores for this population. The manuals for the DAS-II, KABC-II, WNV, WISC-IV, and UNIT, however, did include discussion of comparing these students to the normative sample. Reesman and colleagues (2014) concluded that there is no one superior measure for all individuals with D/HI, and they recommended considering child and testing factors in selecting, administering, and interpreting intellectual assessment measures for these students. They called for future empirical research on the appropriateness and statistical bias of various tests with this population (Reesman et al., 2014). Notably, they also highlighted the possible future impact of technological developments that may allow for greater test accessibility, such as video-assisted administration. It remains to be seen how advances like tablet and computerized administration and scoring will affect the validity and reliability of testing with this group.

When examiners are assessing fluid reasoning skills, Hill-Briggs and colleagues (2007) suggest emphasizing spatial reasoning tasks, while keeping in mind that language differences and cognitive processing delays or use of an interpreter may affect the delivery of instructions. On Digit Span working memory tasks, they also remind clinicians that the average forward span for deaf signers is approximately five digits, and that the backward span is usually equivalent. Differences between signing system and English grammatical structure or syntax must be considered in using subtests such as the WJ IV COG Visual–Auditory Learning test and other sentence or story recall tasks.

Notably, the SB5 test manual includes an entire appendix titled "Use of the Stanford–Binet Intelligence Scales, Fifth Edition, with Deaf and Hard of Hearing Individuals: General Considerations and Tailored Administration" (Roid, 2003, Appendix E). The appendix divides individuals with D/HI into four categories: those who use sign language, simultaneous communication, cued speech, or auditory verbal–oral communication. The categories are based on the SB5 standardization administration to a special sample of individuals with D/HI, and suggestions for the appropriateness of administering each SB5 subtest to each of these groups are provided. In addition, both the WISC-V and WJ IV COG manuals provide suggested accommodations specifically for individuals with D/HI, as well as a table of appropriate subtests for use with such children by primary mode of communication (see Table 24.1).

Miller (2007) suggests including the SB5 in CHC-based cognitive assessment of children with D/HI, as the SB5 provides scores for the five broad abilities Gf, Gc, Gq, Gsm, and Gv, and has adequate information in Appendix E of the test manual (Roid, 2003). In the KABC-II (Kaufman & Kaufman, 2004) manual, the authors report no significant differences between a subgroup (n = 18) of students with D/HI and the hearing standardization group. Therefore, the KABC-II can also be used as part of a CHC-based cognitive assessment for children with D/HI. The KABC-II manual (Kaufman & Kaufman, 2004) reports that hearing and D/HI norms for the following factors were not significantly different, suggesting that the KABC-II is a stable measure of these abilities in children with D/HI: long-term retrieval (Glr), Gf, and Gv. Lastly, the DAS-II manual (Elliott, 2007) reports equivalent performances for children with D/HI and a matched hearing control group on subtests composing the test's Gf and Gv cluster scores. The DAS-II manual (Elliott, 2007) also includes tables of suggestions for administration to children with D/HI by subtest and communication mode, as well as a sign language CD and norming information from a clinical sample with D/HI. Instead of using one of these batteries alone to assess cognitive functioning in a child with D/HI, clinicians should consider employing the XBA approach (Flanagan et al., 2013; see also Flanagan et al., Chapter 27, this volume), based on Miller's suggestions for this special population. It is worth noting, however, that subtests contributing to cluster scores for broad-stratum abilities such as auditory processing (Ga) may be inappropriate to administer to these children or may have problematic interpretations.

With perceptual–motor tests, clinicians can usually use standard tasks from neuropsychological batteries such as the HRB and LNB, with careful attention to how directions are given and processed by the examinee. Again, the NEPSY-II is perhaps more appropriate for use with school-age children but is not yet empirically validated for individuals with D/HI, although it offers D/HI norms from a special D/HI clinical sample. As mentioned previously, examiners should provide an alternative to blindfolding or to asking individuals with D/HI to close their eyes during some neuropsychological tasks (e.g., balance tasks), as these modifications restrict their use of vision, an important mode of communication for individuals with D/HI. Hill-Briggs and colleagues (2007) note that standard visual–motor tasks in neuropsychological batteries are suitable for individuals with D/HI, but that caution should be exercised in interpreting the Rey Complex Figure task because children with D/HI may have different organizational strategies from those of typically developing children.

PHYSICAL DISABILITIES

According to the U.S. Census Bureau (2010), an estimated 8.2% of the general population had a physical disability (i.e., some limitation in basic physical activities), amounting to 19.9 million people in the United States. Difficulties surrounding the assessment of individuals with physical disabilities have recently become more prevalent—due in part to an increase in the number of individuals with such disabilities, as well as the proliferation of health services for these individuals (O'Keefe, 1994), and the increasing presence of these individuals in both post-secondary education (Fleischer, Zames, & Zames, 2012) and the workforce (Nevala, Pehkonen, Koskela, Ruusuvuori, & Anttila, 2015; Verhoef, Miedema, Meeteren, Stam, & Roebroeck, 2013). Many of these difficulties stem from an inability to adequately measure abilities or to interpret test scores on various assessments when an individual's disability inhibits him or her in some way. The difficulties specific to assessing individuals with physical disabilities, as well as the potential testing accommodations, are dependent on the type and severity of the disabilities.

Typically, children with some sort of physical impairment (PI) are served under the IDEA 2004 category of *orthopedic impairment*. Federal guidelines (U.S. Department of Education, 2006) define this as follows:

> *Orthopedic impairment* means a severe orthopedic impairment that adversely affects a child's educational performance. The term includes impairments caused by a congenital anomaly, impairments caused by disease (e.g., poliomyelitis, bone tuberculosis), and impairments from other causes (e.g., cerebral palsy, amputations, and fractures or burns that cause contractures). (pp. 46756–46757)

According to the U.S. Department of Education (n.d.), approximately 6,325 children ages 3–5 and an additional 46,268 children and youth ages 6–21 in the United States were served under this category in the fall of 2015. Occasionally, children with a PI may qualify for special education services under the category of *other health impairment* (OHI). According to the IDEA regulations, OHI is defined as

> having limited strength, vitality, or alertness, including a heightened alertness to environmental stimuli, that results in limited alertness with respect to the educational environment, that—
>
> (i) Is due to chronic or acute health problems such as asthma, attention deficit disorder or attention deficit hyperactivity disorder, diabetes, epilepsy, a heart condition, hemophilia, lead poisoning, leukemia, nephritis, rheumatic fever, sickle cell anemia, and Tourette syndrome; and
>
> (ii) Adversely affects a child's educational performance. (U.S. Department of Education, 2006, p. 46757)

According to the U.S. Department of Education (n.d.), 23,652 children ages 3–5 and 857,544 children and youth ages 6–21 in the United States were served under this category in the fall of 2015. However, OHI covers more than just PI, so these figures are overestimates. Nevertheless, each individual with PI, whether qualifying for school services under orthopedic impairment or OHI, or under a federal Section 504 Accommodation plan, requires some unique testing considerations at both the individual and test level.

Etiologies: A Brief Overview

Motor skill development occurs in stages, preceded and accompanied by the growth and development of the endocrine and nervous systems. The typically developing child passes through a sequence of milestones, such as holding his or her own head up at about 2 months of age, crawling at about 6 months, and walking at about 1 year of age (Sigelman & Rider, 2009). It is during this time of rapid development that some types of PI become apparent. Specifically, delayed walking is often indicative of a motor impairment. PI can be either acquired (e.g., spinal cord injury [SCI] and amputation) or congenital. Congenital disabilities become apparent either at birth or during infancy and toddlerhood when a child fails to reach one or more typical milestones. Cerebral palsy (CP), for example—the most common motor disability in childhood, occurring 2.0–3.6 times in every 1,000 live births (Accardo, 2008; Arneson et al., 2009; Bhasin, Brocksen, Avchen, & Van Naarden Braun, 2006; Cans, 2000)—has many potential causes, including genetic abnormality, intrauterine infection, complications during labor or birth, or experiencing a TBI before the age of 5. CP generally causes problems associated with movement and posture, although comorbid disorders (e.g., intellectual disabilities, sensory disorders, seizures, and growth abnormalities) often occur (Pellegrino, 1997).

Special Considerations for Assessment: Child Factors

There is little literature on the neuropsychological testing of children with PI, and much of what exists is very specific to one disorder or another. Two of the most researched conditions are CP and SCI. For example, a recent study examined the performance of children with CP on the Wechsler Preschool and Primary Scale of Intelligence—Third Edition (WPPSI-III) (Sherwell et al., 2014). Results indicated that a proportion of the children (20.5%) were unable to complete the full test battery, due to insufficient pointing or verbal responses. Of those who were able to complete the WPPSI-III, fine/gross motor weaknesses depressed their overall scores (i.e., Full Scale IQ) by approximately 5 points (i.e., one-third of a standard deviation). Another variable contributing to the heterogeneity of this population is a child's age at onset of a disability. Many physical disabilities are the result of congenital defects or diseases (e.g., CP, muscular dystrophy [MD], and multiple sclerosis). The age of onset can significantly affect one's ability to compensate for mild to severe PI. Individuals with congenital disabilities learn to cope with their limitations from birth. Those who acquire impairments at a relatively young age are less likely to have multiple deficits as adults. Li and Moore (1998) found that both younger participants and those with congenital disabilities had higher levels of disability acceptance. Those with PI acquired as the result of disease, amputation, or accidents have the added difficulty of relearning many tasks without the full use of a particular body part. Research conducted on motor recovery following stroke, SCI, and CP has indicated that motor recovery, if it occurs, can be incomplete or deficient (Krishnan, 2006).

To qualify for services under federal programs (IDEA or Section 504), an individual's disability must be severe. The type and severity of disability will greatly affect test selection and interpretation. For individuals who fatigue easily as a result of their disability, for example, it may be appropriate to extend the time to allow for additional breaks (AERA et al., 2014). Individuals with PI may also suffer from comorbid conditions. For example, in assessing individuals with CP, associated difficulties—such as learning difficulties, attention-deficit/hyperactivity disorder, intellectual disability, and sensory impairment—warrant consideration. It is these problems that put students at the greatest disadvantage when contrasted with their peers (Pellegrino, 1997). In the case of students with chronic disease or those with PI, distinguishing gaps in achievement resulting from the illness or impairment from indirect effects, such as those caused by school absence, pain or fatigue, depression, and low self-efficacy, is imperative (Donnelly, 2005). Comorbidity is also a possible source of construct-irrelevant variance,[1] which should be considered in interpreting the results of assessments conducted on individuals with PI.

Special Considerations for Assessment: Test Factors

Historically, accommodations for PI have been considered less salient than those for sensory disabilities, such as VI/B or D/HI (Lezak, Howieson, & Loring, 2004). In the past, clinical judgment and prior experience alone were considered acceptable standards for modifying test administration (Pratt & Moreland, 1998). Currently, many assessments suggest accommodations in the administration or technical manuals, in an attempt to retain standardization even in work with special populations (see Table 24.1). Common test accommodations include modifications in presentation, response format, or timing, as well as in test selection (AERA et al., 2014). Test setting and environment can also be modified for accessibility and physical comfort due to problems associated with a disability (AERA et al., 2014; Pratt & Moreland, 1998). A few test manuals provide normative information for clinical populations such as those with PI (see Table 24.1), but those that do are typically based on small samples that are not necessarily representative of the greater population with PI.

Motor functioning is a primary consideration for those assessing individuals with PI to bear in mind (Hill-Briggs et al., 2007), as motor functioning dictates the use of various response options. Specifically, impairment or loss of motor function in the upper extremities is of utmost concern, as it can affect fine motor control and/or dexterity. Impairments in this area will significantly reduce response format options because such individuals will not be able to complete tasks such as those requiring the manipulation of stimuli, or holding or utilizing a writing utensil (e.g., writing, drawing, or copying a figure). If standardized test administration requires such motor skills, then test accommodations for these individuals are necessary (Nester, 1994). The only exception would be when the goal of testing is to determine the extent of limitation caused by the PI.

Awareness of the individual's level of discomfort is another important variable for consideration and may require continual evaluation throughout the duration of testing. Individuals with PI may require repositioning or additional breaks to combat discomfort or fatigue, and some individuals (e.g., those with CP or MD) may additionally experience pain or cramping. Studies conducted on secondary pain (often the result of treatment) in adults with CP illustrated the immense impact of pain. From 67 to 84% of participants across three studies reported chronic pain (Engel, Jensen, Hoffman, & Kartin, 2003; Schwartz, Engel, & Jensen, 1999; Turk, Geremski, Rosenbaum, & Weber, 1997), and 18–56% reported daily incidents of pain (Andersson & Mattsson, 2001; Engel et al., 2003; Schwartz et al., 1999). Similarly, Zebracki and Drotar (2008) found that 54% of those with Duchenne MD and 80% of those with Becker MD reported experiencing pain associated with their disease. Also, according to the Child Activity Limitations Interview (CALI; Palermo, Witherspoon, Valenzuela, & Drotar, 2004), sitting was endorsed most frequently as causing discomfort in daily life, further justifying the need to monitor discomfort during an assessment (Zebracki & Drotar, 2008). Accessibility is also a concern. For example, if an individual uses a wheelchair, the testing location needs to be wheelchair-accessible.

Instruments for Assessing Individuals with PI

Since specialized cognitive tests do not exist for persons with PI in the same way that they do for individuals with VI/B or D/HI, great care must be taken to accommodate varying degrees of impairment within the framework of existing measures such as the WISC-V, WJ IV COG, or SB5. Many popular tests like these provide recommended test accommodations/modifications and norming information (see Table 24.1). Although the norms exist, they are unlikely to be representative; resultant scores should therefore be interpreted with caution.

Within SCI research, certain measures have been noted as being particularly useful in cases of paraplegia and quadriplegia. Others should be avoided; for example, the Trail Making Tests would not be an ideal selection for someone with a fine motor impairment because of construct-irrelevant variance. The following are some of the most commonly used measures within a motor-free neuropsychological assessment battery: the Wechsler Memory Scale (minus visual reproduction); the verbal subtests of the WAIS; the Symbol Digit Modalities Test; the Stroop Test; the Rey Auditory Verbal Learning Test; the Hooper Visual Organization Test; the Halstead Category Test; and the California Oral Word Association Test (Davidoff, Roth, & Richards, 1992; Dowler et al., 1997; Richards, Bown, Hagglund, Bua, & Reeder, 1988; Roth et al., 1989). Using various tests in this way is reminiscent of the XBA cognitive assessment approach (Flanagan et al., 2013), in which subtests from a variety of batteries can be combined in order to provide a comprehensive assessment of an individual's cognitive abilities. A mixed approach, like XBA, can provide the opportunity to assess individuals with PI more fully. Using such an approach could allow for subtest substitutions, which could assess an individual's skills in a different way, independent of his or her PI.

TRAUMATIC BRAIN INJURY

Approximately 1.7 million individuals suffer from a TBI every year, and children and youth between the ages of 0–4 and 15–19 are in the highest risk categories for sustaining a TBI (Brain Injury Association of America, 2012). Approximately 24% of children with severe head injuries do not survive (White et al., 2001). Comprehensive evaluations that include neuropsychological assessment are critical in assisting neurologists, determining the degree and severity of functional impairment resulting from the injury, and documenting changes in impairment over time (American Academy of Neurology, 1996). Schools and educational institutions are obligated under federal law to identify and provide special educational assistance to children with TBI. TBI is specified in IDEA 2004 as one of 13 categories under which students may receive special education services. The IDEA 2004 regulations define TBI as

> an acquired injury to the brain caused by an external physical force, resulting in total or partial functional disability or psychosocial impairment, or both, that adversely affects a child's educational performance. The term applies to open or closed head injuries resulting in impairments in one or more areas, such as cognition; language; memory; attention; reasoning; abstract thinking; judgment; problem-solving; sensory, perceptual, and motor abilities; psychosocial behavior; physical functions; information processing; and speech. [The term] does not apply to brain injuries that are congenital or degenerative, or to brain injuries induced by birth trauma. (U.S. Department of Education, 2006, p. 46757)

According to the U.S. Department of Education (n.d.), approximately 1,106 children ages 3–5 and an additional 25,419 children and youth ages 6–21 in the United States were served under this category during the 2014–2015 academic year. Although the federal definition explicitly excludes children whose brains may be affected by congenital problems or injury at birth, these children may still be eligible for special education under Section 504 of the Americans with Disabilities Act.

TBI may result from penetrating or nonpenetrating wounds. Impairment may range from none to severe, and injuries to the brain may result from direct damage to the brain or from indirect damage caused by brain swelling or bruising. Because falls and motor vehicle accidents are the most common causes of TBI (Faul, Xu, Wald, & Coronado, 2010) and usually result in diffuse injury, the deficits and symptoms associated with TBI vary widely. Early research on the developmental sequelae of brain injuries in childhood suggested that most children fully recover from the injury by adulthood, due to brain plasticity. However, more contemporary research has suggested that TBI sustained during childhood—even a mild brain injury—may in fact have lasting deficits in adulthood that include not only cognitive but psychiatric problems (Konrad et al., 2011; Pirozzolo & Papanicolaou, 1986), as well as lower quality of life (Anderson, Brown, Newitt, & Hoile, 2011).

The specific location of injury also influences long-term outcomes. Counterintuitively, right-hemispheric injuries have been shown to result in more long-term impairments than left-hemispheric injuries, even though the left hemisphere is typically the dominant hemisphere and highly involved in language functions. However, the right hemisphere seems to deal with new learning experiences (novelty) more proficiently than the left hemisphere—and, for children, almost all experiences are new learning experiences.

Neuropsychological Assessment

No specific cognitive profile or cluster of symptoms has been considered diagnostic of TBI; this is not surprising, considering that injuries may be focal (one specific area) or diffuse (general). Focal neurological damage results in more specific behavioral dysfunction than does diffuse damage (Berninger & Richards, 2002; Halstead, 1947; Kolb & Whishaw, 2003; Luria, 1980). Clinical hypothesis testing within an individualized assessment plan is important, to match the clinical symptoms and measured neuropsychological deficits to the type and location of the injury. However, two common cognitive deficits of children with TBI are slowed processing speed and attention problems (Rutter, 1981). Recent literature has identified these deficits by using a variety of measures and batteries (Allen, Thaler, Donohue, & Mayfield, 2010; Belanger, Curtiss, Demery, Lebowitz, & Vanderploeg, 2005; Frencham, Fox, & Maybery, 2005; Mathias & Wheaton, 2007). Cognitive deficits from TBI are direct causes of academic and educational problems, which require specialized attention from educational professionals (Blosser & DePompei, 1991; D'Amato & Rothlisberg, 1996).

Although the connection between TBI and cognitive deficits is well known, the neurological mechanisms have only recently begun to be understood, primarily due to advances in brain imaging technology. Thatcher, Walker, Gerson, and Geisler (1989) used quantitative electroencephalography (QEEG) to compare 264 patients with mild head injuries to a control group, and found differences in the frontal and fronto-temporal regions of the brain. Results from this study suggested that QEEG measures of brain activity could distinguish patients with TBI from controls with 93% accuracy, which clearly indicates that TBI causes changes in brain activity. Using functional magnetic resonance imaging, Kraus and colleagues (2007) found that TBI resulted in white matter disruption, and that the degree of disruption was correlated with neuropsychological impairment, particularly with measures of executive functions and attention. White matter disruptions were found in children with TBI who had persistent motor control deficits. Compared to controls, these children showed greater brain activation in the parietal and cerebellar areas, which resulted from greater attentional resources needed for motor action (Caeyenberghs, Wenderoth, Smits-Engelsman, Sunaert, & Swinnen, 2009). Finally, a study by Wilde and colleagues (2011) investigated working memory tasks in children with TBI. Compared to an orthopedic control group, children with TBI displayed disrupted attentional and working memory functioning in fronto-parietal regions. Additionally, reduced white matter integrity in the cingulum bundle and frontal lobes was associated with slower reaction times. Together, these studies suggest that white matter disruption caused by TBI is a core underlying cause of both cognitive and motor deficits in children with TBI. Cognitive deficits including slowed processing speed are directly linked to white matter disruption, which interferes with automatized behaviors. Compensation with effortful behaviors ultimately results in slowed performance, detected as slowed processing speed and attentional problems on standardized tests.

Neuropsychological consultation has been recommended as a core educational service to be provided by school psychologists (D'Amato, 1990; Decker, 2008; Hale & Fiorello, 2004; Miller, 2007). School psychologists who serve children with TBI, but who lack neuropsychological training, may consider referring the children to or directly consulting with a neuropsychologist. Neuropsychological consultation involves not only direct service delivery, but also an understanding of recovery patterns, rehabilitation and effective interventions, and school reentry assistance. Critically, families commonly experience an often overlooked emotional reaction to loss of a "normal" child. Consultation with families is necessary to help set appropriate expectations for academic and behavioral performance.

Special Considerations for Assessment: Child and Test Factors

One primary function of the school psychologist is to conduct a comprehensive, broad-based assessment of a child with TBI, to ensure that a valid picture of the child can be communicated to parents and teachers and incorporated into intervention (Havey, 2002). Test accommodations are most needed for children with TBI when sensory impairments or PI are evident. When such impairments are not evident, most measures frequently used by school psychologists are appropriate for assessing the underlying impairment that has resulted from the TBI. However, it is important for clinicians to be aware of how core deficits caused by a TBI may inadvertently affect a variety of test constructs, thereby creating construct-irrelevant variance. For example, attention problems and slowed processing speed may have an impact on any variety of cognitive measures, not just those subtests explicitly targeting attention and processing speed. To minimize construct-irrelevant factors, it may be necessary to administer directions at a slower pace to children with TBI to ensure comprehension. In addition, children with TBI may need examiners to repeat directions to ensure proper encoding. When engaging in longer tasks, children with TBI may require more frequent prompting to prevent lapses in attention. More frequent breaks may be necessary, too, as children with TBI may become fatigued more quickly than other children of similar developmental age without a TBI. Most adaptations needed for assessment of children with mild TBI should not seriously jeopardize test validity.

As previously mentioned, age is an important variable for several reasons. First, age is a risk factor in two ways: Younger children (ages 0–4) are at higher risk for TBI due to falls, and older adolescents (ages 15–20) are at higher risk for TBI due to automobile accidents (Faul et al., 2010). Age also moderates the sequelae of behavioral impairment: TBI in younger children may interfere with the later development of skills, whereas TBI in adolescents may result in the loss of learned skills.

Estimating preinjury functional status is important to determine the degree to which cognition has changed as a result of the injury. Premorbid intelligence is typically estimated by a qualitative review of historical records (past educational achievement) and quantitative performance on cognitive measures typically resistant to neurological injury. Measures of crystallized intelligence (e.g., vocabulary) are used to measure abilities most resistant to neurological injury (Königs, Engenhorst, & Oosterlaan, 2016; Lezak et al., 2004; Russell, 1980).

Instruments for Assessing Individuals with TBI

As with standard school psychology assessment procedures, no one test or test battery can comprehensively assess the emotional, cognitive, and behavioral status of a child with TBI. Thus various measures from different domains are required. The Glasgow Coma Scale is widely used in making the initial determination of injury severity (mild, moderate, or severe). This is a short rating scale of eye, verbal, and motor responses that is used at or near the time of injury. Scores range from 3 to 15, with 3 representing no eye, verbal, or motor response and 15 representing a fully awake and functioning person. Similarly, a structured interview specifically tailored to important factors related to neurological injury is recommended (Dean, Woodcock, Decker, & Schrank, 2003). Sensory–motor measures are useful adjuncts to intellectual assessment, to rule out basic input–output deficits as a source of impairment on cognitive measures and to validate clinical hypotheses of cortical injury. Residual sensory–motor impairment from a brain injury has been demonstrated in children several weeks after release from the hospital (Gagnon, Forget, Sullivan, & Friedman, 1998).

Telzrow (1991) recommends assessing a variety of domains of intellectual functioning in children with TBI. Although a variety of assessment models may work for this purpose (Hale & Fiorello, 2004; Miller, 2007), a cross-battery model (e.g., the XBA approach) provides ample coverage to assess comprehensively different domains of cognitive functioning (see Flanagan et al., Chapter 27, this volume). A cross-battery model not only provides a close correspondence between cognitive functions of interest to neuropsychologists, but also enjoys wide familiarity among school psychologists (Decker, 2008). The cognitive domains incorporated in the XBA approach (Flanagan et al., 2013) include processing speed, a crucial area of assessment for children with TBI. Attention is not an explicit cognitive domain within the model, and so clinicians should be familiar with test-specific attentional demands and how attention may influence underlying test performance.

SUMMARY

This chapter has discussed issues related to sensory and physical disabilities as well as TBI within a neuropsychological framework. A neuropsychological framework is necessary because the causes of VI/B, D/HI, PI, and TBI all have some basis in the physiological disruption of typical sensory, motor, and cognitive pathways in the brain and body. In a school setting, individuals with all of these impairments may be eligible for services under IDEA 2004. We have reviewed the ways in which individual child factors—such as age at onset, nature and severity of the disability, etiology, comorbidity, primary modes of communication, and reading and language ability—can affect test selection, administration, and interpretation. We have also offered examples of the ways in which individual differences within each disability category may manifest themselves during academic and testing situations. Some important considerations noted for all disability categories include attention to within-category heterogeneity; the child's communicative style and linguistic skill level; the fit between educational environment and child; and the necessity of collaborating with both families and a multidisciplinary team to achieve systematic data-based decision making on a case-by-case basis.

This chapter has highlighted special considerations required for the assessment and evaluation of children with neurological conditions involving sensory or cortical impairment. Specifically, we have reviewed the availability of cognitive and neuropsychological test batteries with special standardized procedures for test accommodations, appropriate subtests, and normative information in special populations. Clinical judgment is required for modifying standardized tests and interpreting test results in light of a child's particular sensory or motor deficits. With careful attention to both child and test factors, and the help of a multidisciplinary team, many currently available cognitive and neuropsychological test batteries can be used effectively for the assessment of children with VI/B, D/HI, PI, and TBI. Cautious interpretation of the results, along with multisource information from systematic observations and from professional colleagues and specialists, can be integrated to provide a sound psychoeducational plan for every child, regardless of sensory or physical disability.

NOTE

1. The term *construct-irrelevant variance* is used to describe instances in which variability in responses is affected by something unrelated to the interpreted construct (Messick, 1995). This can occur as a result of changes in methodology, and as such it is especially important for practitioners to keep in mind when testing individuals who require modifications to standardized procedures.

CHAPTER 25

Testing with Culturally and Linguistically Diverse Populations

New Directions in Fairness and Validity

Samuel O. Ortiz
Nicole Piazza
Salvador Hector Ochoa
Agnieszka M. Dynda

As the racial and ethnic composition of the U.S. population continues to diversify at a rapid pace, practitioners are increasingly likely to find themselves evaluating individuals who come from culturally and linguistically diverse backgrounds. Among children of school age across the United States, ethnic minorities now constitute the majority group in various areas (e.g., New Jersey, Washington, D.C.; see Llorente & Sheingold, 2010; Smith, 2008), and the precollege grade-level population of Hispanics currently exceeds that of white non-Hispanics in states such as Arizona, California, and Nevada (U.S. Census Bureau, 2017). Reports from the U.S. Census Bureau's (2010, 2014) American Community Survey also indicate that one-fourth of children in U.S. public school kindergarten classes are Hispanic, and that ethnic minority children will become the majority by 2023. The time when practitioners might only encounter ethnic minority children on rare occasions has long since passed. The data make it clear that diversity within the population is increasing quickly and rapidly becoming a fact in everyday life and clinical practice.

In a survey of current practices in psychological assessment of students with limited English proficiency (LEP), Ochoa, Riccio, Jimenez, Garcia de Alba, and Sines (2004) found that practitioners engaged in the assessment of diverse individuals utilized a variety of different instruments. The most commonly used combination included an intelligence scale (most often a Wechsler scale administered completely in English), a test of visual–motor integration, an informal projective drawing test, and a nonverbal intelligence instrument. Interestingly, Ochoa and colleagues noted that this makeshift battery is not substantially different from the instruments employed in the evaluation of mainstream, monolingual English speakers. Indeed, even when a practitioner had professional bilingual capability, the battery remained largely the same; the only notable changes occurred in the language version or language of administration of the tests. This finding was replicated to some extent more recently by Sotelo-Dynega and Dixon (2014). Whether this practice is driven by staunch adherence to training or by mere inertia, the similarity in test usage and its continued ubiquity in current practice suggest that practitioners still largely ignore major factors that differ markedly in the testing of one population versus another. These factors include such things as inadequately representative norms and inappropriate comparison groups, as well as linguistic and cultural confounds that are manifested in unequal levels of age and grade-expected language and acculturative knowledge acquisition—and that occur primarily as a function of limited experience and exposure, not actual lack of ability.

Perhaps one of the reasons why testing practices with diverse populations have remained rather stagnant for so long is the fact that there are very few researchers whose theoretical or empirical work centers on this topic. Although it is not an area of study that is in any way limited to those who are themselves from diverse backgrounds, there remains a significant lack of knowledgeable and committed researchers interested enough to advance the field. When research is conducted along these lines, it is often carried out by researchers and academicians with only a passing interest in the subject, whose limited understanding of the many facets and variables involved tends to undermine the quality of their results and the conclusions they draw from them (cf., Kranzler, Flores, & Coady, 2010; Styck & Watkins, 2013, 2014). Another problem that stifles advances in this area has more to do with a general failure to look beyond the traditional reliability-based view of test bias; there has been little focus on the concept of validity, particularly construct validity. When notions of bias were first leveled at tests and testing applied to diverse populations, there was a concerted effort to investigate the claims and provide some sort of scientific analysis of the truth. At this early stage, it was believed that factors such as race and ethnicity posed threats to the inherent reliability of tests—threats that were manifested in supposed bias in regard to factor structure, difficulty level, or prediction. Yet such bias was rarely found (Figueroa, 1983; Reynolds & Ramsay, 2003; Sandoval, Frisby, Geisinger, Scheuneman, & Grenier, 1998). This is hardly surprising, especially when the issue is considered in the bluntest sense: That is, why should people's skin color dictate their level of performance on a test of intelligence or cognitive ability, any more than would their favorite flavor of ice cream or their first pet's name? For these reasons, many early researchers adopted the notion that the differences in performance must be genetically based. In other words, they concluded that if these differences exist (they do), and they are real and measurable (they are), and the only other difference between populations is skin color (this is where the error occurs because it isn't), then the mean differences must be rooted in some sort of genetically driven explanation (Gottfredson, 1997; Jensen, 1969).

These arguments have felt quite convincing for a long time, and with respect to the lack of *psychometric* bias as related to its typical definition, they are correct. What is wrong is that there has been a tendency to overlook the manner in which factors other than skin color or cultural heritage actually affect test performance. Indeed, it is better understood now, but not widely known, that simple racial or cultural differences are not what create the noted mean differences in performance; rather, it is the degree to which individuals' racial or cultural characteristics might have affected two particular developmental processes that are the foundations for measurement comparisons and believed to be inherently tied to physical maturation and age. These variables are language and cultural knowledge. The color of an individual's skin is not what matters. Rather, what matters is the degree to which any individual, regardless of race or cultural heritage, has had the same opportunity to learn and develop in the language of the test being administered and the same opportunity to learn, acquire, and automatize the cultural knowledge that is invariably built into the test's tasks (Ortiz, 2014; Rhodes, Ochoa, & Ortiz, 2005; Salvia & Ysseldyke, 1991; Valdés & Figueroa, 1994). These factors, however, do not in any real way directly affect the reliability or accuracy of measurements taken with psychometrically sound instruments. Rather, bias comes only as an issue of construct validity. More pointedly, it stems from interpretation of a measurement's meaning when it is based on comparisons among individuals who, despite being of the same age or grade, nevertheless possess differential rates of language and cultural knowledge acquisition. For example, a 10-year-old native English speaker raised in the U.S. mainstream by fully acculturated and native-English-speaking parents, in a home and community in which English is the cultural language, is not comparable to—and cannot be used as the standard for expectations of performance for—a 10-year-old whose parents speak limited English, who is raised in a non-mainstream culture, and who must learn to speak English independently or with limited experiential opportunities (such as at school).

The survey by Sotelo-Dynega and Dixon (2014) highlights another important point: Practitioners are not simply choosing the "wrong" test because the reality is that there is no "right" test, at least not yet. Rather, regardless of what test is selected, practitioners appear to administer and interpret it in much the same way with examinees who have LEP as they do with any other individuals, regardless of whether the test is given in English or the examinees' native language. Thus, although tests continue to need significant improvement, advances in practice will not stem only from better psychometrics. Rather, there is likely to be more value for practice in being able to assist in rendering valid interpretation of results. For example, it has been reported that 98% of school psychologists who evaluate culturally and linguistically diverse individuals stated that they consider both the "validity of test scores" and "an examinee's level of English language proficiency before selecting a test and interpreting test scores" (Sotelo-Dynega, Cuskley, Geddes, McSwiggan & Soldano, 2011). But when asked how they actually evaluate such individuals so that the relevant issues are properly considered, particularly the validity of the test scores, the vast majority simply reported using different types of tests; there was no mention of how any of them actually addressed test score validity. Approximately 88% reported using nonverbal tests, 40% reported use of an interpreter to administer a test, 20% reported use of a native-language test, and 2% reported "on-the-fly" translation of a test. Practitioners thus appear to be presuming that validity issues are resolved merely by decisions regarding test selection. In short, there seem to be few indications that practitioners are actually examining issues of validity directly or attempting to integrate current research regarding the manner in which cultural and linguistic factors are known to influence test performance. As a consequence, there is often no defensible or scientific basis for the types of interpretations, conclusions, and diagnoses stemming from the use of tests in such practice.

The first purpose of this chapter is to describe the current issues pertaining to the use of standardized, norm-referenced tests in attempts to evaluate the abilities (intellectual, cognitive, academic, and neuropsychological) of individuals from culturally and linguistically diverse backgrounds and provide direction for future test development. The second purpose is to discuss the advances that have been made in providing guidance for evidence-based practice in this area, as well as technical and psychometric innovations that can increase practitioners' ability to more directly ameliorate concerns over test score validity. Specific sections of this chapter are devoted to (1) evaluating current standards of practice; (2) evaluating the advantages and disadvantages of current practices; (3) integrating research into defensible practice; and (4) describing new directions in test development.

EVALUATING CONTEMPORARY STANDARDS OF PRACTICE

Changing demographics will continue to place pressure on graduate training programs and their trainees to acquire the requisite multicultural competency necessary for conducting fair and equitable evaluations of individuals from culturally and linguistically diverse backgrounds (Ortiz, 2014). It is unclear at present whether sufficient faculty and supervisors exist, or sufficient resources are available, to ensure that all graduate students will gain adequate experience in formulating appropriate knowledge and skills, but it seems safe to say that supervised experience with multicultural populations probably remains somewhat limited. When practitioners find themselves at a loss or in need of guidance on the matter, they are likely to refer to the usual sources of information. For example, over 20 years ago the American Psychological Association (1993) published *Guidelines for Providers of Psychological Services to Ethnic, Linguistic, and Culturally Diverse Populations,* which emphasizes the need for psychologists to acknowledge the influences of language and culture on behavior, and to consider those factors when working with diverse groups. The guidelines also include admonitions regarding appraisal of the validity of the methods and procedures used for assessment and interpretation. But exactly what should or can be done when validity is deemed questionable, or what specific steps exist to reduce bias and maintain validity in the first place, are unfortunately absent from this rather dated set of guidelines.

The search for more definitive answers invariably leads practitioners to the *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA], American Psychological Association, & National Council on Measurement in Education, 2014), known simply as "the *Standards*." Through revised editions with contributions from leading experts in the field, the authors of the *Standards* have made progress in providing more definitive guidance for practitioners faced with evaluating the knowledge and abilities of individuals from culturally and linguistically diverse backgrounds.

The 2014 edition provides a comprehensive chapter (Chapter 3) centered on elements of testing that support various facets of fairness, protection against measurement bias, and validity for testing culturally and linguistically diverse individuals. Specifically, Chapter 3 outlines fairness provisions to be considered in (1) test design, development, administration, and scoring procedures that minimize barriers to valid score interpretations for the widest possible range of individuals and relevant subgroups; (2) validity of test score interpretations for intended uses for the intended examinee population; (3) accommodations to remove construct-irrelevant barriers and support valid interpretations of scores for their intended uses; and (4) safeguards against inappropriate score interpretations for intended uses. The *Standards* volume also posits two distinct, novel concepts to be adopted by test makers and administers to minimize bias and promote fairness. The first is *accessibility* to all test takers—that is, allowing examinees "an unobstructed opportunity to demonstrate their standing on the construct(s) being measured." The second is *universal design,* or testing that ensures "clarity surrounding construct(s) to be measured," including the target, purpose, inferences to be made, and characteristics of examinees for a given test. However, while the new *Standards* volume is improved in organization and comprehension, it remains nondefinitive in providing concrete answers for practitioners related to the complex issues presented.

The opening description of purpose and background in Chapter 3 of the 2014 *Standards* provides a broad definition of *fairness*:

> A test that is fair within the meaning of the Standards reflects the same construct(s) for all test takers, and scores from it have the same meaning for all individuals in the intended populations; a fair test does not advantage or disadvantage some individuals because of characteristics irrelevant to the intended construct . . . characteristics of all individuals in the intended test population, including those associated with race, ethnicity, gender, age, socioeconomic status, or linguistic or cultural background, must be considered throughout all stages of development, administration, scoring, interpretation, and use so that barriers to fair assessment can be reduced. (p. 50)

Chapter 3 also clearly identifies the measurement bias that is rampant in traditional methods of testing the ability of culturally and linguistically diverse individuals:

> Individuals who differ culturally and linguistically from the majority of the test takers are at risk for inaccurate score interpretations because of multiple factors associated with the assumption that, absent language proficiency issues, these individuals have developmental trajectories comparable to those of individuals who have been raised in an environment mediated by a single language and culture. (p. 53)

These themes serve as the common thread woven throughout the *Standards* in discussing the multifaceted issues surrounding testing the abilities of culturally and linguistically diverse individuals and provisions to address those issues.

Perhaps the most fundamental issue that cuts across measurement bias is that socially constructed categories, such as race and ethnicity, do little in achieving accurate representation along the relevant and important dimensions that actually affect test performance. Neither skin color nor an individual's ethnic heritage affects test performance directly. It is the individual's developmental background, particularly with respect to linguistic and acculturative experiences, that influences the manner in which the individual responds on standardized, norm-referenced tests. Salvia and Ysseldyke (1991) make this point clear in their statement regarding the *assumption of comparability*:

> When we test students using a standardized device and compare them to a set of norms to gain an index of their relative standing, we assume that the students we test are similar to those on whom the test was standardized; that is, we assume their acculturation is comparable, but not necessarily identical, to that of the students who made up the normative sample for the test. When a child's general background experiences differ from those of the children on whom a test was standardized, then the use of the norms of that test as an index for evaluating that child's current performance or for predicting future performances may be inappropriate. (p. 18)

Controlling for racial or ethnic differences via stratified random sampling may provide a desired measure of "face validity" for the norm sample, but in fact it only ensures that proportionate numbers of individuals from such backgrounds are included in the norm sample. It does not ensure that individuals from such backgrounds have comparable experiences, particularly as related to linguistic development and acculturative experiences. The 2014 *Standards* volume does clearly acknowledge this point: "In attempting to ensure fairness, we often generalize across groups of test takers . . . however, this is for convenience and not to imply that subgroups themselves are homogenous, or that, consequently, all members of a group should be treated similarly when making interpretations of test scores for individuals" (p. 53). But guidelines on *how* to treat culturally and linguistically diverse subgroups as individuals, and *how* to account for individual characteristics that may interact with different testing situations, are still lacking. It is unfortunate that current researchers continue to examine a multitude of issues related to test performance in studies that use groups formed exclusively on racial or ethnic categories (e.g., Hispanic). When constructed in such a manner, such studies lack generalizability and do not inform practice in any substantive way and are effectively flawed in methodology. As described by Lohman, Korb, and Lakin (2008),

> most studies compare the performance of students from different ethnic groups . . . rather than ELL [English-language learner] and non-ELL children within those ethnic groups. . . . A major difficulty with all of these studies is that the category Hispanic includes students from diverse cultural backgrounds with markedly different English-language skills. . . . This reinforces the need to separate the influences of ethnicity and ELL status on observed score differences. (pp. 276–278)

In a manner quite similar to differences in language skills, differences in test performance related to acquisition of cultural knowledge also preclude valid comparisons of performance. Validity can only be inferred when an examinee's background and experiences are comparable to those of the individuals who make up the norm sample. Whenever this assumption is not met, conclusions regarding the meaning of test results become dubious at best. This notion has also been described by Salvia and Ysseldyke:

> Incorrect educational decisions may well be made. It must be pointed out that acculturation is a matter of experiential background rather than of gender, skin color, race, or ethnic background. When we say that a child's acculturation differs from that of the group used as a norm, we are saying that the *experiential background* differs, not simply that the child is of different ethnic origin, for example, from the children on whom the test was standardized. (1991, p. 18; original emphasis)

It would seem that if they are to advance our scientific understanding, empirical investigations that make their way into academic journals in the future need to begin acknowledging this issue and incorporate participant groupings more representative of the true linguistic and cultural differences that play pivotal roles in how an individual performs on a test.

Perhaps a more utilitarian discussion for practitioners can be found in Chapter 3 of the *Standards,* which deals with fairness in testing and test use, as indicated above. In addition to the ubiquitous discussions regarding psychometric bias, the chapter provides an important definition and analysis of fairness as "opportunity to learn," as well as of content-, response-, and context-related sources of test bias. It is noted that "the extent to which individuals have had exposure to instruction or knowledge that affords them the opportunity to learn the content and skills targeted by the test has several implications for the fair and valid interpretation of test scores" (p. 56). Individuals who move between a home environment where the language and content emanate from their heritage culture, and a school environment where the language and content emanate from the majority, mainstream culture, are likely to fall under this definition of having limited opportunity to learn. Parents who do not speak English at all or well, and who were not raised or educated in the cultural mainstream and content of the school, can do little to transmit to their children the incidental knowledge or language skills that often accompany the requirements of academic and cognitive tests. When an individual comes from such circumstances, test performance will be adversely affected. But how does this help the practitioner? The *Standards* volume addresses problems that arise when a test requires an ability that is not the intended construct under measurement, or a construct-irrelevant component: "A prime threat to fair and valid interpretation of test scores comes from aspects of the test or testing process that may produce construct-irrelevant variance in scores that systematically lowers or raises scores for one identifiable group of test takers and results in inappropriate score interpretations for intended users" (p. 54). Examples of potential construct-irrelevant components that can create bias include "inappropriate sampling of test content, aspects of the test context such as lack of clarity in test instructions, item complexities that are unrelated to the construct being measured and/or test response expectations or scoring criteria that may favor one group over another" (p. 54).

As mentioned earlier, the authors of the *Standards* recommend that test developers and users rely on standardized tests with universal design, to "facilitate accessibility and minimize construct-irrelevant barriers." Universal design "emphasizes the need to develop tests that are usable as possible for all test takers in the intended test population, regardless of characteristics such as gender, age, language background, culture, socioeconomic status, or disability" (p. 57). Yet later the authors note that researchers are still gathering evidence to support the principles of universal design, and that even when principles of universal design are employed, there will still be situations where the test is not appropriate for all in the intended population. Moreover, in recognizing that the concept of degree is critical in these matters, a curious contradiction remains embedded in the *Standards*. For example, in discussing context-related sources of test bias, the *Standards* authors identify that "Construct-irrelevant variance may result from . . . unrelated complexity or language demands in test tasks" (p. 55). In Standard 3.2, it is recommended that

> unnecessary linguistic, communicative, cognitive, cultural, physical, and/or other characteristics in test item stimulus and/or response requirements can impede some individuals in demonstrating their standing on intended constructs . . . the level of language proficiency, physical response, or other demands required by the test should be kept to the minimum required. (p. 64)

Just what constitutes an appropriate level of response demand is not explained, and adopting a stance that there is even a minimal level of language that would not in some way affect performance is inconsistent with the view of language as a developmental process. Such a stance seems to view language proficiency as a threshold ability, beyond which further development provides no benefit to test performance. The well-known correlation between level of education and IQ contradicts such a view (Brody, 1997; Gustafsson & Undheim, 1996; Neisser et al., 1996; Ormond, 2008; Sattler, 2001). Indeed, the fact is that all tests, including nonverbal ones, require some level of communication between the examiner and examinee; thus some tests will indeed be subject to heavy linguistic demands (e.g., expressive vocabulary), and some tests will be less subject to these (e.g., block construction). Test performance is therefore likely to be affected continuously and linearly, and not in an either–or manner (i.e., it is affected or not affected), as is implied by the *Standards*.

The *Standards* volume does pay attention to minimizing construct-irrelevant components through increasing accessibility for specific individuals via test adaptations, accommodations, and modifications. Chapter 3 provides an excellent overview of the salient issues that may lead to significant problems in reliability and validity, including test content, context, response format, and opportunity to learn, as just described. A common theme emerging throughout the discussion is the notion that differences in language, culture, and development must be attended to throughout all aspects of test development, administration, and interpretation, to avoid measurement bias in test content, context, and response format. This is best captured in the opening overview of Chapter 3, which we have quoted above. Unfortunately, the associated practice guidelines are noteworthy in their lack of definitive guidance for practitioners. For example, Standard 3.9 states: "Test developers and/or test users are responsible for developing and providing test accommodations when appropriate and feasible, to remove construct-irrelevant barriers that otherwise would interfere with examinees' ability to demonstrate their standing on the target construct" (p. 67). However, the commentary that follows provides no concrete guidance or examples for addressing construct-irrelevant components that may arise in assessing culturally and/or linguistically diverse individuals. Moreover, little attention is paid to providing guidance on how and when test adaptations meet the threshold of changing the intended construct being measured, thereby also hindering validity.

Standard 3.9 continues: "For example, individuals who are not fully proficient in English may need linguistic accommodations that address their language status" (p. 67). This statement implies that some tests are appropriate for use with individuals whose knowledge of the language of the test is questionable; perhaps it alludes to nonverbal instruments or ones that are otherwise less verbally demanding. Beyond the use of nonverbal tests, however, what assessment methods are likely to comply with this standard? What factors should professionals take into account when making a decision about language differences and whether they are relevant? Won't language differences of any kind always be relevant, especially in connection with potential limited opportunity for learning? Another point is that for practitioners who are interested in measuring visual processing, memory, or reasoning abilities, this statement might be sufficient guidance. But what about evaluations where the referral concern involves reading difficulties, which create a need to measure phonological processing skills, extent of vocabulary, and facility with language (e.g., with verbal analogies)? Such abilities cannot be measured in a nonverbal way. They are verbal by definition, and language development and proficiency are integral aspects of what they intend to measure.

For practitioners who are looking for specific advice about the testing of culturally and linguistically diverse individuals, there remains a need to look beyond the *Standards*. Without question, the *Standards* volume is an important and significant work. But although it provides significant direction in the understanding and accommodation of experiential differences in the assessment of culturally and linguistically diverse populations, and the degree to which these differences will affect nearly every aspect of test development, construction, administration, and use, practitioners still must review and evaluate empirical evidence independently and find a manner in which such evidence can be used to make critical decisions in testing and interpretation. A later section of this chapter provides a discussion along these lines, but first, a critical examination of current testing and interpretive practices is necessary.

EVALUATING CURRENT METHODS OF PRACTICE

The problems inherent in applying tests that were developed in the U.S. cultural milieu and normed primarily on monolingual English speakers to examinees with LEP were noted at the very advent of psychological testing (Brigham, 1923; Goddard, 1913; Yerkes, 1921), but they appear to have been either ignored or simply dismissed in the face of prevailing beliefs and arguments to the contrary (Sanchez, 1934). Despite a persistent pattern of lower performance among culturally and linguistically diverse individuals as compared to native English speakers, the matter of differential performance remained largely confined to notions regarding genetic differences (Jensen, 1974, 1976). Perhaps spurred by the spirit of social justice and civil rights that permeated the prior decades, other researchers in the 1970s began to reexamine the issue (e.g., Oakland & Laosa, 1976)—particularly in light of the 1975 passage of Public Law 94-192, the original Education for All Handicapped Children Act, later renamed and currently known as the Individuals with Disabilities Education Improvement Act of 2004 (IDEA, 2004). In the early forays into "nondiscriminatory assessment," the crux of the problem was broadly defined as "one dimension of the more general problem of valid assessment of any child" (Oakland, 1976, p. 1).

Despite the fact that examinations of test bias had been largely focused on issues of reliability, Oakland (1976) was one of the first to note that the most important aspect in testing of diverse individuals was validity. The issues described in the preceding section regarding the recommendations outlined in the *Standards* all reinforce the importance and centrality to the concept of validity in fairness, far more so than the concept of reliability. But as we have also noted previously, the authors of the *Standards* were rather silent until the 2014 edition regarding the manner in which test results are to be examined for evidence of validity, and practitioners have historically been forced to resort to a variety of methods in attempts to address it—often without any empirical support to defend their use. Indeed, many of the methods in current use appear to be based on the mistaken idea that validity, like reliability, is a continuous variable. From a strict psychometric standpoint, a measure or scale can be considered valid or not, depending on whether there is sufficient evidence to support it one way or the other. Viewing validity as shades of gray instead of as a dichotomous concept is easily forgiven in light of the fact that practitioners are simply trying to do whatever can be done to ensure the validity of their obtained test results. Thus doing more should be better than doing less or nothing at all in accomplishing the goal. Unfortunately, more often than not, practitioners cannot actually evaluate the success of their efforts in establishing validity. That is, the extent to which factors such as LEP or differences in opportunity for learning cultural knowledge actually affect the results of testing is rarely addressed in reports, apart from the ubiquitous but hollow warnings that "results should be interpreted with extreme caution." Use of a particular method or strategy may lead practitioners to assume that validity has been "increased" or "maintained," but typical methods simply do not permit independent verification that this is in fact the case. As will be discussed, such unverified assumptions (i.e., that validity has been achieved when in fact it has not) are common to all current approaches and limits their utility as avenues for achieving fairness.

In general, a review of the literature reveals four basic approaches that have been touted as viable methods for dealing with validity issues that stem from cultural and linguistic differences. Each approach is intended in some manner to address questions of fairness, so that test results emerge as valid—and each method has its own particular advantages and disadvantages, many of which do not appear to be acknowledged or recognized by those who employ them. It is especially important that the limitations of each approach be well understood by any practitioner with a desire to implement any of them in actual testing practice.

Modified or Adapted Testing

Perhaps some of the first attempts to address the various problems inherent in the evaluation of culturally and linguistically diverse individuals with standardized tests involved modifications or adaptations of the tests or testing protocols themselves. In this approach, tests are administered primarily in English, but are modified in some way so as to increase their fairness. Among the various adaptations are that have been suggested, the most common include eliminating or not administering certain test items with presumed culturally biased content; mediating culturally based task concepts prior to administration; repeating verbal instructions to ensure full comprehension; accepting responses in either the native language or the language of the test; administering only the subtests that do not rely on oral expression; and eliminating or modifying time constraints (Figueroa, 1983, 1990a, 1990b; Sattler, 1992, 2001). Such procedures are extensions of what is often referred to as "testing the limits" and represent a clinical approach to evaluating diverse individuals. These procedures are designed to aid examinees in performing to the true extent of their actual ability by reducing aspects of the testing process that might attenuate the scores. Unfortunately, any time a test is administered with such alterations, by definition it no longer remains standardized. Unknown amounts of error are introduced into the testing situation, resulting in a loss of confidence in the test's psychometric properties, especially those that determine its validity. Despite the benevolent intent of such procedures, any results derived from their application are rendered suspect at best, and thus they effectively preclude valid and defensible interpretation.

Another common testing adaptation involves attempts to overcome the language barrier via use of a translator/interpreter. Up to 20% of practitioners working with culturally and linguistically diverse children employ this method (Sotelo-Dynega et al., 2011). The presumption that testing will be valid as long as an individual comprehends what is being said or asked has intuitive appeal; however, it neglects the culturally based aspects of the testing process itself, as well as the fact that the test remains culturally bound. More importantly, even if we ignore the significant problems in translating tests "on the fly" with or without the aid of trained and untrained interpreters and the presence of third-party observers, tests have yet to be standardized with the use of a translator/interpreter. That is, the use of a translator/interpreter in the testing process represents another violation of standardized procedures, which again by itself undermines the reliability and validity of the results and continues to prevent interpretation.

Beyond issues related to test administration and modification, it is important to note that such procedures do nothing to address problems related to norm sample representation. Even if modification of the test or its administration protocol did not invalidate the process, could the test scores be interpreted fairly? Even if threats to validity are controlled in some areas, it does not mean that validity has been addressed in all areas. This is particularly true with respect to the adequacy of the norm sample against whom the test scores will be compared. Test developers often attempt to control for cultural or linguistic differences by including individuals from diverse racial and ethnic backgrounds. But race and ethnicity are not the same as culture or cultural differences and do not directly account for differences in experience that affect language or acculturative knowledge development, as noted by Salvia and Ysseldyke (1991) and discussed in the preceding section. Representation within a test's norm sample on the basis of racial or ethnic categories is simply not a sufficient proxy for the degree to which an individual is or is not familiar with the culture of the test. Likewise, neither race nor ethnicity provides specific information about the extent of an individual's proficiency in English. Despite demonstration of high-quality technical characteristics and the use of sophisticated sampling techniques, norm samples that are stratified on the basis of race or ethnicity, but that contain individuals who are predominantly or exclusively monolingual English speakers, are unlikely to meet the necessary standards for adequate representation of genuinely "bilingual" and "bicultural" individuals. For the most part, test developers and researchers have not addressed or recognized this issue. Until norm samples for tests are based upon stratification variables that matter to culturally and linguistically diverse individuals, the results simply cannot be construed as valid, even when tests are carefully modified, adapted, or translated.

Because altering the standardized requirements of the testing process in any manner effectively precludes the assignment of meaning to the collected data, modifications or adaptations in testing are of limited utility. Even if such adaptations could be seen as valid, the significant problems with norm sample adequacy would still preclude validity of any conclusions regarding comparative differences. In practice, such procedures may be most useful in allowing practitioners to derive qualitative information—that is, by observing behavior, evaluating learning propensity, evaluating developmental capabilities, analyzing errors, and so forth. Perhaps the best recommendation for practitioners who are considering use of these types of methods would be to administer tests in a standardized manner first, and then retest with any modifications or adaptations that might help illuminate the actual or true level of the individual's ability. In this way, it may be possible to evaluate the issue of validity by limiting the threats rather than adding to them.

Nonverbal Testing

Much as in the development of the Beta version of the Army examination (Yerkes, 1921), the use of nonverbal methods and tests in the evaluation of English learners has been predicated on a simple notion: Eliminate the language barrier, and testing can proceed as usual. Nonverbal tests have in fact become quite popular in psychological practice, and a variety of tools have been published expressly for this purpose. According to the Sotelo-Dynega and colleagues (2011) survey, when evaluating the intelligence of culturally and linguistically diverse individuals, 88% of all practitioners choose to administer a nonverbal test. Similar to the claims originally put forth by Brigham (1923), these tests offer the promise of validity based on the idea that language has been effectively removed from the testing equation. For example, according to Weiss and colleagues (2006), administration of a nonverbal cognitive assessment is still promoted as "an acceptable answer to this problem" (p. 49). This appears, however, to be an overly optimistic view.

The phrase *nonverbal testing* is itself a bit of a misnomer; what is meant is probably better characterized as *language-reduced testing/assessment*. This is because no matter what a test is like, its use in any evaluation requires that the examiner and examinee be able to communicate with each other. Even tests whose developers claim that they can be administered in a completely nonverbal manner (i.e., via gestures or pantomime) first require that the examinee understand and comprehend the meaning of the gestures. This meaning must necessarily include instructions on when to start, when to stop, what is a right answer, and when to work quickly. Other testing issues (establishing rapport, explaining the purpose of testing, etc.) also need to be conveyed to the examinee. How all this is to be communicated in the absence of any verbal interaction is not clear. Even if it were possible to do so, the fact remains that the teaching of gestures is akin to the teaching of a new, albeit very brief and limited, "language." Thus, whether spoken language is used or not, administration of a test always requires some type of communication between examinee and examiner. Nonverbal testing may well reduce the language barrier, but it clearly does not eliminate it.

In a similar manner, the claim that a test's cultural fairness is increased because it is nonverbal does not mean that cultural content embedded in the test is eliminated. Given the emphasis on abilities that are less verbal, there may be some reduction in cultural content unless the use of visual stimuli includes pictures of actual objects and artifacts, which continue to embed culture even with the reduction in language. Many nonverbal tests continue to rely on visual images that remain culturally bound (Sattler, 1992). In addition, nonverbal tests are often used to derive a score that will serve as an indicator of an individual's general intelligence. Such practice, especially in the context of evaluation for specific learning disabilities (SLD), is problematic for several reasons. First, it has been demonstrated that nonverbal estimates of intelligence may be no more fair or valid than those that include verbal abilities (Figueroa, 1989). Second, the range of abilities measured by a nonverbal composite is by definition likely to be narrower than that measured by verbal batteries, despite correlations with broader measures of intelligence (Flanagan, Ortiz, & Alfonso, 2007; Ortiz, 2014). Third, the majority of referrals for SLD evaluation are based on problems in language arts, particularly reading. This means that in terms of evaluating the cognitive deficits most likely responsible for reading difficulties, an assessment for SLD will need to include testing for those abilities most related to reading, including auditory processing (Ga) and crystallized knowledge (Gc) (Flanagan et al., 2007; Flanagan, Ortiz, Alfonso, & Mascolo, 2006). These abilities cannot be easily measured or measured at all with nonverbal tests, and such tests are therefore not useful for evaluation of SLD in a large majority of cases. Finally, nonverbal tests are also subject to the same problems with norm sample representation as those that exist for verbal tests, as described earlier. That is, neither type of tests has norm samples that systematically and adequately control for differences in acculturative experiences or language development characterizing bilingual and bicultural individuals. In sum, language-reduced tests are not as helpful in the evaluation of the abilities of individuals from diverse cultural and linguistic backgrounds as their developers often claim. Although such tests may provide better estimates of true functioning in certain areas, they do not represent a satisfactory solution with respect to validity and fairness in testing, and in the majority of cases they will be inadequate to serve the purpose of SLD identification.

It seems likely that these problems may help explain why the empirical evidence for the predictive validity of nonverbal tests tends to be rather dubious (Figueroa, 1989; Lohman et al., 2008). In an examination of three different nonverbal tests often used to identify gifted children from culturally and linguistically diverse backgrounds, Lohman and colleagues (2008) noted that "one cannot assume that nonverbal tests level the playing field for children who come from different cultures or who have had different educational opportunities" (p. 292). For example, in contrast to claims of reduced "ethnic" score differences for many nonverbal measures, Lohman and colleagues found "large differences between the scores of ELL and non-ELL children on the three nonverbal tests"; these findings indicated that practitioners "must consider opportunity to learn not only for tests that measure verbal and quantitative abilities and achievements but also for those abilities measured by nonverbal tests" (p. 292).

Despite their widespread popularity, immense intuitive appeal, and long history of clinical use with culturally and linguistically diverse individuals, nonverbal instruments simply do not fulfill their developers' vision of them as tests of innate ability unaffected by culture, education, or experience. This is not to say that such tests are not helpful or valuable in evaluating diverse individuals, but only that they are not the sole or definitive solutions to issues of fairness and validity, as they are often purported to be. The best recommendation that can be made regarding the evidence base for the use of nonverbal tests is that they should be viewed as only one component of a broader, comprehensive evaluation—a component that assists in examining functioning in the particular areas such tests measure. Whether the obtained results are valid remains a question not adequately addressed merely by their use in practice.

Native-Language Testing

The relatively recent development of psychometrically sound, standardized tests of intelligence and cognitive abilities in languages other than English, coupled with a slight increase in the number of psychologists with sufficient competency in evaluations conducted in languages other than English, has led to a growth in approaches based on the use of examinees' native languages. Unfortunately, such practice has become identified with the inaccurate label of *bilingual assessment*. Bilingual assessment implies evaluation that is to be conducted bilingually—that is, with the concurrent use of two languages as the situation may dictate, or desired by the individuals, as is the custom when bilingual persons speak to each other. Native-language tests, however, are not standardized using two languages, but only one. Of course, it would probably be impossible to standardize rote transitions from one language to another because artificial and arbitrary changes by an individual would lead to considerable awkwardness in communication. Except on some tests where responses are accepted when given in either language, code switching (into or out of English) is not specified or standardized. Thus *bilingual assessment* is better described as *monolingual testing,* even in those situations where a test is given in one language followed by retesting in another language.

Regardless of how it may be best characterized, use of a native-language test requires that psychologists speak the language of the test (i.e., they need to be bilingual themselves). The ability to communicate with an examinee directly is an important and significant benefit to this approach; it places a psychologist in a position to conduct assessment activities in a manner (i.e., bilingually) not available to a monolingual psychologist even with the aid of a translator/interpreter. This notion may partly explain why the simple hiring of a bilingual practitioner is often seen as an acceptable solution to the problem of evaluating diverse individuals. However, "mere possession of the capacity to communicate in an individual's native language does not ensure appropriate, nondiscriminatory assessment of that individual. Traditional assessment practices and their inherent biases can be easily replicated in any number of languages" (Flanagan, McGrew, & Ortiz, 2000, p. 291). Speaking the same language as the examinee and utilizing a test available in the language which the examinee speaks do not, by themselves, resolve issues of fairness or validity. Indeed, they may actually lead practitioners, and those for whom they work, into a false sense of security about the meaning of their obtained test results. In addition, not only are there no truly "bilingual" tests or assessment protocols, but very little is currently known about the performance of bilingual individuals on monolingual tests administered in the primary language. Compared to the body of research on the use of tests administered in English, research on testing in the native language is a relatively new tradition, with very little empirical evidence to guide appropriate activities or use as a basis for standards for practice. The general question regarding how a bilingual individual born in or recently moved to the United States would be expected to perform on a test administered in the native language has yet to be answered. Such a question is bound to be complicated by various factors, such as the individual's age, his or her level and type of prior education, the current language of instruction, and the type of instructional program (Goldenberg, 2008).

In addition, when native-language testing is accomplished in the United States, an examinee cannot rightly be viewed as a monolingual speaker or from a monocultural background. Because the norms of native-language tests often utilize monolingual speakers from other countries who are being raised by parents who speak the language and who are being educated in the native language, they do not form an adequately representative norm sample for comparison of performance to individuals now residing in the United States. In such cases, the experiential backgrounds of these two populations are no more similar than they are to the backgrounds of monolinguals. As noted by Harris and Llorente (2005), "these children indeed represent a proportion of U.S. school children who are ELLs. Realistically, however, little is known about the language abilities of these learners and the degree to which they are bilingual" (pp. 392–393). Even when test developers attempt to include bilingual speakers, they are not sampled systematically with respect to the two major variables (current proficiency in both languages and level of acculturation) that would be necessary to create representative groups. For example, despite inclusion of bilinguals in the developmental sample of the Wechsler Intelligence Scale for Children—Fourth Edition (WISC-IV) Spanish version (Wechsler, 2005), they are grouped primarily by country of origin, length of time in the United States, or length of schooling in the United States, all of which fail to account for the influence of cultural and linguistic differences (Harris & Llorente, 2005). In addition, it should be noted that the actual WISC-IV Spanish norms are equated to the WISC-IV English norms, and thus the Spanish version does not have actual, separate norms (Braden & Iribarren, 2005).

It would appear that until such time as a sufficient body of knowledge exists on which bilingual psychologists can base expectations of performance on native-language tests, their use will continue to provide results that are of dubious validity and extremely difficult to interpret. Accordingly, the most prudent recommendation for practice involving the use of native-language tests is similar to those offered previously: Administer tests in a standardized manner first, and then apply whatever modifications or adaptations that may be appropriate and may inform the referral questions. Well-trained bilingual examiners may be limited by the tools and practices available to them, but they remain the best choice for conducting evaluations of culturally and linguistically diverse individuals. Despite the limitations inherent in all approaches, bilingual examiners have one unique and significant advantage over other examiners employing other approaches—their ability to directly communicate with, and observe the behaviors of, diverse examinees in a controlled setting. This advantage alone places native-language testing in front of all other approaches and represents the current "ideal" situation—not because the test results are necessarily more fair or valid, but because of the examiners' ability to engage in direct interaction with the examinees and to utilize a wide variety of procedures (including authentic assessment, informal measures, error analyses, and whatever other methods may be helpful and informative in understanding and gauging the examinees' true abilities).

English-Language Testing

Given the increasingly large numbers of culturally and linguistically diverse individuals in the U.S. population, coupled with the fraction of professionals with sufficient competency to conduct evaluations in such persons' native languages, it is not likely that all such individuals will be evaluated in the native language or by bilingual professionals. Of the 480 practitioners surveyed by Sotelo-Dynega and colleagues (2011), only about 12% identified themselves as "bilingual/multicultural school psychologists," yet 86% reported that they evaluated students who were culturally and linguistically diverse. The reality is that the majority of diverse individuals are being evaluated by monolingual English-speaking practitioners, and that these evaluations will be conducted primarily (if not exclusively) in English. As compared to the three prior methods, this particular approach would seem to be the most biased and least fair. In many ways it echoes Brigham's (1923) comments about handling a "typically American situation," because it makes no concessions to the fact that such a child is not a native English speaker; it does not alter the content or administration of the test; and it does not investigate the abilities the child may be able to demonstrate in the native language but not in English. On the other hand, if we dispense with Brigham's mistaken notions about personal character, we can in fact recognize that this is also the only approach where there exists a great deal of scientific research regarding how culturally and linguistically diverse individuals actually perform on tests—tests given to them in English.

Although it certainly was not intentional, the field of psychometrics has nevertheless provided perhaps the most empirically supportable basis for evaluating the validity of bilingual individuals' test performance. The development of standardized procedures, coupled with repeated evaluation of participants proficient enough in English to reasonably comprehend test instructions, has established a rather extensive and cohesive database regarding the manner in which such examinees perform on tests administered to them in English (Brigham, 1923; Cummins, 1984; Figueroa, 1989; Goddard, 1913; Jensen, 1974, 1976; Mercer, 1979; Sanchez, 1934; Valdés & Figueroa, 1994; Vukovich & Figueroa, 1982; Yerkes, 1921). A review of this research indicates that non-native speakers of English consistently perform more poorly (about one full standard deviation or more below average) than native English speakers on tasks that rely on English-language development, skills, or proficiency, and that they perform comparably to them (at or near the normative mean) on tasks that do not require such verbal or language-based development or skill (Cummins, 1984; Figueroa, 1989; McShane, 1980; Mercer, 1979; Naglieri, 1982; Valdés & Figueroa, 1994; Vukovich & Figueroa, 1982).

On the surface, assessing diverse individuals with English-language tests appears to result in highly biased estimates of ability, particularly those abilities that may rely heavily on language and acculturative knowledge development. On the other hand, if this research is viewed as illuminating the magnitude and degree to which such factors as differences in language and acculturative development actually affect test performance, it seems reasonable that it may be an effective way to develop an empirically based approach for evaluating the validity of obtained test results. Available research provides an estimate of the degree of attenuation that may have occurred in testing as a function of the presence of the main operating variables—namely, English-language proficiency and acculturative knowledge. Whether or not the results are valid can thus be examined by comparing diverse examinees' performance to that of a group far more similar to the examinees in developmental background and experience than existing norm samples are. Ideally, individuals from diverse cultural and linguistic backgrounds should rightly be evaluated by qualified, competent professionals with specific expertise in nondiscriminatory assessment and knowledge of the manner in which such differences influence test performance (Ortiz, 2014). There is nothing, however, that prevents any practitioner from evaluating such an individual in both the native language and English. And when there is no other option available but to evaluate in English, the same type of expertise, knowledge, and research base may well be applied to assist in evaluating validity—a process that is often couched in terms of determining "difference versus disorder." The potential application of this body of literature in support of an evidence-based approach using English test administration is explored further in the next section regarding integration of research into practice. For the moment, testing in English only without regard for the inherent problems in fairness and validity will certainly lead to extremely discriminatory interpretations and conclusions.

INTEGRATING RESEARCH INTO PRACTICE

Fallacies and Misconceptions in Early Research

Although tests can be quite reliable, even perfect reliability does not guarantee validity. It is possible that something can be measured very accurately and consistently over time, but this does not ensure that the construct one *believes* is being measured is actually the one that is. The difference between reliability and validity is central to the issue of testing with culturally and linguistically diverse individuals. Although this notion was certainly well understood by early psychometricians and psychologists, preconceptions and the early cultural *zeitgeist* may have prevented their recognition.

A particularly stark example can be seen in the work of Henry Herbert Goddard, a leading American psychologist who translated the Binet–Simon Scale into English and promptly set about working with bilingual examinees and individuals from diverse cultural backgrounds. Goddard's intent was not to study bilingualism or its effect on test performance, but rather to prove an a priori conviction—that IQ was an innate, inherited trait, and that it explained the division between the "haves" and "have-nots." To examine the issue, he went to Ellis Island in New York and began testing immigrants—not randomly selected ones, but those whom he already believed were intellectually inferior, primarily on the basis of their appearance. In the process of his investigation, Goddard (1913) eventually came to conclude that approximately 80% of all immigrants arriving from Eastern Europe were mentally defective or feeble-minded, a level of functioning. He even developed a specific word to define their level of functioning—*moron*. The degree to which Goddard was working from preconceptions that made him oblivious to patterns in his own data can be seen in his explicit comments, such as "We picked out one young man whom we suspected was defective, and, through the interpreter, proceeded to give him the test" (p. 105); in his inability to entertain any hypothesis contrary to his own when the interpreter questioned the fairness of the testing by stating, "I could not have done that when I came to this country" (p. 105); and in his curt and decisive reply to the interpreter, "We convinced him that the boy was defective" (p. 105).

Not much later, Robert Yerkes, already an eminent American psychologist, developed the Army mental tests in response to the Department of the Army's request to help in distinguishing men who would be good officer candidates from those who could serve merely as infantrymen. In the course of his work, Yerkes (1921) did in fact recognize and acknowledge the problem posed by individuals from diverse cultural and linguistic backgrounds, which he viewed mostly as an issue of illiteracy. Because his initial (Alpha) test had components that required reading, he could not administer the test to anyone (regardless of country of origin) who could not read English. He therefore set about creating an alternative (Beta) version, which eliminated any test requiring reading and which utilized "nonverbal" demonstrations via blackboard to provide presumably comprehensible instructions. He believed that the Beta test represented a valid method for evaluating the abilities of the millions of men he needed to test who were illiterate, at least in English, or who did not speak English. In examining his data on nearly 1.75 million American men, Yerkes noted that the average raw score on the Beta for native English speakers (even those who could not read at all in English) was a stout 101.6, which classified them as Very Superior (Grade A). In contrast, the average raw score for non-native speakers of English (who also could not read in English) came in at only 77.8, which placed these individuals in the Average (Grade C) classification. For Yerkes, and for the contingent of other notable psychologists working with him (e.g., Carl Brigham, David Wechsler, and Lewis Terman), the results confirmed their own beliefs that immigrants—particularly those from certain countries and from lower classes—were merely displaying their inherited lack of intelligence. Questions regarding the potential issues involved in testing individuals with LEP or no English at all, and with limited opportunity for learning about the cultural content embedded in the test, were not addressed, even if they hovered in the air when the pattern of results was examined. Given the atmosphere of the era, none of these psychologists were inclined to seriously abandon their causal explanations related to intelligence as an innate quality even when the data strongly suggested otherwise.

Figure 25.1 provides an example of this tendency using Yerkes's data, which were later reanalyzed by Brigham in his 1923 monograph *A Study of American Intelligence*. The increase in mental age as time of residence in the United States increased is particularly striking. Nevertheless, this particular finding seemed to bother Brigham—perhaps subconsciously, as he first admitted—but then he dismissed the obviously correct interpretation and instead provided a convoluted hypothesis consistent with his and the prevailing beliefs. In examining the data in Figure 25.1, Brigham gave the following explanation:

> Instead of considering that our curve indicates a growth of intelligence with increasing length of residence, we are forced to take the reverse of the picture and accept the hypothesis that the curve indicates a gradual deterioration in the class of immigrants examined in the army, who came to this country in each succeeding 5 year period since 1902.

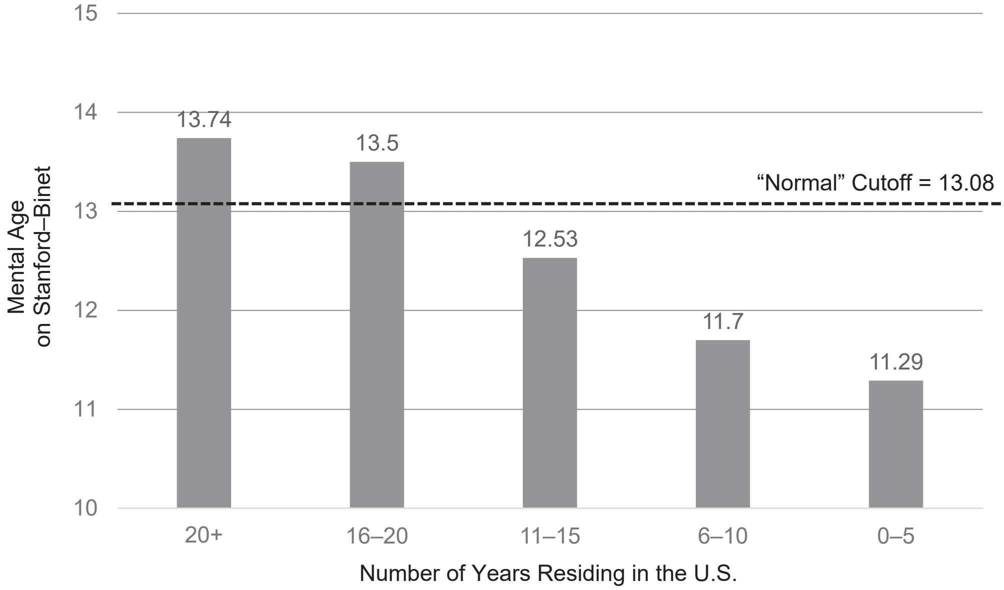

FIGURE 25.1. Mean mental age on the Binet–Simon Scale for immigrants tested with the Army Beta examination. Average raw score for native English speakers on the Beta test = 101.6 (Very Superior; Grade A). Average raw score for non-native English speakers on the Beta test = 77.8 (Average; Grade C). Data from Yerkes (1921).

> (pp. 110–111) . . . The average intelligence of succeeding waves of immigration has become progressively lower. (p. 155)

When combined with the data showing significantly lower raw scores on the Army Beta test for non-native than for native English speakers, to which Brigham had access, it seems reasonable that the far more plausible interpretation as previously noted should also have been reached by Brigham: that the longer one lives in the United States, the more English one learns (which increases comprehension), and the more familiar one becomes with U.S. cultural artifacts (including those that appeared on the test). That such an obvious conclusion was not offered by Brigham again emphasizes the degree to which evidence indicating that testing was being affected by differences in the cultural and linguistic backgrounds of individuals went largely unappreciated. Even when deliberate attempts were made to bring the issue to light, it was often buried in obscure journals or flatly dismissed as inconsistent with scientific fact, as is evident in Terman's (1916) comment:

> The common opinion that the child from a cultured home does better in tests solely by reason of his superior home advantages is an entirely gratuitous assumption. Practically all of the investigations which have been made of the influence of nature and nurture on mental performance agree in attributing far more to original endowment than to environment. (p. 115)

George Sanchez, a Mexican American psychologist, was one of the few who did manage to publish his research on bilingual individuals' performance in scholarly journals (Sanchez, 1932, 1934). He explicitly outlined the idea that differences in language development and proficiency, as well as differing levels of experience with the cultural content embedded in the test, were in fact the variables responsible for the observed difference in test scores between native and non-native English speakers. According to Sanchez (1934), "as long as tests do not at least sample in equal degree a state of saturation [i.e., assimilation of fundamental experiences and activities] that is equal for the 'norm children' and the particular bilingual child it cannot be assumed that the test is a valid one for the child" (p. 770). By the time the issue was being given serious considerations in the 1970s, the legacy of these early studies remained embedded in psychological science, and genetic explanations of test performance remained dominant or were replaced by ones suggesting that bilingualism itself was a handicap (Valdés & Figueroa, 1994).

One of the individuals who helped to promote and maintain notions regarding genetic explanations was Arthur Jensen (1974, 1976, 1980). Ironically, Jensen was also one of the first researchers to admit to the existence of bias (as related to validity) through an experiment of his own, which, unlike his more controversial assertions, garnered very little attention. In an investigation of the convergence of two separate measures of intelligence with Mexican and European American ("white") groups, one using a verbal modality and one using a nonverbal modality, he expected to find similar patterns of performance on the tests and equivalent degrees of difficulty among items for both groups. In fact he did find equivalent degrees of difficulty among items for both groups, but he did not find similar patterns of performance. Instead, he found that whereas both groups did show similar score patterns on the nonverbal task, the Mexican group had significantly lower scores on the verbal task than the European American group. The lack of concurrence between test scores on the two tasks for the two groups led Jensen (1974) to the following conclusion:

> The fact that the Mexican group is very similar to the white in rank order of *p* values and *p* decrements on both the PPVT [Peabody Picture Vocabulary Test] and the Raven, yet has lower scores on the PPVT than on the RAVEN, suggest that some factor is operating to depress the PPVT performance more or less uniformly for all items and that this factor does not depress Raven performance, at least to the same degree. It seems plausible to suggest that this factor is verbal and may be associated with bilingualism in the Mexican group. (pp. 239–240)

Two years later, in a separate publication, Jensen (1976) offered the following comment on the result of his earlier study: "Thus, there is some evidence that a vocabulary test in English may be a biased test of intelligence for Mexican-Americans" (p. 342). Shortly thereafter, other researchers reached much the same conclusion. Although Jensen and others kept pointing to a verbal–nonverbal dichotomy in performance, the evidence began to demonstrate a pattern that was much more consistent with what Yerkes and Brigham had found originally with the Binet Scales—a more or less continuous, linear variation in decline. Table 25.1 provides a comparison of means from ten of the subtests from the WISC-R/WISC-III among "Hispanic" (Mercer, 1972, cited in Vukovich & Figueroa, 1983), "ESL" (Cummins, 1984), and "bilingual" (Nieves-Brull, 2006) groups as compared to the norm sample mean (ScS = 10). Two things are particularly evident in the data: (1) The Verbal tests show significantly more attenuation than the Performance tests; and (2) the degree of attenua-

**Data for this subtest were not reported in the study.*

tion lessens across the tests and does not depress performance in a manner that can be considered equal within either the Verbal or the Performance domain. In general, it is clear that all four groups show a variable but systematic decline in performance, and not merely a difference between verbal and nonverbal. Some tests that are considered verbal (e.g., Arithmetic) do not attenuate performance as much as others that are very verbal in nature (e.g., Information). Likewise, some tests that are considered nonverbal and have very low linguistic demands (e.g., Coding) have smaller adverse effects on test performance than other nonverbal ones with low linguistic demands (e.g., Picture Arrangement).

This type of declining pattern is particularly evident when scores are graphed and arranged in terms of highest mean to lowest mean. Figure 25.2 provides such an illustration and demonstrates several important dimensions relevant to the present discussion, including the fact that the change in scores does not appear to be an either–or proposition, but rather a smooth, gradual decline as the tasks increase in their measurement of language skills and cultural knowledge. These graphs are particularly striking in their similarity to Yerkes's data shown in Figure 25.1—data that are from 50 to 80 years older than those illustrated. Another pattern in the data can be seen in the difference in the magnitude of the means between the 1972 Mercer and 1983 Vukovich and Figueroa groups. Although both groups show a clear and similar decline in test performance relative to increasing verbal and knowledge demands, the means for the latter group are consistently higher than those for the former and would suggest the existence of differences between them in the two principal variables (language proficiency and opportunity for learning about the culture). Personal communication with Vukovich (September 29, 2008) has confirmed the difference in these factors and highlights the necessity to account for them in evaluations, as well as for the mistakes that can occur if all "bilingual" individuals are treated as equal or as a monolithic

group. In sum, these studies all point to the notion that adherence to a strict verbal–nonverbal conceptualization of test performance for culturally and linguistically diverse individuals is much too simplistic and not entirely supported by the evidence. To understand performance and the extent to which it is affected by cultural and linguistic influences instead appears to require paying attention to the unique characteristics of each subtest, as well as the construct it purports to measure.

Despite research spanning over a century thus far, as well as the robust and persistent finding regarding the pattern of performance for bilingual groups on tests given to them in English, very little of this information has found its way into actual practice. This question was raised some time ago by Valdés and Figueroa (1994), who wondered why "these and other anomalous psychometric outcomes associated with bilingual populations (such as the ubiquitous and intractable low-VIQ, high-PIQ bilingual profile) are curious in and of themselves, but not quite as perplexing as psychometricians' lack of interest about why such outcomes occur" (p. 108). Practitioners do not have the same luxury as academicians in being able to ignore such issues. Perhaps the seductive nature of the verbal–nonverbal duality has resulted in its unquestioned use among practitioners—or, more likely, there simply has not been much of an alternative. As we have noted earlier, there are few general approaches a practitioner can employ in conducting an evaluation of an individual from a diverse cultural and linguistic background, and none of the methods we have discussed provide a truly satisfactory or evidence-based solution, particularly in addressing the issue of validity. Moreover, it cannot be said that any of them are based on any substantive body of research, although nonverbal testing has relied on the general verbal/nonverbal pattern. Nevertheless, even when nonverbal methods are employed, several significant problems remain (Figueroa, 1989, 1990b; Flanagan & Ortiz, 2001; Lohman et al., 2008; Ortiz, 2014), especially in cases where there is a need to measure the full range of cognitive abilities (Carroll, 1993; Horn & Blankson, 2005; McGrew & Flanagan, 1998; Woodcock, 1990).

Moving toward Research-Based Practice

If the currently available instruments have limitations in terms of demonstrating adequate validity, and if such tools lack evidence to support their use with various linguistic or cultural subgroups (i.e., groups that vary in terms of proficiency and experience within a larger ethnic group), and if the notion of verbal–nonverbal views of performance is highly overgeneralized, then what is the average practitioner to do in terms of engaging in evidence-based practice? At this time, the answer to this question may be rather surprising. Despite the more detailed and comprehensive practice guidelines outlined in the *Standards,* if evidence-based practice must still rest on just that—evidence—then the only sufficient body of empirical research currently available to guide the practice of evaluating a wide range of cognitive abilities in individuals from diverse cultural and linguistic backgrounds is the use of standardized tests administered in English. It is perhaps ironic, but the fact remains that there is a considerable amount of information (much of which has been discussed previously) regarding the performance of bilingual individuals on tests given to them in English. If this literature is combined with defensible psychometric procedures (particularly maintenance of standardization without alteration), and if the main focus in evaluation is placed on examining the validity of the obtained test data (leaving interpretation to occur only if the data are deemed valid), it would be possible to conduct evaluations on diverse individuals that begin to meet the criteria for being both evidence-based and defensible. At present, few such methods that are expressly designed to deal with the matter of validity have been proposed in the literature. Those that do exist are discussed below.

The Culture–Language Test Classifications and Interpretive Matrix

Regardless of the type, language, or number of tests selected for an evaluation, the mere inclusion of a standardized, norm-referenced test in a battery means that practitioners must then contend with the need to establish the construct validity of the obtained test scores; otherwise, interpretation is likely to remain inequitable, discriminatory, and purely speculative. If practitioners are to comply with relevant legal and professional standards, there must be evidence that the validity of test scores has been directly examined, and (at a minimum) a description of how the determination of validity was made. In other words, practitioners are required to provide some sort of convincing evidence that measurement of an ability domain that gave rise to a standard score or percentile rank is, in fact, a valid estimate of that specific ability and is not instead a reflection of the influence of some other construct (e.g., LEP). The familiar refrain "difference versus disorder" elegantly captures this dilemma regarding test score validity, which is the heart of the matter in the evaluation of culturally and linguistically diverse individuals. If test scores are believed to be valid, low performance may then be interpreted as possibly reflecting the lack of an ability or attribute. If test scores are not believed to be valid, low performance may then be interpreted as a reflection of the influence of cultural and linguistic differences. So how do practitioners accurately account for linguistic and cultural differences, to avoid misinterpretation of test results? The manner in which this fundamental question may be addressed is the purpose and intent of the Culture–Language Test Classifications (C-LTC) and the Culture–Language Interpretive Matrix (C-LIM).

The Culture–Language Test Classifications

Development of the C-LTC (Flanagan et al., 2000, 2007; Flanagan & Ortiz, 2001; McGrew & Flanagan, 1998) and its companion the C-LIM (Flanagan & Ortiz, 2001, Flanagan et al., 2007; Ortiz, 2001, 2004; Ortiz & Flanagan, 1998) was spurred by the need to consider the "difference versus disorder" question, as well as by the wealth of research available on the performance of bilinguals tested in English. The C-LTC was initially developed as an extension of the Cattell–Horn–Carroll (CHC) theoretical classifications presented as the basis of the CHC cross-battery assessment and interpretive approach (Flanagan et al., 2000; McGrew & Flanagan, 1998). The C-LIM evolved shortly afterward as a refinement of the C-LTC, designed specifically to aid in interpretation by allowing practitioners to assess whether or not what is measured is due primarily to the influence of cultural or linguistic variables (Flanagan & Ortiz, 2001; Flanagan et al., 2007; Mpofu & Ortiz, 2009; Ortiz, 2001, 2004; Ortiz & Dynda, 2010). Although the C-LTC and the C-LIM were initially linked to the CHC cross-battery approach, they can be used independently, and their utility does not depend on the use or application of any particular assessment procedure. The C-LTC and C-LIM are designed to evaluate whether obtained test results are either valid (permitting interpretation) or invalid (thereby precluding interpretation).

In an appeal for less discriminatory practices, Figueroa (1990a, 1990b) suggested that application of defensible theoretical frameworks in the assessment of culturally and linguistically diverse individuals was an important avenue to explore. In addition, he admonished practitioners to pay particular attention to the cultural and linguistic dimensions of tests that were often ignored or misunderstood in evaluation. In response to such issues, Ortiz and Flanagan (1998), Flanagan and Ortiz (2001), and Flanagan and colleagues (2000) developed the C-LTC, essentially a classification system for cognitive ability tests based on two critical test dimensions: degree of cultural loading and degree of linguistic demand. These two dimensions were deliberately selected because they have been identified as factors that have a significant and powerful relationship to test performance, and can render results invalid for individuals who are culturally and linguistically diverse (Figueroa, 1990a, 1990b; Sandoval et al., 1998; Valdés & Figueroa, 1994). What establishes the C-LTC as an evidence-based practice is the fact that the initial and some of the subsequent test classifications were and continue to be drawn directly from actual research on bilingual persons tested in English. By using the comparative subtest means available for such groups (see Table 25.1), one can easily sort tests into categories that correspond to the three basic classification levels (low, moderate, high) used for both dimensions of the C-LTC framework. It bears repeating that the classifications are data-driven, organized by the available empirical studies on the testing of bilingual individuals in English. In cases where no such data exist, classifications have been made via an expert consensus procedure as well as by examination of task characteristics, manner of administration, and construct that the subtest was designed to measure. Given the extent to which ability tests establish validity via correlations with other ability tests and via factor-analytic methods, test classifications based on this information also represent an application of research.

The manner in which standardized, norm-referenced tests included in the C-LTC are organized represents a departure from the more common organization related to the theoretical construct to be measured. The C-LTC categorizes tests only on the basis of the degree to which subtest means indicate that bilingual examinees' performance is attenuated. High attenuation earns classification in the high category; moderate attenuation suggests the moderate category; and little attenuation points to the low category. Classification of tests in this manner is meant to reflect the degree of cultural loading and the extent of linguistic demand that are embedded in a particular subtest and that are responsible for the degree of test score attenuation. In effect, the organization of the C-LTC provides a unique frame of reference from which to view test performance. An example of the C-LTC for various subtests of the Woodcock–Johnson IV Tests of Cognitive Ability (WJ IV COG; Woodcock, McGrew, & Mather, 2001) is presented in Figure 25.3.

As is evident in Figure 25.3, the C-LTC is organized as a matrix, with degree of cultural loading as the variable along the vertical axis and degree of linguistic demand along the horizontal axis. Each variable is subdivided into three levels (low, moderate, and high) that are intended to distinguish the classifications further. In the resulting 3 × 3 matrix, some of the nine cells contain tests that share a particular combination of cultural loading and linguistic demand. The classifications are not based on cognitive ability constructs; that is, two tests within the same cell are not there because they measure the same thing (e.g., visual processing), but rather because research has indicated that they appear to share similar levels of cultural loading and linguistic demand, as manifested in comparable subtest means. Subtests classified as high along both dimensions have relatively lower means, and those classified as low along both dimensions have relatively higher means. A notable feature of the C-LTC is that the arrangement of the tests is dynamic and easily altered to be consistent with new research on the performance of bilingual individuals as it may emerge as well as adaptations in the subtests that compose the tests themselves. The C-LTC classifications do not imply significant differences between subtests classified in one cell or in one category versus another, but rather provides a guide to the order in which performance may be expected to decline as a function of increasing cultural loading and linguistic demands of the tests. The C-LTC for the WJ IV COG, as illustrated in Figure 25.3, thus suggests the following order from highest to lowest value for the first seven subtests of the Standard Battery: Number Series, Visualization, Letter-Pattern Matching, Phonological Processing, Verbal Attention, Oral Vocabulary, and Story Recall.

It was initially thought that the C-LTC would allow practitioners to select tests measuring a particular construct that would have the best chance of producing valid data. Naturally, this meant selecting tests that were classified as low in cultural loading and linguistic demand. As discussed previously, individuals who have had less opportunity for learning about mainstream U.S. culture, or who have a level of English-language proficiency different from that of same-age or same-grade peers who are native speakers, tend to obtain lower scores than the individuals on whom virtually all tests are typically normed (Aguera, 2006; Dynda, 2008; Figueroa, 1990a, 1990b; Hamayan & Damico, 1991; Jensen, 1974; Mercer, 1979; Nieves-Brull, 2006; Sotelo-Dynega, 2007; Tychanska, 2009; Valdés & Figueroa, 1994). Consequently, scores for diverse individuals are expected to be better approximations of true ability on tests that are lower in cultural loading and linguistic demand, and poorer estimates of true ability on tests that are higher in cultural loading and linguistic demand. Unfortunately, use of the C-LTC in selecting tests for administration runs up against some problems. Despite the use of research to guide the classifications, the presumption of validity remains a question not answerable by simply selecting tests that are low in cultural content and linguistic demands. In addition, it quickly became apparent that some abilities, particularly those related to language skills and verbal ability, simply could not be measured through tests that were culturally or linguistically reduced or classified as low on both dimensions. The problem of "difference versus disorder" remained, and it was not until the development of the C-LIM (Flanagan & Ortiz, 2001; Flanagan et al., 2007) that this issue was more fully addressed.

The Culture–Language Interpretive Matrix

The classification of tests on the C-LIM according to shared levels of cultural loading and linguistic demand helped to identify tests that might result in the fairest estimates of true ability for culturally and linguistically diverse individuals. But this turned out to be only one benefit of the manner in which the tests were organized. In reviewing the decades of research on the test performance of bilingual individuals, Flanagan and colleagues (2007) realized that the arrangement of the classifications meant that tests in the upper left cell of the C-LIM (low cultural loading/low linguistic demand) would collectively produce a much higher aggregate score than tests in the lower right cell (high cultural loading/high linguistic demand). Data from numerous studies supported not only the classifications themselves, but also the nature of expected patterns of performance for diverse individuals (Aguera, 2006; Brigham, 1923, 1930; Cummins, 1984; Dynda, 2008; Figueroa, 1990a; Gould, 1996; Jensen, 1974, 1976, 1980; Nieves-

FIGURE 25.3. The Culture–Language Test Classifications (C-LTC) matrix for the WJ IV Tests of Cognitive Abilities, depicted in a screen capture of the Culture–Language Interpretive Matrix (C-LIM) from the Cross-Battery Assessment Software System (X-BASS; Flanagan, Ortiz, & Alfonso, 2017).

Brull, 2006; Sanchez, 1932, 1934; Sotelo-Dynega, 2007; Tychanska, 2009; Valdés & Figueroa, 1994; Vukovich & Figueroa, 1983; Yerkes, 1921). This pattern is illustrated in Figure 25.4, which depicts the C-LIM.

Although placed in an orthogonal arrangement, the two dimensions in Figure 25.4 are in fact highly correlated because it is not entirely appropriate to separate the effects of culture from language or vice versa. Nevertheless, the arrows in the illustration depict the three possible ways in which the test results of diverse individuals may be attenuated. First, test performance may decrease primarily as a function of the increasing cultural loading of tests. Similarly, test performance may decrease largely as a function of the increasing linguistic demands of tests. And finally, test performance may decrease as a function of the combination of cultural loading and linguistic demand. In practice and research, however, there has not been significant evidence of a singular effect for either culture or language, with the exception that strong, primary language effects have been seen in culturally and linguistically diverse children who also have significant speech–language disorders (Aziz, 2010; Lella, 2010; Tychanska, 2009). Therefore, except for some specific occasions, interpretation of the pattern of test performance via the C-LIM should be limited to examination of the combined effect of both dimensions, and should not be focused on the singular influence of either one alone. This information, coupled with knowledge regarding an individual's cultural and linguistic experience, makes it possible to accomplish defensible interpretation through analysis of the patterns formed by test data collected over the past century.

The value of understanding this declining pattern of performance lies in its empirical base, which provides predictability not only for diverse groups, but also for diverse individuals. The research on the test performance of bilingual individuals reflects a linear and continuous decline in performance on tests as a function of their cultural content and linguistic demands. For example, apart from their examination of the classification of the WJ III COG subtests, Kranzler and colleagues (2010) conducted additional analyses and concluded that a "statistically significant (decreasing) trend was observed for the effect of linguistic demand and cultural loading combined" (p. 431). Despite their concerns stemming primarily from expectations of statistically significant differences, their investigation provides an independent replication of the robust, linearly declining performance of bilingual examinees as subtests increase

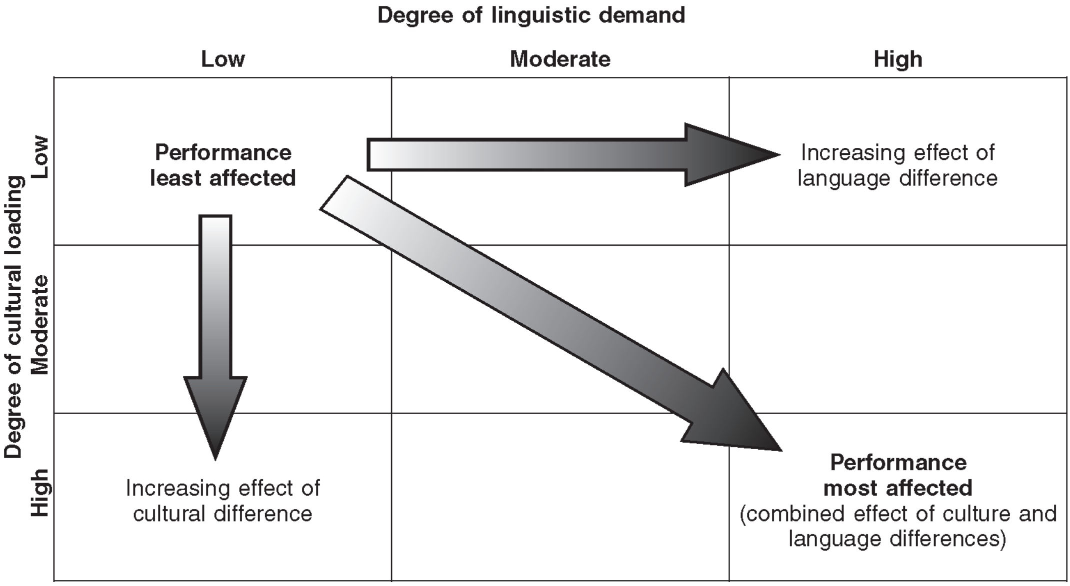

FIGURE 25.4. The Culture–Language Interpretive Matrix (C-LIM): General pattern of expected performance for culturally and linguistically diverse children. From Flanagan and Ortiz (2001). Copyright © John Wiley & Sons, Inc. Reprinted by permission.

their demands for acquired cultural knowledge and developmental language proficiency.

In short, the Kranzler and colleagues (2010) study reinforces the very foundations upon which the C-LIM is built and the principles that guide examination of test score validity. To evaluate issues of validity, an individual's obtained subtest scores are classified within the cells specified by the C-LTC and are then aggregated to create values across the matrix. These mean values then permit closer examination and more importantly, comparison against the means obtained for other bilingual examinees as reported in the literature. For example, if the pattern of aggregate scores within the matrix approximates the declining pattern of scores (in terms of both magnitude and rate of decline) derived from the literature, the results can be said to be invalid, in that they are reflecting primarily the effects of cultural and linguistic influences—not the constructs the subtests were intended to measure. Conversely, if the pattern of aggregate scores within the matrix does not approximate the pattern of scores derived from the literature (i.e., the magnitude of scores is lower than the range predicted, or there is an absence of systematic decline as linguistic and cultural demands increase), then the results can be said to be valid, in that they are reflecting the primary influence of a variable or variables other than those related to cultural or linguistic differences. Use of the term *primary* is important here because cultural and linguistic differences may never be completely absent in such cases, and may well be contributory factors in most all situations where bilingual examinees are concerned. However, any potential deficits must be identified on the basis of performance that cannot be attributed primarily to cultural or linguistic difference. This is where the C-LIM provides significant utility to practitioners. Failure to identify a clear pattern of decline within the expected range for bilingual individuals implies that cultural or linguistic factors cannot be viewed as the primary or only factors affecting the results (although they may be contributing to some part of the pattern), and this strongly suggests that the test results are valid.

However, an extremely important caveat in using the C-LIM is that there are many other variables that might have affected test score performance apart from the possibility of cognitive deficits or disorder (e.g., lack of motivation, emotional disturbance, incorrect scoring or administration). As such, the lack of a declining pattern does not automatically indicate disorder, and any diagnosis involving deficient ability must be made by excluding other potential explanations and making use of corroborating data. In any event, the C-LIM appears to provide a solid, evidence-based method for establishing test score validity and for helping practitioners ask and answer the question of "difference versus disorder." Moreover, two particular advantages of the C-LIM make it exceedingly practical. First, the use of testing in English allows it to remain accessible to all practitioners; second, once applied to evaluate the validity of obtained test scores, it permits use of any interpretive method, schema, or framework with which a practitioner may already be familiar or comfortable. Thus, apart from learning how to use and apply it, the C-LIM does not require alteration of procedures that virtually every practitioner already knows and uses.

A complete discussion of the C-LTC and C-LIM is beyond the scope of this chapter. The reader is referred to the original sources for better and more detailed guidance on their use and application in testing practices. In addition, despite the research base upon which these approaches have been developed, neither of them should be relied upon as the only method for establishing validity and making defensible interpretations. Rather, both of these approaches are intended to supplement those assessment and evaluation practices already in use by practitioners. They are designed and intended to bring more rigor and defensibility to current testing practices, not to replace them entirely. When used in conjunction with other relevant assessment data and information (e.g., direct observations, review of records, interviews, language proficiency testing, socioeconomic status, developmental data, family history), these methods should assist in bringing assessment and testing procedures into accordance with current calls for evidence-based practice.

INNOVATIONS IN TEST DEVELOPMENT

As emphasized throughout this chapter, significant measurement biases arise when traditional testing and assessment batteries are applied to culturally and linguistically diverse individuals. Construct-irrelevant components emerge, fostering unfair testing conditions and producing invalid results. However, key practice guidelines have been established and detailed in the publication of the 2014 *Standards*, and these guidelines offer the beginnings of a roadmap toward creating and implementing more reliable and valid testing procedures. Moreover, as discussed in the previous section, the research-supported C-LTC and C-LIM now provide perhaps the most concrete, data-driven recommendations for choosing cognitive subtests that offer the greatest chance of producing valid test results for individuals from linguistically and culturally diverse backgrounds. These research-based approaches highlight that recognizing the source of potential bias and adopting tests that seek to minimize potential bias are the first steps in ensuring validity. Although the C-LTC and C-LIM lack sufficient empirical support to stand alone as viable or defensible evidence-based practices, they can serve as an excellent foundation for the progression of the field and the push toward evidence-based assessment for ELLs.

Efforts to Overcome Language-Based Limitations

Contemporary assessment practices have emerged that build on key components of the C-LTC and C-LIM. An example of these practices is allowing assessment of vocabulary acquisition, for which reliability and validity can be maintained for culturally and linguistically diverse individuals, particularly ELLs. It is not surprising that many of the most widely used batteries of intelligence testing incorporate measures of vocabulary acquisition. Vocabulary acquisition is a key component of verbal ability, which has been analytically proven to account for 20–50% of variance in measures of general intelligence or ability, depending on the number of factors in the model being tested (Flanagan, Ortiz, & Alfonso, 2017; Schrank, Decker, & Garruto, 2016); it also relates to reading and writing skills, receptive and expressive language ability, general academic attainment, broad linguistic proficiency, and competence (Cattell, 1943; Schneider & McGrew, 2012; Thorndike, 1914). Aside from associations with intelligence, vocabulary is a foundational and inherent aspect of language, necessary in perhaps all assessments and evaluations, given the need for communication in even so-called "nonverbal" tests. It is therefore not surprising that measurement bias and fairness concerns arise when traditional tests for native English speakers are used to assess ELLs. It is also not surprising that attempts to rid intelligence tests of language components (e.g., the Army Beta test [Yerkes, 1921]; Performance IQ [Wechsler, 1939]), and those aimed at managing language through the creation of instruments in languages other than English (Schlueter, Carlson, Geisinger, & Murphy, 2013), have historically fallen short.

Perhaps the most compelling attempt to overcome language-based limitations is the creation of true "bilingual" tests (e.g., the Bilingual English–Spanish Assessment [BESA]; Pena, Gutierrez-Clellan, Iglesias, Goldstein, & Bedore, 2014). The BESA employs a unique normative sample based fully on bilingual English–Spanish speakers, and it provides guidelines on language use for administration in either language or only one. Although the BESA is an innovative and concentrated effort to reduce common measurement and testing biases, its testing format is still not without significant shortcomings. For example, while individuals are granted the opportunity to demonstrate both their English- and native-language proficiency, the age range of individuals for whom the test is appropriate is narrow; the evaluator is required to be bilingual, or a trained interpreter is necessary, which removes the evaluator from the clinical aspects of testing; and the test is limited to Spanish–English learners. Although the BESA is thus a step in the right direction, fairness and validity concerns remain. Combined, the BESA and C-LTC/C-LIM highlight the need for test procedures to employ appropriate peer normative samples and to control for construct-irrelevant factors, particularly amount of English-language exposure.

Group-Specific Norms

The development of novel, valid testing methods striving for fairness for non-native speakers of English is complex and requires careful consideration of test innovations and associated limitations. Dual norming may be the perfect answer to achieve a reliable, valid test assessment that not only is consistent with the *Standards* as outlined earlier in this chapter, but also builds on effective data-driven practices such as the C-LTC and C-LIM. The use of more than one normative sample for a particular test may be a key to producing the fairest and most valid test results possible for culturally and linguistically diverse individuals, in that it allows such individuals to be compared to a "true peer" group. More specifically, the creation of one standardized test with accompanying administration procedures that include two distinct normative samples—one for native English speakers and a separate one for ELLs—begins to address some of the psychometric issues discussed throughout this chapter that are inherent in obtaining valid test results for ELLs. Specifically, it begins to account for differences in English exposure and other unique aspects of the linguistic and cultural backgrounds of ELLs that too often contaminate testing results. Additionally, adoption of dual-norming approaches has the significant advantage of providing diagnostic capability for ELLs. Traditional single-norm tests limit practitioners' capacity to diagnose disability in English learners, as comparison to normative samples of native English speakers is inherently biased and discriminatory for the reasons previously discussed. Dual-norming techniques thus free practitioners from the confines of evaluating solely for instructional need or intervention intensity. The value of providing ELL-specific norms, and the utility for practitioners in being able to draw valid interpretations from test results even when these are obtained by using English, are illustrated in Figures 25.5 and 25.6.

Figure 25.5 depicts the predicted performance on the Ortiz Picture Vocabulary Acquisition Test (PVAT; Ortiz, 2017) of individuals grouped by level of English exposure (i.e., ELLs with low, moderate, and high exposure, and native English speakers). As is evident from the curves, the predicted mean scores (based on the performance of each group, taken as an average) increase not only with age from 2 to 22 years, but also with level of English exposure. Native English speakers are predicted to have the highest scores at each age, followed by the high-, moderate-, and low-exposure groups, respectively and without variance. English exposure thus emerges as a construct-irrelevant factor implicated in test score achievement. Likewise, Figure 25.6 illustrates the differences between scores similarly based on level of English exposure. At first glance at the graph on the left, the figure appears to illustrate disordered performance of non-native speakers of English. However, this is primarily due to the ELLs' performance being compared to native English speakers' performance

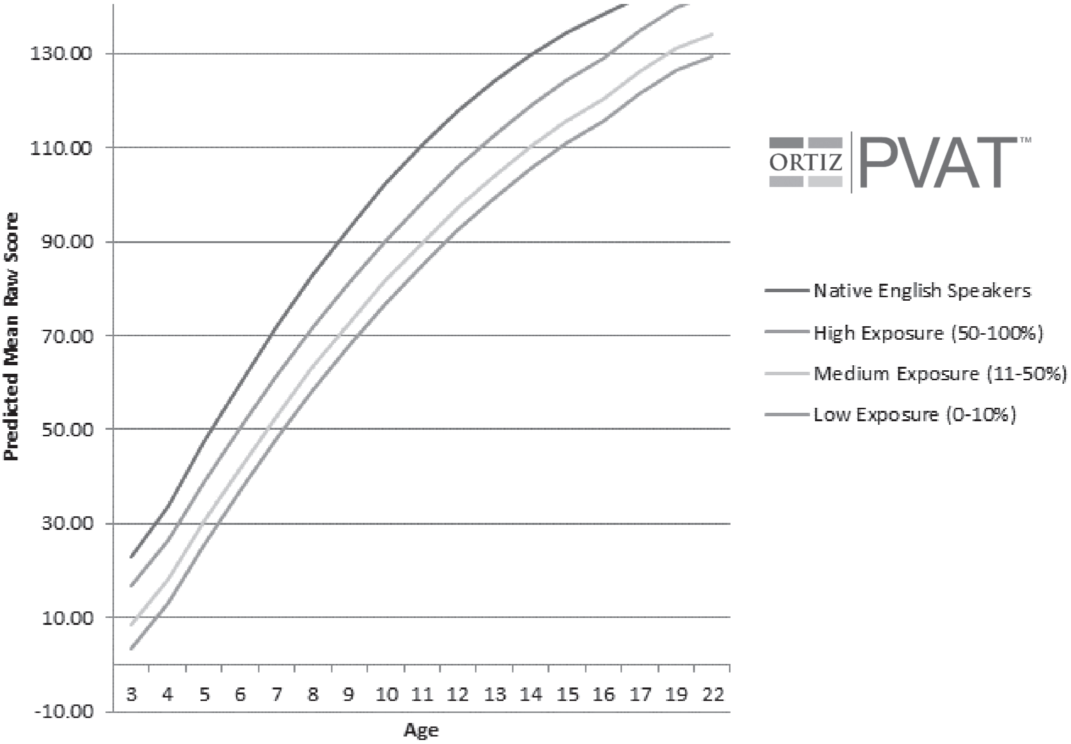

FIGURE 25.5. Comparison of performance on the Ortiz Picture Vocabulary Acquisition Test (PVAT) by samples of English learners with low, medium, and high exposure to English, and of native English speakers. From Ortiz (2017). Copyright © Multi-Health Systems. Used by permission.

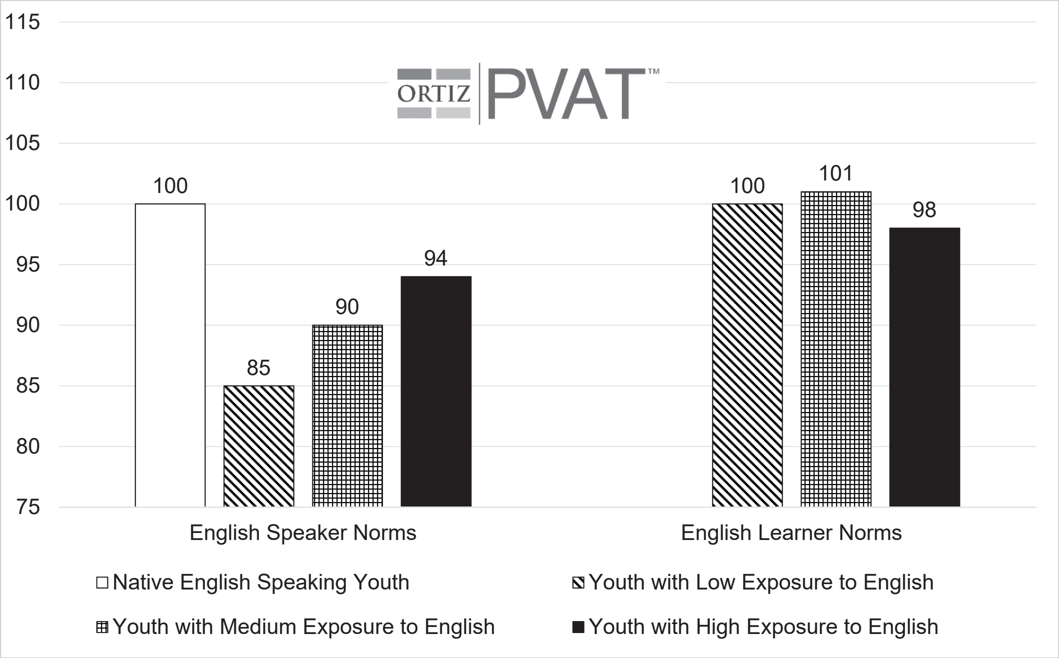

FIGURE 25.6. (Left) Comparison of performance on the Ortiz PVAT by the same four samples as in Figure 25.5, based on norms for native English speakers. (Right) Comparison of the three groups of English learners, based on norms for English learners (controlled for length of English exposure). From Ortiz (2017). Copyright © Multi-Health Systems. Used by permission.

without controls for developmental differences in English-language exposure and opportunity for acculturative knowledge acquisition. The graph on the right shows the performance of the three ELL groups according to norms for English learners, with the application of such controls. It becomes evident that comparison of non-native speakers of English to native speakers is discriminatory, and that the potential for misidentification of a disorder is stark. Native English speakers simply do not represent a "true peer" comparison group for ELLs. The absence of controls for differential linguistic and developmental experiences typical of ELLs in the United States permeates even native-language tests.

By controlling for differential amounts of English exposure, the creation of group-specific norms for ELLs effectively provides the necessary "true peer" foundation for making valid comparisons of performance. In this way, the use of a single test that can be administered to any individual who speaks English (as a native or otherwise) not only yields efficiency in the evaluation process, but directly addresses the "difference versus disorder" dilemma in a manner that is easily accessible and consistent with current practices and procedures. Indeed, the use of dual norms is an innovative approach to the issue of test score validity and may serve as a model for future test development. Considering that more than 350 languages are spoken in the United States alone (U.S. Census Bureau, 2015), producing adaptations or translations of tests into all these other languages is simply untenable and impractical. Rather, creating tests that serve dual purposes, and that remain accessible to and usable by every practitioner (whether bilingual or not), is a promising avenue for test development—one that seeks to embrace the concept of universal design as recommended in the *Standards,* as well as to meet the need for ensuring test score validity.

SUMMARY

The purpose of this chapter has been to present a discussion of the main issues facing practitioners seeking to evaluate the cognitive abilities of diverse individuals in a manner that integrates research and results in evidence-based practice. Practitioners must have a solid understanding of these issues, in order to integrate them into current practice in a manner that is not only comprehensive and systematic but guided by the available scientific literature. Fair and equitable assessment is accomplished via recognition of the nature and sources of potential bias, and by application of methods and procedures that are specifically designed to ensure validity. Toward that end, cognitive assessment of culturally and linguistically diverse individuals must move beyond traditional practices that lack defensibility or utility in addressing problems with validity, and must dispense with simplistic notions that recognition of a verbal–nonverbal pattern of differences is sufficient. Integration of research into practice appears to necessitate a good grasp of the basic influences on test performance including developmentally based cultural and linguistic differences and their relation to tests and testing, such as norm sample representation, degree and patterns of score attenuation, and test characteristics and demands. Existing approaches lack sufficient empirical support to stand alone as viable or defensible evidence-based practice and require supplementation via emerging methods that are designed specifically to examine issues of validity. Without application of frameworks that permit direct inspection of score validity, use of any particular approach—whether testing in an examinee's native language, testing in English, nonverbal testing, modified/adapted testing, or any combination of them—will remain limited in the extent to which the obtained results can be interpreted validly as measures or estimates of true ability. Success in these endeavors may be facilitated by emerging research-based techniques, including the C-LTC and C-LIM. Such approaches, as well as other contemporary testing approaches (e.g., dual norming), appear to hold significant promise for elevating current assessment practices to meet the call for evidence-based assessment.

Whether current practitioners and researchers realize it or not, differences in the cultural and linguistic backgrounds and experiences of diverse individuals have always posed and will continue to pose serious threats to the validity and meaning of test results. As we have discussed, the type of bias that stems from such differences is not related to any technical or psychometric flaws within the tests themselves, but rather primarily to violations of the assumption of comparability. Individuals who are culturally and linguistically different cannot be held to the same expectations as those for their same-age or same-grade peers when their linguistic or acculturative development is not comparable to theirs; unfortunately, this is what is done when performance standards are based on mainstream, monolingual English speakers. Questions regarding validity are crucial, if not central, to the task of evaluating individuals from diverse cultural and linguistic backgrounds. And such complicated questions will not be answered via simple prescriptions. Bilingualism and level of acculturation are such complex concepts that practitioners should not expect that the question of how to conduct nondiscriminatory assessment can ever be reduced to the question of what is the "right" test to use. Sattler (1992) notes:

> Probably no test can be created that will entirely eliminate the influence of learning and cultural experiences. The test content and materials, the language in which the questions are phrased, the test directions, the categories for classifying the responses, the scoring criteria, and the validity criteria are all culture bound. (p. 579)

At the core of any evaluation lies the issue of validity, and this issue, more than any other, will require significant attention and scrutiny because it alone provides the defensible foundation upon which meaning can be ascribed confidently to obtained results. In the measurement of cognitive abilities in individuals from culturally and linguistically diverse backgrounds, the question of validity will always be tied directly to the success of the chosen methods and procedures in discerning the influence of cultural and linguistic differences on test performance.

PART V

Linking Assessment Data to Intervention

CHAPTER 26

Cognitive Hypothesis Testing

Linking Test Results to the Real World

Catherine A. Fiorello
Kirby L. Wycoff

IMPORTANCE OF COMPREHENSIVE COGNITIVE ASSESSMENT

This chapter presents a model, *cognitive hypothesis testing* (CHT), which is a balanced approach to assessment and intervention (Hale & Fiorello, 2004). Cognitive assessment rests on a foundation of cognitive, neuropsychological, and neuroscientific research, and can inform our interventions with children displaying academic and behavioral difficulties. Research into the neuropsychology of specific learning disabilities (SLD) has made tremendous strides over the last 30 years (Hale, Fiorello, Miller, et al., 2008; Hale, Wilcox, & Reddy, 2016), and provides support for cognitive and neuropsychological assessment that can lead to the development of truly individualized education programs.

The CHT model described in this chapter encourages the use of response to intervention (RTI) as a *prevention* and *intervention* program, although not a *diagnostic* one (Hale, Wycoff, & Fiorello, 2010). We hope that a balanced practice model that includes CHT will provide the basis for a new paradigm shift—a multi-tiered model that combines academic and behavioral interventions for all children who need them, with comprehensive psychoeducational evaluations for those who do not respond to those interventions (Decker, Hale, & Flanagan, 2013; Hale, 2006; Hale, Chen, et al., 2016). For students who do not respond to increasingly intensive intervention approaches, a comprehensive evaluation that includes assessment of cognitive processing will allow us to examine their learning and psychosocial needs, as well as to determine whether or not they have SLD (Backenson et al., 2015; Compton, Fuchs, Fuchs, Lambert, & Hamlett, 2012; Fiorello, Hale, Snyder, Forrest, & Teodori, 2008; Fuchs & Deshler, 2007; Hale, Fiorello, Dumont, et al., 2008; Hain, Hale, & Glass-Kendorski, 2009; Miller & Hale, 2008). This model acknowledges that students may fail to respond to interventions for a variety of reasons—one of which is SLD, a set of neuropsychological disabilities requiring individualized instruction designed to meet students' unique needs (Fenwick et al., 2016; Hale, Flanagan, & Naglieri, 2008). Students who do not respond to RTI service delivery approaches are a heterogeneous group, and a comprehensive CHT evaluation of neuropsychological relationships will aid in both differential diagnosis and intervention for these children.

Diagnosis

The Education for All Handicapped Children Act (Pub. L. No. 94-142, 1975) defined SLD as a deficit in the basic psychological processes that adversely affects academic achievement, and its regulatory language required the presence of a severe discrepancy between ability and achievement. The formal definition was deemphasized, and instead the regulatory language of "severe discrepancy" was emphasized (e.g., Mercer, Jordan, Alsopp, & Mercer, 1996), as it was in most subsequent research and practice. Unfortunately, the process deficits presumed to underlie the academic difficulties were not given the same attention as the ability–achievement discrepancy (AAD)—partly because there was little consensus as to what processes were involved in learning, and partly because good measures of basic psychological processes were not available at the time (Hale & Fiorello, 2004). Much has changed since then, as there are now many well-standardized tools with excellent technical quality to assess psychological processes (Hale & Fiorello, 2004; Hale, Wycoff, & Fiorello, 2010).

As the SLD definition and implementation of the AAD method differed among districts and states (Reschly & Hosp, 2004) and identification of processing disorders was not required, SLD became anything but "specific," and there was an enormous increase in prevalence (MacMillan, Gresham, Lopez, & Bocian, 1996; MacMillan & Speece, 1999). Students with SLD eventually accounted for about half of all special education students (Kavale, Holdnack, & Mostert, 2005). In response, there were calls for a paradigm shift (e.g., Reschly & Ysseldyke, 2002) that would focus on intervention for learning problems rather than diagnosis of them. There are unquestionably problems with the AAD; in particular, the lack of specificity and sensitivity of measures leads to overclassification (e.g., MacMillan, Siperstein, & Gresham, 1996). We do not believe that this condemns all cognitive assessment, however. Instead, we argue that we need to use our well-standardized cognitive assessment tools more wisely, within the context of a comprehensive CHT approach (Fiorello, Hale, & Snyder, 2006; Hale & Fiorello, 2004).

RTI advocates suggest that many learning problems are due to delays that can be remedied by more intensive instruction (e.g., Barnett, Daly, Jones, & Lentz, 2004). We agree; however, there are many reasons why children might not respond to intervention, only one of which is SLD (Hale, Kaufman, Naglieri, & Kavale, 2006). SLD and other neuropsychological disorders are characterized by specific deficits, not just delays (Berninger & Richards, 2002; Collins & Rourke, 2003; Compton et al., 2012; Fenwick et al., 2016; Fiez & Petersen, 1998; Filipek, 1999; Fine, Semrud-Clikeman, Keith, Stapleton, & Hynd, 2007; Francis, Shaywitz, Stuebing, Shaywitz, & Fletcher, 1996; Geary, Hoard, & Hamson, 1999; Hale, Chen, et al., 2016; Hale & Fiorello, 2004; Kubas et al., 2014; Naglieri & Bornstein, 2003; Nicholson & Fawcett, 2001; Pugh et al., 2000; Shaywitz, Lyon, & Shaywitz, 2006; Simos et al., 2005; Stein, 2001). These specific deficits are markers that differentiate SLD from simple delays or lack of instruction, and can also identify subtypes of SLD. In a study of 684 students across grades 3–5, Compton and colleagues (2012) found distinct patterns of strengths and weaknesses; they thus showed that the individual differences found in SLD, which have clinical utility, are lost when disparate individuals are collapsed into a single heterogeneous SLD sample. Meta-analysis also supports the deficit model, with phonological awareness, processing speed, working memory, and executive function deficits being the strongest indicators of SLD status (Johnson, Humphrey, Mellard, Woods, & Swanson, 2010). These deficits require comprehensive evaluation, according to the law (e.g., Dixon, Eusebio, Turton, Wright, & Hale, 2011), and a survey of renowned SLD experts interprets this to mean use of a *pattern of strengths and weaknesses* (PSW) approach to identification of SLD (Hale, Alfonso, et al., 2010).

Children with SLD have specific cognitive deficits in the presence of cognitive integrities that can be ascertained during comprehensive evaluations with well-standardized cognitive and neuropsychological tests (Fiorello, Hale, & Snyder, 2006; Hale, 2006). Research by Hale and colleagues has demonstrated significant profile variability, and more predictive validity for subtests over global composites like IQ, for students with SLD, attention-deficit/hyperactivity disorder (ADHD), and traumatic brain injury (Elliott, Hale, Fiorello, Dorvil, & Moldovan, 2010; Fiorello, Hale, McGrath, Ryan, & Quinn, 2001; Fiorello et al., 2006, 2007; Hale, Fiorello, Dumont, et al., 2008; Hale, Fiorello, Kavanagh, Holdnack, & Aloe, 2007), indicating that empirically based interpretation of strengths and weaknesses is necessary for these students. Research on the diagnostic role of cognitive and neuropsychological assessment will continue to be important, especially for students who do not respond to intervention (Berninger, 2006; Hale et al., 2006; Hale, Fiorello, Dumont, et al., 2008; Kavale et al., 2005; Semrud-Clikeman, 2005; Willis & Dumont, 2006).

As researchers have moved away from AAD, and have started to develop a better understanding of PSW in this heterogeneous population, studies have shown that children with reading SLD may have similar deficits but multiple causes, with subtypes linked to specific PSW (Feifer & Della Tofallo, 2007). These deficits include auditory speech processing (Boets et al., 2011), phonological processing (Cho et al., 2015; Fletcher et al., 2011; Morris et al., 1998; Ramus et al., 2003), visual orthographic processing (Facoetti et al., 2009), integration/mapping of sounds and letters (the alphabetic principle; Blau, van Atteveldt, Ekkebus, Goebel, & Blomert, 2009), rapid automatic naming (Cho et al., 2015; Fletcher et al., 2011; Morris et al., 1998; Norton & Wolf, 2012), processing speed (Morris et al., 1998), working memory (Morris et al., 1998; Swanson, 2011), fluid reasoning (Fletcher et al., 2011), and receptive and expressive language, verbal knowledge, and following directions (Cho et al., 2015; Fletcher et al., 2011; Hulme & Snowling, 2011). Similarly, various subtypes of SLD in written expression have been identified (Fenwick et al., 2016), including ones characterized by weaknesses in working memory, processing speed, left-hemisphere (crystallized) functions, right-hemisphere (fluid) functions, and executive functions.

Students with math SLD have not been studied as extensively, but there too research has identified a number of processing weaknesses in these students compared to low achievers. Students with math SLD show weaknesses in memory retrieval, rapid automatized naming, and processing speed (Cowan & Powell, 2014; Geary, 2011), working memory (Cowan & Powell, 2014; Geary, 2011), fluid reasoning (Cowan & Powell, 2014), number sense and estimating (subitizing and associating numerals with sets; Geary, 2011), oral language (Cowan & Powell, 2014), procedural knowledge (Geary, 2011), and number systems knowledge (Cowan & Powell, 2014).

The Individuals with Disabilities Education Improvement Act of 2004 (IDEA 2004; Pub. L. No. 108-446) no longer requires an AAD for identification of SLD, allows the use of an RTI methodology, and also allows what has become known as a *third-method* approach. The final IDEA 2004 regulations (34 C.F.R. Parts 300 and 301; U.S. Department of Education, 2006) indicate that states "may permit the use of other alternative research-based procedures" (p. 46786) for identifying SLD. Although the language is nonspecific, it has typically been interpreted to refer to the PSW approach to identification (Flanagan, Fiorello, & Ortiz, 2010; Hale, Flanagan, & Naglieri, 2008) and is considered an appropriate alternative for SLD classification by several state boards of education (Zirkel & Thomas, 2010). Evaluation of cognitive and neuropsychological processing, as well as academic achievement, for PSW that are diagnostic of SLD is therefore consistent with the IDEA 2004 SLD definition (Fiorello et al., 2008; Hale, Fiorello, Dumont, et al., 2008; Kavale et al., 2005).

When we look more closely at specific types of SLD, we see clear differences in subtype profiles, which further supports the need for an assessment method that examines processing strengths and weaknesses. Students with different strengths and weaknesses do not perform comparably on measures, and make different cognitive and academic errors based on their PSW (Flanagan & Mascolo, 2016; Koriakin et al., 2017). Unlike AAD or RTI outcome variables, understanding PSW requires a careful examination of within- and between-subtest differences. In particular, understanding the pattern of response and error analysis holds a critical key for understanding the disability and guiding intervention (Hale, Wilcox, & Reddy, 2016). The analysis of the pattern of performance within and across measures, validated by concurrent data sources, helps us understand each student's individual profile and thus provide the most appropriate intervention to address the student's needs. This type of comprehensive evaluation is also helpful in identifying other possible disorders or difficulties that may be interfering with academic achievement because there are many reasons for nonresponse in an RTI model, not just SLD (Hale et al., 2006).

A large group of experts came together to publish a white paper on the identification of SLD (Hale, Alfonso, et al., 2010). This group offered five major recommendations:

1. The SLD statutory requirements that include processing deficits in the definition of SLD should be strengthened and adhered to in practice.
2. Neither RTI nor AAD is sufficient for SLD identification.
3. A PSW approach to the identification of SLD has the most empirical and clinical support.
4. RTI is appropriate as a prevention approach, but should be combined with a PSW approach to identify and serve children who fail to respond to interventions.
5. Identification and intervention development for students with SLD should include neuropsychological assessment (process) approaches.

Although an RTI approach can improve outcomes for many children (e.g., Jimerson, Burns, & VanDerHeyden, 2016), lack of response to interventions is not effective in identifying SLD (e.g., Barth et al., 2008; Brown-Waesche, Schatschneider, Maner, Ahmed, & Wagner, 2011). In addition, one large-scale study, conducted under the auspices of the U.S. Department of Education, using hundreds of children and dozens of schools, found that using a multi-tiered RTI approach in the absence of differentiated instruction does not lead to better academic outcomes for struggling learners (Balu et al., 2015). In fact, when a standard instructional approach was compared to the multi-tiered system of support approach using RTI, children in the standard approach did better than those in RTI, with results suggesting little to no gains in the undifferentiated RTI approach (Balu et al., 2015). We believe that RTI is an excellent first step to helping children learn and overcome challenges, but is not alone sufficient to diagnose SLD (Hale et al., 2006) or guide individualized interventions to help children overcome their learning difficulties (e.g., Balu et al., 2015).

Work by Hale and colleagues (Hale, Betts, Morley, & Chambers, 2010; Hale & Morley, 2009) has demonstrated that not all nonresponders in an RTI model have SLD. These researchers successfully used a combined RTI–CHT approach to provide RTI services to all children, and this approach dramatically reduced referrals for special education evaluation. Although all of the nonresponders in their multi-tiered RTI approach did meet IDEA 2004 criteria for a disability, the comprehensive CHT evaluation revealed that these children had many different types of disorders (e.g., ADHD, anxiety disorder) or different subtypes of SLD (e.g., orthographic SLD, working memory SLD). Not only did the CHT evaluation help identify each child's unique PSW and disabling condition, but it also led to targeted interventions designed to meet each child's unique needs, and ultimately to treatment efficacy.

The third-method PSW approach to identifying SLD is supported not only by SLD experts (Hale, Alfonso, et al., 2010), but also by samples of school psychology practitioners (Caterino, Sullivan, Long, & Bacal, 2008; Machek & Nelson, 2007) and several national organizations, including the National Association of School Psychologists (2007), the American Academy of School Psychology (Schrank, Miller, Caterino, & Desrochers, 2006), and the Learning Disabilities Association of America (Hale, Alfonso, et al., 2010).

Different approaches to SLD identification lead to differing outcomes, depending on the methodology and data examined (Kranzler, Floyd, Benson, Zaboski, & Thibodaux, 2016; Maki, Burns, & Sullivan, 2016), so we must return to a critical defining element of SLD to guide our methodology. The statutory requirement of IDEA specifies that children with SLD have a deficit in the basic psychological processes. Focusing on both the SLD construct and measurement issues of SLD identification, instead of solely considering the methodology, will enable us to develop a more nuanced and sophisticated approach to serve this diverse population for both diagnostic and intervention purposes. The idea that children with SLD are different from their neurotypical peers, both in their processing characteristics and in their brain functioning, is confirmed time and again in the neuroscience literature (Hale, Chen, et al., 2016)—wherein students with different PSW may have similar achievement deficits, but profile and error pattern differences attest to just how they are different (Koriakin et al., 2017). The point has been supported by meta-analysis (Johnson et al., 2010).

Several studies of the PSW model have reported negative results, using simulated and actual data (e.g., Kranzler et al., 2016; Miciak et al., 2016; Stuebing, Fletcher, Branum-Martin, & Francis, 2012). Although these studies question the utility of the PSW approach, we argue that the negative results are related to the study methodology, rather than constituting a critique of the model itself. Specifically, studies that examine the PSW model often identify the lowest score relative to the highest score and make few actual attempts to *verify* that the weakness is related to a disability, as we (Hale, Wycoff, & Fiorello, 2010) suggest is necessary before identification should occur (see also Flanagan, Alfonso, Costa, Palma, & Leahy, Chapter 22, this volume). In addition, those students are essentially collapsed into one "big bucket" for single-heterogeneous-group analysis, which misses the essence of the model entirely (Kranzler et al., 2016; Taylor, Miciak, Fletcher, & Francis, 2017; see Flanagan & Schneider, 2016, for commentary on this type of analysis). Researchers' assumptions have played a large role in these analyses, and are thus likely to have undermined potential findings, with designs likely to maximize the likelihood of Type II errors. For instance, Kranzler and colleagues (2016) only used the cognitive–achievement relationships determined for a typical population (i.e., they used McGrew & Wendling, 2010), not those with a SLD or subtypes of disability. Although we agree that the relationships found between Cattell–Horn–Carroll (CHC) factors and achievement measures is a good place to start in understanding these relationships, results from our work and others suggest that there is not just one cause of a particular academic disability, but several. As a result, collapsing disparate scores from disparate subpopulations (subtypes) into a single group for subsequent analysis is akin to the measurement problems seen in both AAD and undifferentiated RTI.

As Decker and colleagues (2013) note, it is easy to create studies that lead to Type II errors when individual cognitive–achievement differences are minimized, and then to ignore the literature that could guide more accurate analyses. In fact, it is interesting to note that many of these anti-PSW papers ignore the positive PSW findings in the literature. For instance, the Miciak and colleagues (2016) and Kranzler and colleagues (2016) studies do not cite one positive PSW study, as if the research was never conducted. These studies also avoid reviewing any neuropsychology or neuroscience literature on SLD. A quick review of their reference lists shows little attention to this broad and telling literature, which attests to both the importance of individual processing differences for identification of SLD and targeted intervention specific to child needs (see Hale, Chen, et al., 2016). Ignoring the literature and creating designs that maximize Type II errors do not bode well for the conclusions rendered by these researchers. Regardless, the great asset of PSW is its specificity, but this specificity is lost as we climb the nomothetic ladder or treat all children with SLD as if they have the same processing cause for their disorder.

In education, we often hear of the problems associated with a "one-size-fits-all" orientation. It fails us with AAD. It also fails us in an RTI approach. What makes researchers think that PSW would be any different? As long as the individual processing differences are ignored in researcher designs, PSW will suffer the same fate as AAD and RTI. In their comprehensive analyses of the topic, Compton, Fuchs, and others have demonstrated that when these students are collapsed into a single group, the effects disappear. The sensitivity of the PSW model is lost when we do not attempt to verify that the weakness may be related to a disability (Flanagan & Schneider, 2016; Fuchs et al., 2012; Fuchs, Fuchs, & Compton, 2010; McMaster, Fuchs, Fuchs, Compton, 2005), and when students are collapsed into a heterogeneous SLD group.

Intervention Development

Evaluations for students who do not respond to intervention must be comprehensive, and we define *comprehensive* as including cognitive and neuropsychological measures in addition to other data sources. The goal of the comprehensive evaluation before tier 3 service delivery is not just differential diagnosis or determination of special education eligibility, but also development of targeted interventions designed to meet a child's unique needs. Most eligibility assessment procedures have not been directly linked to intervention and have poor validity for this purpose (Bocian, Beebe, MacMillan, & Gresham, 1999). Although early special education research suggested that there were no "aptitude–treatment interactions" (Reschly & Ysseldyke, 2002), neuropsychological research has been more fruitful in linking assessment to intervention (see a summary in Hale, Fiorello, Miller, et al., 2008). In fact, a special issue of the *Journal of Learning Disabilities*, titled "Cognitive and Neuropsychological Assessment Data That Inform Educational Intervention" (see Fuchs, Hale, & Kearns, 2011), attests to recent advances in the area of linking these types of data to intervention. Of course, there is no easy "cookbook" approach for linking assessment results to interventions. Our CHT model calls for a complete problem-solving process: collaborative development of interventions, regular monitoring of progress/results, and recycling of the process until a successful intervention is found for each individual child.

MODELS OF COGNITIVE FUNCTIONING: CHC THEORY AND NEUROPSYCHOLOGY

CHC theory, based in psychometrics and large-scale factor analyses, is the predominant model of cognitive functioning today (Newton & McGrew, 2010). The broad and narrow cognitive abilities identified in CHC theory have been linked with a variety of educational outcomes (Elliott et al., 2010; Hale, Fiorello, Dumont, et al., 2008; McGrew & Wendling, 2010). Most measures of cognitive functioning today are designed to measure a variety of constructs, rather than simply to provide a single IQ or *g* measure (Elliott et al., 2010; Fiorello et al., 2001, 2007; Flanagan, Ortiz, & Alfonso, 2013; Hale et al., 2006, 2007; Hale, Fiorello, Dumont, et al., 2008; Hale, Fiorello, Miller, et al., 2008; McGrew & Wendling, 2010), and CHC theory is often the model used for that development (Keith & Reynolds, 2010).

At the same time as CHC has been coming into prominence as a psychometric theory of cognitive functioning, neuropsychological research has burgeoned; much of it has examined learning disabilities, ADHD, and other high-prevalence disorders (e.g., D'Amato, Fletcher-Janzen, & Reynolds, 2005; Feifer & Rattan, 2009; Hale & Fiorello, 2004; Miller, 2010). The convergence of evidence that cognitive and neuropsychological processes can be reliably and validly measured and linked to outcomes is leading to a synthesis of the psychometric and neuropsychological approaches to assessment (Fiorello et al., 2008). This knowledge can be used during CHT evaluations for nonresponders in a multi-tiered RTI model—an approach that includes the strengths of both CHT and RTI models.

COGNITIVE HYPOTHESIS TESTING

Overview of the Model

The CHT model is based on the idea that professionals must *intervene* to *assess* (Hale & Fiorello, 2004). A multi-tiered RTI model, implemented with fidelity, will ensure that the number of students referred for comprehensive evaluations will be relatively small. When professionals are completing an assessment on every child who is at risk for school failure, they do not have time to complete the kind of comprehensive assessment that we recommend. However, if most students are served through an RTI process, the number who require an assessment for diagnosis and placement eligibility should be manageable. School psychologists operating in typical public schools are often faced with an overwhelming number of students who are referred for full psychoeducational evaluations. Many of these clinicians cringe at the thought of having to do additional testing on top of what is already a very demanding caseload. However, the CHT model does not simply advocate for "more testing." The model is not intended to place more responsibility on school psychologists, but rather to help redistribute that responsibility back to general education teachers, special educators, and others who are intervening at tiers 1 and 2. When RTI is correctly implemented, all team members are responsible for data collection. When other team members are responsible for interventions and data collection at tiers 1 and 2, the number of referrals for full evaluations will decrease, and school psychologists will have more time to assess the small subset of the student population with true, neurologically based learning disabilities. An RTI model that includes both standard protocol and collaborative problem-solving approaches (that also include participation from special educators across tier levels) will ultimately maximize external and internal validity in the decision-making process (Hale, Flanagan, & Naglieri, 2008). This position is advocated by a majority of leading researchers in SLD (Hale, Alfonso, et al., 2010).

The CHT model (Hale & Fiorello, 2004; see Figure 26.1) uses cognitive and neuropsychological measures to assess students who do not respond to intervention. Based on a scientist-practitioner approach, the CHT model uses the scientific method to assess children over time; this mitigates some of the difficulties with one-shot assessments, and establishes concurrent and ecological validity in the process. Any hypotheses about processing weaknesses derived from the initial cognitive battery or other data sources are tested further with more specific measures, and are evaluated to ensure their ecological and treatment validity (Hale & Fiorello, 2004). Although we do recommend empirical profile analysis (Elliott et al., 2010), CHT avoids many of the difficulties of that process by confirming or disconfirming hypotheses with further data collection, including further testing of psychological processes beyond a single cognitive test.

The beginning stages of CHT are similar to typical assessment practices. A student who has failed to respond to instruction and intervention is referred for formal evaluation. The referral question is considered together with historical records, classroom permanent products, and RTI data to develop a theory of the problem. Hypotheses are proposed to explain the academic or behavioral deficits, and if the hypothesis revolves around a question of cognitive functioning, a cognitive/intelligence test is used during the first round of data collection. The initial battery should be chosen to cover a broad range of cognitive processes, and to be a fair measure of the student's functioning based on his or her cultural and linguistic background. That measure should be scored and interpreted to identify possible processing strengths and weaknesses—using clinical references to generate initial hypotheses (such as Dehn, 2013; Flanagan et al., 2013; Hale & Fiorello, 2004; Miller, 2013; Naglieri & Goldstein, 2009; Sattler, 2008), and using *demands analysis* (see below) as needed

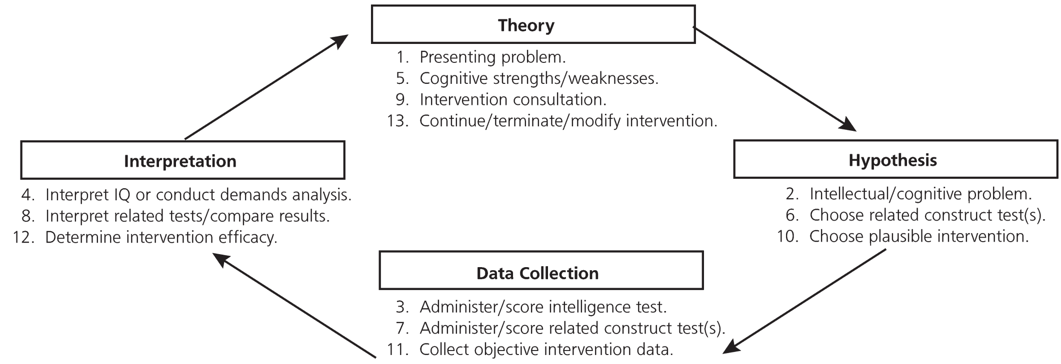

FIGURE 26.1. The cognitive hypothesis testing (CHT) model. From Hale and Fiorello (2004). Copyright © The Guilford Press. Reprinted by permission.

to determine what cognitive processes are being assessed by a given measure.

Although large-group studies can provide valuable information about what particular tests measure, they are often based on the standardization samples of cognitive batteries (e.g., McGrew & Wendling, 2010), and therefore do not capture the differences in what is measured that may be found in individuals or subgroups. Students with disabilities, in particular, may use different cognitive processes to complete complex tasks from those used by the typically developing majority (e.g., Elliott et al., 2010; Hale, Fiorello, Dumont, et al., 2008; Shaywitz et al., 1998). Neuroimaging research confirms that most students use multiple brain areas to solve complex tasks, but that different brain areas are primarily responsible for different components of cognitive tests (Glascher et al., 2009). In addition, most complex cognitive tasks can be completed in a variety of ways, so using a "cookbook" approach by listing all potential processing possibilities is not helpful in intervention development. For example, poor Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V) Processing Speed performance may result from many different problems, including attention, visual acuity, visual scanning, visual–spatial functioning, visual memory, associative learning, somatosensory functioning, processing speed, psychomotor speed, fine motor coordination, and/or graphomotor skills. Further testing and comparison to ecological information should evaluate these hypotheses to allow development of appropriate interventions.

Practically speaking, this process may unfold in the following way: The school psychologist generates hypotheses about the potential reasons for a student's poor WISC-V Processing Speed score. Next, the school psychologist consults with the special educator who was responsible for the tier 2 interventions. The special educator provides work samples, classroom examples, and progress-monitoring data to suggest that the student's visual memory and visual–spatial functioning are poor, but that graphomotor skills appear intact. The school psychologist can then choose specific subtests (e.g., Wide Range Assessment of Memory and Learning, Second Edition subtests for Visual Memory; NEPSY-II Arrows, Design Copy) from different neuropsychological and cognitive measures to test the specific hypotheses about the underlying processes—visual memory, visual–spatial processing, and graphomotor skills—that may be responsible for poor Processing Speed scores on the WISC-V. If the visual memory hypothesis is confirmed, then the school psychologist is in a better position to recommend very specific, clear recommendations and accommodations focusing on poor visual memory. On the other hand, if the school psychologist stops the process prematurely and simply reports back to the team that this child has "poor processing speed," little headway will be made with regard to providing appropriate, practical suggestions to help this child learn.

Clinical interpretation that takes into account a variety of empirical information about what tests measure, together with deep knowledge of the tests themselves and close observation of *how* a student performs the required tasks, can identify potential strengths and weaknesses. Both level (i.e., nomothetic) and pattern (i.e., idiographic) of performance are examined to determine the student's cognitive, neuropsychological, academic, and behavioral state at the time of the evaluation (Hale

& Fiorello, 2004). Note that it is not assumed that the psychologist is assessing unchanging *traits* of the student, but obtaining a picture of the student's current *state* of functioning. Since cognitive states are measured, it is important to administer measures over more than one session to confirm or refute the hypotheses derived from any given session, which is why CHT is so critical for interpretation. However, at this point in a typical psychoeducational assessment, most clinicians write a report describing the purported strengths and weaknesses and make recommendations for placement and interventions. But this is only the beginning of the CHT process because any hypotheses developed need to be confirmed or disconfirmed by using additional data sources and conducting additional testing (Hale & Fiorello, 2004).

Many supplemental tests are brief neuropsychological processing measures with adequate sensitivity and more specificity, so this additional testing need not take an inordinate amount of time. The results of the additional testing are examined in light of all the data collected about the child, and a theory about a likely intervention approach is developed (Hale & Fiorello, 2004). Through a process of collaborative consultation with the teacher and/or parent, an intervention plan is devised. The intervention is implemented with regular progress monitoring, and evaluated to determine efficacy. If the intervention is not effective, the psychologist revises the plan or recycles through the process until a successful intervention is found (Hale & Fiorello, 2004). In this way, CHT combines information about cognitive and neuropsychological functioning within a collaborative problem-solving approach, and uses single-subject methodology to evaluate the effectiveness of interventions (Fiorello et al., 2006; Hale et al., 2006; Reddy & Hale, 2007).

CHT can be used to link assessment to intervention for students with difficulties in various areas, including reading (Fiorello et al., 2006), math (Hale et al., 2006), and attention (Reddy & Hale, 2007). CHT has also been recommended for use in neuropsychological settings (Fletcher-Janzen, 2005; Miller, Getz, & Leffard, 2006), as well as in schools (Elliott et al., 2010; Hale, Fiorello, Dumont, et al., 2008). Because CHT is incorporated within the context of a collaborative problem-solving approach, it is inherently self-correcting and leads to successful intervention for children with a number of disabilities (Fiorello et al., 2006; Hale, Fiorello, Miller, et al., 2008).

Demands Analysis

Interpreting an IQ score is simple, but it seldom is reflective of a child's ability, nor is it the best predictor of academic achievement (Fiorello et al., 2007; Hale, Fiorello, Miller, et al., 2008). Instead, we must acknowledge that interpretation of intelligence/cognitive subcomponent scores is necessary, and that it is not a simple or straightforward process. Various intelligence tests involve different tasks, different cognitive demands, different cultural and linguistic loading, and different administration procedures. In addition, every test measures, to a greater or lesser extent, a combination of ability and achievement; therefore, an examinee's background and exposure to similar tasks must be taken into account during interpretation. Scores are not interchangeable and should not be interpreted as a measure of a student's *trait* of intelligence, but as a measure of the student's current *state* of cognitive functioning (Hale, Wycoff, & Fiorello, 2010). The choice of a battery should be based on a priori information about the student's prior RTI data, prior experience and education, cultural and linguistic background, and any sensory or motor difficulties, in order to minimize the construct-irrelevant variance that these factors can introduce.

After administration and scoring, the profile should be examined for significant variability. If there is significant subtest or factor variability, the global IQ score should not be interpreted. But even factor scores are complex, and should not be interpreted as unitary clusters if they too show significant subtest variability within the factors. Factor scores should only be interpreted if they hold together, or are reliable, for the child being evaluated. Of course, we do not mean to imply that variability implies a disability, as the majority of people show significant variability on complex batteries like our current IQ tests (Fiorello et al., 2007; Hale, Fiorello, Dumont, et al., 2008). We simply mean that profiles should be interpreted as indicating cognitive strengths and weaknesses when there is significant variability present. In fact, it may even be necessary to examine differences *within* a subtest if it contains disparate tasks, such as Digits Forward and Digits Backward on the WISC-V Digit Span subtest. For instance, research has shown that the difference between Digits Forward and Backward can be useful in identification of children with SLD (e.g., Hain et al., 2009) and attention problems (Hale, Hoeppner, & Fiorello, 2002), suggesting that interpretation of a Digit Span score may not accurately reflect a child's functioning. The newly added process scores may help in evaluating a child's performance.

Many school psychologists report using factor scores, profile analysis, or both to examine cognitive strengths and weaknesses in practice (Pfeiffer, Reddy, Kletzel, Schmelzer, & Boyer, 2000). However, we need a consistent methodology for interpreting the pattern of strengths and weaknesses to increase the reliability and validity of those conclusions. We have derived our CHT model in such a way as to increase the reliability and validity by systematically testing our hypotheses, and evaluating ecological and treatment validity. *Demands analysis* (see Figure 26.2) systematizes the process of identifying the input, processing, and output demands of individual tasks. Rather than just basing interpretation on a score and the test maker's description of what a subtest measures, demands analysis provides a wide range of possible interpretive factors to be considered in evaluating a student's strengths and weaknesses. After testing these hypotheses with further evaluation, demands analysis allows professionals to develop an individualized education program that will truly meet a student's individual needs.

Demands analysis is a combination of the "intelligent testing" approach begun by Alan Kaufman (1979) and in widespread use in school psychology (e.g., Sattler, 2008), along with the CHC cross-battery approach advocated by McGrew, Flanagan, and colleagues (e.g., Flanagan et al., 2013; McGrew & Wendling, 2010) and a neuropsychological assessment "process approach" (e.g., Groth-Marnat, Gallagher, Hale, & Kaplan, 2000; Hebben & Milberg, 2002). This emphasis on the neuropsychological processes underlying task completion has become more widespread in school psychology since the introduction of the process in *School Neuropsychology: A Practitioner's Handbook* (Hale & Fiorello, 2004; see, e.g., D'Amato et al., 2005; Dehn, 2013; Miller, 2010, 2013).

To complete a demands analysis, a professional must first consider the *input* demands of the task. This refers to the directions and stimulus materials—what modalities are used; the presence of pictures, manipulatives, oral directions, or written materials; how abstract or meaningful the content is; how much English-language mastery is called for; and how much cultural loading there is in the task. Next, the *processing* demands must be considered. It is important not to depend solely on the primary process suggested in the test manual or the loading on CHC abilities indicated by factor-analytic research, but to consider other neurological processing demands, such as executive and working memory skills. As Goldberg (2001) suggests, several brain processes are typically involved in any given task, so it is important to interpret

Student's Name: ______________________ Age: ________ Grade: ________

this interrelationship among cognitive processes when examining any given test result. Also, it is important to consider the different ways that examinees can solve a given task. Some students use the visual gestalt to solve Block Design on the Wechsler scales; others use a trial-and-error approach; still others talk their way through the problem in a linear, sequential manner and instead focus on stimulus details.

Finally, it is important to consider the *output* demands of the task. What modalities and skills are required to complete the task—simple pointing, a complex motoric task, a complex verbal explanation? Taking copious notes on the student's actual behavior on the task, even at the level of individual items, is required for this fine-grained interpretation. A poor score on the Wechsler Information subtest may be due to memory retrieval problems or lack of general knowledge—but it may also be due to lack of knowledge in one specific area, like science. Once a professional has noted the demands of the tasks on which a student exhibits strengths and weaknesses, it is important to examine the notes for commonalities and contradictions. The practitioner must keep in mind that input and output difficulties are most likely due to sensory or motor difficulties or even to cultural or linguistic differences, whereas processing difficulties are likely to be characteristic of neuropsychological disorders (e.g., SLD, ADHD, or depression).

After a theory of the student's strengths and weaknesses is developed, the practitioner will then determine what measures are necessary to confirm or refute this theory during subsequent testing. Tasks that assess these specific hypotheses are more sensitive and specific for the processes in question. Then these results are compared to data from history, work samples, behavior observations, or rating forms to confirm or refute initial findings. Comparing the conclusions about input, processing, and output demands that are drawn from a child's test performance to indicators of classroom performance and behavior will help establish the accuracy of interpretation and establish ecological validity of findings. Tests that are specifically designed to cleanly assess narrow abilities (like the Woodcock–Johnson IV [WJ IV] Tests of Cognitive Abilities and Oral Language), or neuropsychological instruments that yield a variety of process scores (like the WISC-V Integrated, the NEPSY-II, and the Delis–Kaplan Executive Function System), are good places to look for tasks that can test hypotheses.

Concordance–Discordance Model

In order to identify SLD, our concordance–discordance model (C-DM; Hale & Fiorello, 2004) (see Figure 26.3) provides practitioners with an empirical approach to examining patterns of performance on cognitive and academic measures to establish that a processing deficit is the cause of the SLD, and therefore meets the IDEA 2004 statutory definition for the disorder (Hale et al., 2006). Establishing this PSW, and associated achievement deficit(s), appears to be the preferred method among those advocating third-method approaches to SLD identification (Flanagan et al., 2010; Flanagan, Ortiz, & Alfonso, 2015; Hale, Alfonso, et al., 2010; Hale, Flanagan et al., 2008), and is growing in popularity across states (Zirkel & Thomas, 2010). By identifying a pattern of cognitive and

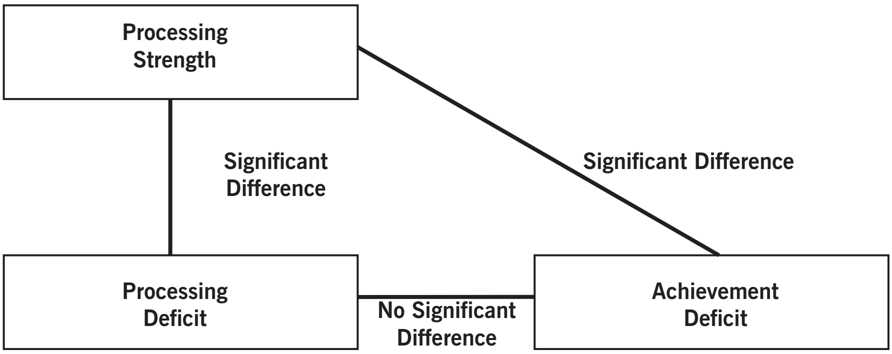

FIGURE 26.3. The concordance–discordance model (C-DM) of SLD identification. Based on Hale and Fiorello (2004).

academic strengths and weaknesses, and evaluating whether they are statistically and clinically different from each other, practitioners can determine the presence of SLD as part of the CHT model.

A step-by-step approach for using the C-DM model can be found in Hale, Wycoff, and Fiorello (2010). The C-DM approach establishes a pattern of cognitive strength(s), together with cognitive weakness(es) associated with an academic weakness. Each component should be composed of a test or cluster score that is reliable and valid for individual, high-stakes decision making. A cluster score may be provided by the test itself, like a General Ability Index score from the WISC-V or a Nonverbal Index score from the Kaufman Assessment Battery for Children—Second Edition in the cognitive area, or practitioners may have to construct a cluster themselves. In most cases, if professionals do this, they will have to calculate the mean cluster score and reliability coefficient themselves, using Fisher's z' transformation (Hale, Fiorello, Miller, et al., 2008).

It is important that practitioners not merely use the highest and lowest cognitive scores and lowest academic scores to calculate the C-DM differences. The cognitive strength should be one that the literature indicates is seldom related to the academic weakness (e.g., visual processing and reading comprehension), while the cognitive weakness should be empirically linked to the academic weakness (e.g., working memory and reading comprehension). Following the standard error of the difference (*SED*) formula (Anastasi & Urbina, 1997), $SED = SD\sqrt{2 - r_{xx} - r_{xy}}$, the practitioner then calculates the *SED* between the cognitive strength and the academic weakness, using the reliability of those cluster scores. This value is then multiplied by 1.96 to obtain the $p < .05$ difference score (or 2.58 for $p < .01$). If the cognitive strength score minus the academic weakness score is equal to or greater than that number, there is a significant difference. Then the same *SED* formula is applied to the cognitive strength and the cognitive weakness to see whether there is a significant difference. Then the calculation is performed again using the cognitive weakness and the academic weakness, and these scores should *not* be significantly different. If the pattern of results fits the pattern shown in Figure 26.3, this is evidence for the presence of SLD. The null hypothesis is that this pattern will not be found, indicating that something other than SLD is responsible for the learning difficulties.

Establishing Ecological and Treatment Validity

We recommend direct behavior observations in natural environments (e.g., classroom) and behavior rating scales to help establish the ecological validity of assessment findings. If a student has a true neuropsychological disorder, it should manifest itself in some form across settings. Of course, behavior is interactional, so a student's behavior will vary in environments with differing demands; however, if difficulties observed during individual testing are not present in the classroom environment, findings need to be evaluated more closely. Sattler (2014) presents a variety of methods for systematically observing student behavior in the classroom; there are formal coding systems available as well, such as the Achenbach System of Empirically Based Assessment (ASEBA) Direct Observation Form (McConaughy & Achenbach, 2009) and the Behavior Assessment System for Children, Third Edition (BASC-3) Student Observation System (Reynolds & Kamphaus, 2015). Behavior rating scales sample behavior across settings and over a period of time, and so add important data to an evaluation. We recommend starting with a general rating scale so as to evaluate a broad range of behaviors, such as the ASEBA Teacher Report Form (Achenbach & Rescorla, 2001), the BASC-3 Teacher Rating Scale (Reynolds & Kamphaus, 2015), or the Clinical Assessment of Behavior (Bracken & Keith, 2004). If practitioners later want more detailed information about a specific class of behaviors, they can follow up with a more focused rating scale. However, it is important to note that the indirect data gained through behavior ratings are quite different from those obtained through direct assessment, so clinical judgment will be necessary to reconcile differences obtained on these measures (e.g., Hale et al., 2009).

Intervention must occur within the context of a collaborative problem-solving approach, and therefore the importance of ongoing progress monitoring to evaluate treatment efficacy cannot be overstated. Gone are the days when a school psychologist would file an evaluation report and not check back for 1 or even 3 years. Effective practitioners must be involved in treatment implementation and monitoring to ensure that what was recommended is actually implemented with fidelity and is effective; if not, consultation skills are necessary to retool the plan as necessary until treatment efficacy is obtained (Hale & Fiorello, 2004).

Using the CHT model to link cognitive and neuropsychological assessment data to intervention on an individual level can ensure that the students served will obtain the individualized services they need. But more group and single-subject research is needed to establish the utility of the CHT approach, and to identify intervention approaches that are effective with students displaying specific patterns of SLD, especially since there are numerous SLD subtypes (e.g., Compton et al., 2012; Fiorello et al., 2006; Hain et al., 2009; Hale, Fiorello, Dumont, et al., 2008; Kubas et al., 2014; Tolar, Fuchs, Fletcher, Fuchs, & Hamlett, 2016). The evidence is just now emerging that cognitive and neuropsychological processes are relevant for academic and behavioral intervention, and considerable empirical work is needed to establish the validity of these relationships (e.g., Fuchs et al., 2011). Only then will the true promise of special education be realized.

ACKNOWLEDGMENT

We acknowledge James B. Hale for his contribution to the chapter in the third edition of this volume, on which the present chapter is based.

CHAPTER 27

Cross-Battery Assessment, the Cross-Battery Assessment Software System, and the Assessment–Intervention Connection

Meghan A. Leahy
Vincent C. Alfonso
Samuel O. Ortiz

AN OVERVIEW OF THE XBA APPROACH

The Cattell–Horn–Carroll (CHC) cross-battery assessment approach (hereafter referred to as the XBA approach) was introduced by Flanagan and her colleagues approximately two decades ago (Flanagan & McGrew, 1997; Flanagan, McGrew, & Ortiz, 2000; Flanagan & Ortiz, 2001; McGrew & Flanagan, 1998). The XBA approach is a systematic method of augmenting cognitive, neuropsychological, achievement, and speech-language batteries with tests from other batteries, such as special-purpose tests (e.g., memory batteries, tests of phonological and orthographic processing, tests of executive functions), to gain a more complete understanding of an individual's strengths and weaknesses (Flanagan, Ortiz, & Alfonso, 2007, 2013, 2017). When batteries are crossed, the XBA approach ensures that reliable, psychometrically sound, and theoretically defensible composites are generated. Moving beyond the boundaries of a single battery by adopting the theoretically and psychometrically sound principles and procedures outlined in the XBA approach is a significant improvement over single-battery assessment because it allows practitioners to focus on measurement of the cognitive constructs and neurodevelopmental functions that are most germane to referral concerns (e.g., Carroll, 1998; Cheramie, Schanding, & Streich, 2018; Decker, 2008; Hale et al., 2010; Kaufman, 2000; Wilson, 1992).

According to Carroll (2012), the CHC taxonomy of human cognitive abilities "appears to prescribe that individuals should be assessed with regard to the *total range* of abilities the theory specifies" (p. 889; original emphasis). However, because Carroll recognized that "any such prescription would of course create enormous problems," he indicated that research "is needed to spell out how the assessor can select what abilities need to be tested in particular cases" (p. 889). Flanagan and colleagues' XBA approach was developed to "spell out" how practitioners can conduct assessments that approximate the total range of cognitive and academic abilities and neuropsychological processes more adequately than what is possible with a stand-alone battery, as well as most collections of co-normed tests.

In an early review of the XBA approach, Carroll (1998) stated that it "can be used to develop the most appropriate information about an individual in a given testing situation" (p. xi). In Kaufman's (2000) review of XBA, he stated that the approach is based on sound assessment principles, adds theory to psychometrics, and improves the quality of the assessment and interpretation of cognitive abilities and processes. Moreover, Decker (2008) stated that the XBA approach "may improve school psychology assessment practice and facilitate the integration of neuropsychological methodology in school-based assessments . . . [because it] shift[s] assessment practice from IQ composites to neurodevelopmental functions" (p. 804). Most recently, Schneider and Roman (2017) stated, "The XBA approach to understanding individuals is an excellent way to organize one's thoughts about test scores. It helps practitioners decide which scores need follow-up testing and which scores are likely to be accurate" (p. 50; see also Cheramie et al., 2018).

Interestingly, assessment professionals "crossed" batteries well before Woodcock (1990) recognized the need, and before Flanagan and her colleagues introduced the XBA approach in the late 1990s, in part as a response to Woodcock's suggestion. Neuropsychologists have long adopted the practice of crossing various standardized tests to measure a broader range of brain functions than that offered by any single instrument (Lezak, 1976, 1995; Lezak, Howieson, & Loring, 2004; see Wilson, 1992, for a review). However, several problems with crossing batteries plagued assessment-related fields for years. Many of these problems have been circumvented by Flanagan and colleagues' XBA approach (see Table 27.1 for examples). But unlike the XBA approach, the various so-called "cross-battery" techniques applied within the field of neuropsychological assessment, for example, are not typically grounded in a systematic approach that is theoretically and psychometrically sound. Thus, as Wilson (1992) cogently pointed out, the field of neuropsychological assessment was in need of an approach that would guide practitioners through the selection of measures that would result in more specific and delineated patterns of function and dysfunction—an approach that would provide more clinically useful information than one "wedded to the utilization of subscale scores and IQs" (p. 382). Indeed, all fields involved in the assessment of cognitive and neuropsychological functioning have some need for an approach that would aid practitioners in their attempt to "touch all of the major cognitive areas, with emphasis on those most suspect on the basis of history, observation, and ongoing test findings" (Wilson, 1992, p. 382; see also Carroll, 1998; McCloskey, Slonim, Whitaker, Kaufman, & Nagoshi, 2017). The XBA approach met this need. The definition of and rationale for XBA are presented in this chapter, followed by a description of the XBA method, information on linking XBA data to intervention, and a case example of its use. Figure 27.1 provides an overview of the information presented in this chapter.

DEFINITION

The XBA approach is a method of assessing cognitive abilities, neuropsychological processes, and academic skills that is grounded mainly in CHC theory and research. It allows practitioners to measure reliably a wider range (or a more in-depth but selective range) of psychological constructs than that represented by any given stand-alone assessment battery. The XBA approach is based on three foundational sources of information (Flanagan, Ortiz, & Alfonso, 2013; Flanagan et al., 2017) that together provide the knowledge base necessary to organize theory-driven, comprehensive assessments.

THE FOUNDATION OF THE XBA APPROACH

The foundation of the XBA approach is CHC theory (Schneider & McGrew, 2012; this volume)[1]—specifically, the broad and narrow CHC classifications of all subtests included in current cognitive, neuropsychological, achievement, speech-language, and special-purpose batteries. The CHC theory was selected to guide assessment and interpretation because it is based on a more thorough network of validity evidence than any other contemporary multidimensional model of intelligence within the psychometric tradition (see Carroll, 1993; Horn & Blankson, 2012; McGrew, 2005; Messick, 1992; Reynolds, Keith, Flanagan, & Alfonso, 2013; Schneider & McGrew, Chapter 3, this volume; Sternberg & Kaufman, 1998). Because CHC theory is discussed in detail by Schneider and McGrew in Chapter 3, it is not described here.

TABLE 27.1. Parallel Needs in Assessment-Related Fields Addressed by the Cross-Battery Assessment (XBA) Approach

Need within assessment-related fields[a]	Need addressed by the XBA approach
School psychology, clinical psychology, and neuropsychology have lagged in the development of conceptual models of the assessment of individuals. There is a need for the development of contemporary models.	The XBA approach provides a contemporary model for measurement and interpretation of cognitive and academic abilities and neuropsychological processes.
It is likely that there is a need for events external to a field of endeavor to give impetus to new developments and real advances in that field.	Carroll and Horn's fluid–crystallized theoretical models and systematic programs of research in cognitive psychology provided the impetus for the XBA approach and led to the development of better assessment instruments and interpretive procedures. Research in fields of cognitive psychology, neuropsychology, and neuroscience give impetus to revisions and refinements to the Cattell–Horn–Carroll (CHC) theory, which in turn led to further development of XBA methods.
There is a need for truly unidimensional assessment instruments for children and adults. Without them, valid interpretations of test scores are problematic at best.	Some scale and composite measures on ability batteries are mixed, containing excess reliable variance associated with a construct irrelevant to the one intended for interpretation. The XBA approach ensures that assessments include composites that are *relatively* pure representations of CHC broad and narrow abilities, allowing for valid measurement and interpretation of multiple, relatively distinct abilities and processes.
There is a need to utilize a conceptual framework to direct any approach to assessment. This would aid both in the selection of instruments and methods, and in the interpretation of test findings.	The XBA approach to assessment is based mainly on CHC theory and research, as well as sound measurement and interpretive procedures. At this time, over 135 psychological tests, including over 1,000 subtests, have been linked to contemporary CHC theory. As such, test selection and interpretation can be accomplished within the context of an overarching conceptual framework.
It is necessary for the conceptual framework or model underlying assessment to incorporate various aspects of neuropsychological and cognitive functioning, which can be described in terms of constructs that are recognized in the neuropsychological and cognitive psychology literature.	The XBA approach includes various aspects of neuropsychological and cognitive functioning, which are described in terms of CHC broad- and narrow-ability constructs that are recognized in the neuropsychological and cognitive psychology literature, as well as other related fields.
There is a need to adopt a conceptual framework that allows for the measurement of the full range of behavioral functions subserved by the brain. Unfortunately, in neuropsychological assessment there is no inclusive set of measures that is standardized on a single normative population.	XBA allows for the measurement of a wide range of broad and narrow cognitive abilities and processes specified in CHC theory. Although an XBA norm group does not exist, the method of crossing batteries and the processes of creating cross-battery composites is psychometrically sound and theoretically defensible.
Because there are no truly unidimensional measures in psychological assessment, there is a need to select subtests from standardized instruments that appear to reflect the neurocognitive function of interest. In neuropsychological assessment, therefore, the aim is to select those measures that, on the basis of careful task analysis, appear mainly to tap a given construct.	The XBA approach is defined in part by a CHC classification system. Subtests from the major intelligence/cognitive batteries, academic achievement tests, neuropsychological instruments, and special purpose tests were classified as measures of broad and narrow CHC constructs. Use of these classifications allows practitioners to be reasonably confident that a given test taps a given construct.

(continued)

TABLE 27.1. *(continued)*

Need within assessment-related fields[a]	Need addressed by the XBA approach
It is clear that an eclectic approach is needed in the selection of measures—preferably subtests rather than the omnibus IQs, in order to gain more specificity in the delineation of patterns of function and dysfunction.	The XBA approach ensures that two or more relatively pure, but qualitatively different, indicators of each *broad* cognitive ability are represented in an assessment of broad CHC constructs. Two or more qualitatively similar indicators are necessary to make inferences about specific or *narrow* CHC constructs. The XBA approach is eclectic in its selection of measures, but attempts to represent all broad and narrow abilities and processes of interest by using a subset of measures from one or more batteries to augment another battery.
There is a need to solve the potential problems that can arise from crossing normative groups as well as sets of measures that vary in reliability.	In the XBA approach, one can typically achieve baseline data in cognitive functioning across seven or eight CHC broad abilities and processes through the use of two well-standardized batteries that were normed within a few years of one another; this minimizes the effects of error due to norming differences. Also, since interpretation of both broad and narrow CHC abilities is made at the composite (rather than subtest) level, issues related to low reliability are less problematic in this approach. And, because confidence intervals are used for all broad- and narrow-ability composites, the effects of measurement error are reduced further. Finally, composite that emerges as a weakness or deficit must have ecological validity (see Flanagan, Ortiz, & Alfonso, 2013, for details).

[a] Information obtained in part from Wilson (1992).

RATIONALE FOR THE APPROACH IN PRACTICE

The XBA approach was introduced years ago as providing "a much needed and updated bridge between current intellectual theory and research and practice" (Flanagan & McGrew, 1997, p. 322). The need for the XBA "bridge" became evident after a review of the results of several cross-battery factor analyses conducted prior to 2000. The results demonstrated that none of the intelligence batteries in use at that time contained measures that sufficiently approximated the full range of broad abilities defining the structure of intelligence specified in contemporary psychometric theory (see Table 27.2; see also Alfonso, Flanagan, & Radwan, 2005, for a comprehensive discussion of these findings). Indeed, the joint factor analyses conducted by Woodcock (1990) suggested that it might be necessary to "cross" batteries to measure a broader range of cognitive abilities than that provided by a single intelligence battery.

As may be seen in Table 27.2, most batteries fell far short of measuring all seven of the broad cognitive abilities listed. Of the major intelligence batteries in use prior to 2000, most failed to measure three or more broad CHC abilities (viz., Ga, Glr, Gf, Gs) that were (and are) considered important in understanding and predicting school achievement (Flanagan, Ortiz, Alfonso, & Mascolo, 2006; McDonough, Flanagan, Sy, & Alfonso, 2017; McGrew & Wendling, 2010). In fact, Gf, often considered to be the *essence* of intelligence, was either not measured or not measured adequately by most of the intelligence batteries included in Table 27.2 (i.e., the Wechsler Intelligence Scale for Children—Third Edition [WISC-III], Wechsler Adult Intelligence Scale—Revised [WAIS-R], Wechsler Preschool and Primary Scale of Intelligence—Revised [WPPSI-R], Kaufman Assessment Battery for Children [K-ABC], and Cognitive Assessment System [CAS]) (Alfonso et al., 2005).

The finding that the abilities either *not measured* or *underrepresented* by the intelligence batteries listed in Table 27.2 are important in understanding children's learning difficulties provided much of the impetus for developing the XBA approach (McGrew & Flanagan, 1998). In effect, the XBA approach was developed to systematically augment cognitive batteries, such as those listed in Table

27.2, with tests from other batteries to better represent important cognitive abilities and processes in assessment and to allow for measurement of those that are specific to the referral but that nonetheless are not measured by the practitioner's battery of choice. As such, the XBA approach guides practitioners in the selection of tests that together provide measurement of abilities and processes that can be considered sufficient in both breadth and depth for addressing referral concerns.

Table 27.3 is like Table 27.2, except that it includes current tests of intelligence and cognitive ability. A comparison of the two tables demonstrates that the latest versions of commonly used tests measure a greater breadth of CHC cognitive abilities and processes than their predeces-

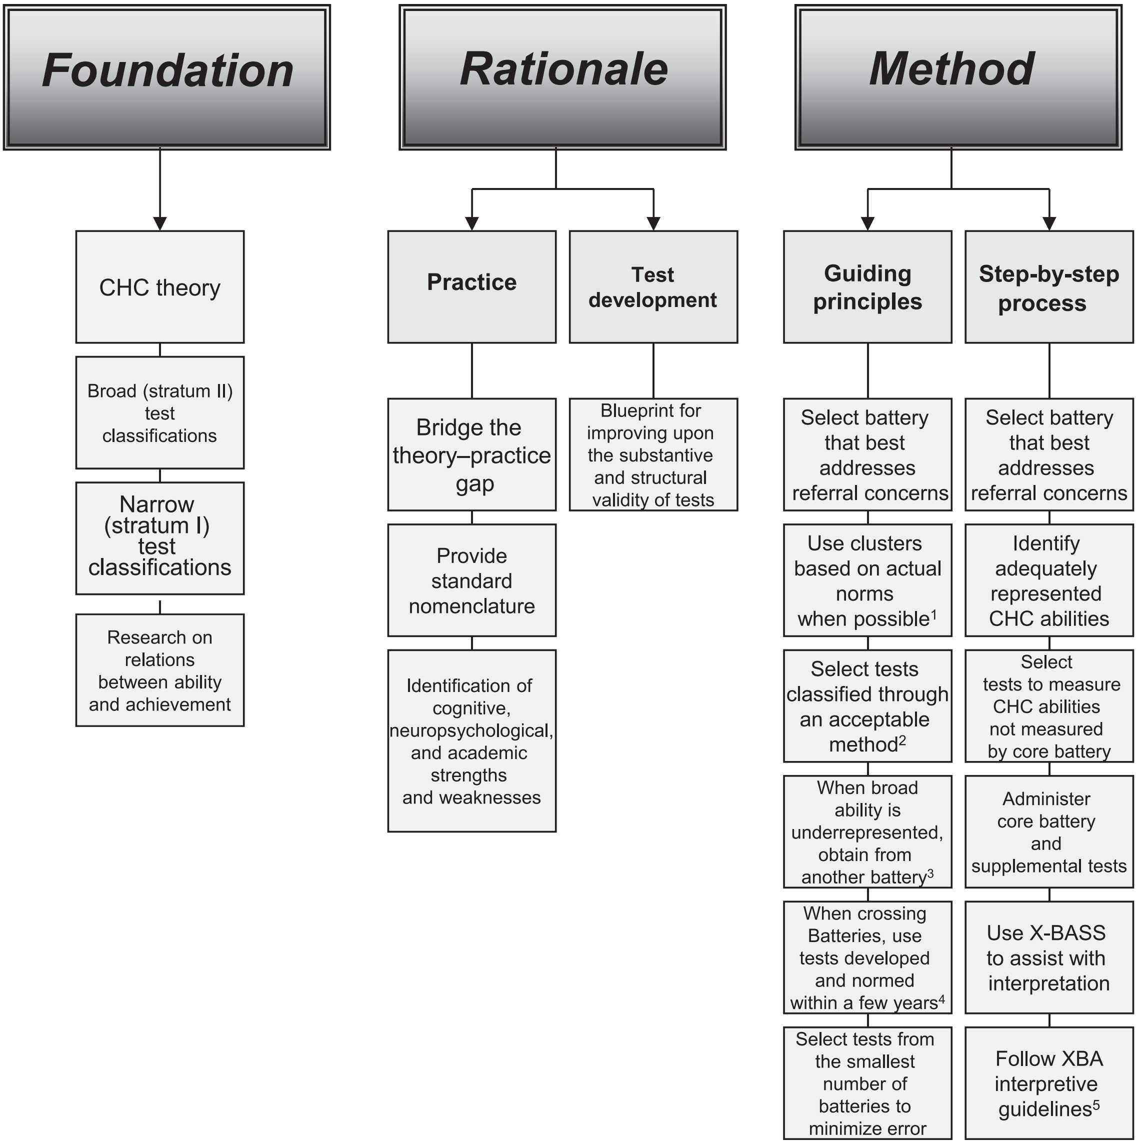

FIGURE 27.1. Overview of the Cattell–Horn–Carroll cross-battery assessment (XBA) approach. sors (see also Table 27.4 for brief highlights of the most salient changes across various editions of intelligence and cognitive tests as they pertain to CHC theory). These changes can be attributed to a number of factors, including (1) greater exposure to CHC theory (formerly known as Gf-Gc theory) in the field of school psychology (e.g., Carroll, 1997; Flanagan, Ortiz, & Alfonso, 2007, 2013, 2017; McGrew, 1997, 2005; Schneider & McGrew, 2012; Woodcock, 1990); (2) the development of XBA and its classification system, which shows what intelligence, cognitive ability, achievement, neuropsychological, speech-language, and special purpose tests measure according to CHC theory (Flanagan & McGrew, 1997; Flanagan, Ortiz, & Alfonso, 2017; McGrew, 1997; McGrew & Flanagan, 1998); (3) the publication of CHC-driven confirmatory factor analyses of the standardization data and independent data sets, most notably by Timothy Z. Keith and his colleagues (e.g., Keith, 1997; Keith, Fine, Reynolds, Taub, & Kranzler, 2006; Keith & Reynolds, Chapter 31, this volume; Reynolds & Keith, 2017; Reynolds et al., 2013).

Another contribution of the XBA approach to practice has been that it facilitates communication among professionals. Most scientific disciplines have a standard nomenclature (i.e., a common set of terms and definitions) that facilitates communication and guards against misinterpretation (McGrew & Flanagan, 1998). For example, the standard nomenclature in chemistry is reflected in the periodic table of elements; in biology, it is reflected in the classification of animals according to phyla; in psychology and psychiatry, it is reflected in the *Diagnostic and Statistical Manual of Mental Disorders*; and in medicine, it is reflected in the *International Classification of Diseases*. Underlying the XBA approach is a standard nomenclature or *table of human cognitive abilities* (McGrew & Flanagan, 1998) that includes classifications of hundreds of tests according to the broad and narrow CHC abilities they measure (Flanagan et al., 2017). The XBA classification system has had a positive impact on communication among practitioners; has improved our understanding of and guided the research on the relations between cognitive and academic abilities (McDonough et al., 2017; McGrew & Wendling, 2010; Niileksela, Reynolds, Keith, & McGrew, 2016); and has resulted in improvements in the measurement of cognitive constructs, as may be seen in the design and structure of current cognitive batteries described in this book, most notably the WJ IV (see Schrank & Wendling, Chapter 14, this volume).

Finally, the XBA approach offers practitioners a psychometrically sound means of identifying population-relative (or normative) strengths and weaknesses. The approach focuses interpretation on cognitive ability composites (i.e., via combinations of construct-relevant subtests) that contain either qualitatively different indicators of each CHC broad-ability construct (to represent broad-ability domains) or qualitatively similar indicators of narrow abilities (to represent narrow- or specific-ability domains or processes), thereby making identification of normative strengths and weaknesses reliable. Adhering closely to the guiding principles of the approach (described later) will help to ensure that any identified strengths and weaknesses are interpreted in a theoretically and psychometrically sound manner. In sum, the XBA approach has addressed the long-standing need within assessment-related fields for methods that "provide a greater range of information about the ways individuals learn—the ways individuals receive, store, integrate, and express information" (Brackett & McPherson, 1996, p. 80; see also Decker, 2008; Wilhoit, 2017).

GUIDING PRINCIPLES

To ensure that XBA procedures are theoretically and psychometrically sound, it is recommended that practitioners adhere to seven guiding principles (Flanagan et al., 2013). These principles are listed in Figure 27.1 and are defined briefly below. Note that the use of the Cross-Battery Assessment Software System (X-BASS; Flanagan, Ortiz, & Alfonso, 2017) ensures that guiding principles 5 and 6 are followed.

1. *Select a comprehensive cognitive battery as the core battery in assessment,* ensuring that it is (a) responsive to referral concerns and (b) suitable to meet each examinee's unique needs. Common core batteries include (but are not limited to) the Wechsler scales; the WJ IV; the Stanford–Binet Intelligence Scales, Fifth Edition (SB5); the Differential Ability Scales—Second Editon (DAS-II); the CAS2; and the KABC-II.

2. *Use subtests and composites from a single battery whenever possible to represent broad and narrow CHC abilities.* In other words, best practice involves using actual norms whenever they are available, rather than a formula. However, when it is necessary to follow up on aberrant score per-

TABLE 27.4. Impact of CHC Theory and XBA CHC Classifications on Intelligence Test Development

Test (year of publication) CHC and XBA impact	Revision (year of publication) CHC and XBA impact
WISC-III (1991) No obvious impact. **WISC-IV (2003)** Eliminated Verbal and Performance IQs; replaced the Freedom from Distractibility Index with the Working Memory Index; replaced the Perceptual Organization Index with the Perceptual Reasoning Index; enhanced the measurement of fluid reasoning by adding Matrix Reasoning and Picture Concepts subtests; enhanced measurement of processing speed with the Cancellation subtest.	**WISC-V (2014)** CHC theory was one guiding theory in the development of this battery; the PRI was divided into the Fluid Reasoning Index (Gf) and Visual Spatial Index (Gv); a Glr factor was added that assesses associate memory and retrieval fluency; improvements were made in measurement of working memory and fluid reasoning.
WAIS-III (1997) No obvious impact.	**WAIS-IV (2008)** Minor impact. Eliminated Verbal and Performance IQs; replaced the Perceptual Organization Index with the Perceptual Reasoning Index; enhanced the measurement of fluid reasoning by adding the Figure Weights and Visual Puzzles subtests; enhanced measurement of Processing Speed with the Cancellation subtest; enhanced measurement of memory with the Working Memory Index.
WPPSI-III (2002) Incorporated measures of processing speed that yielded a Processing Speed Quotient, based on recent research indicating the importance of processing speed for early academic success; enhanced the measurement of fluid reasoning by adding the Matrix Reasoning and Picture Concepts subtests.	**WPPSI-IV (2012)** Minor impact. Eliminated Verbal and Performance IQs; enhanced measures of working memory, processing speed, and inhibitory control.
K-ABC (1983) No obvious impact.	**KABC-II (2004)** Provides a second global score that includes fluid and crystallized abilities; includes several new subtests measuring reasoning; interpretation of test performance may be based on CHC theory or Luria's theory; provides assessment of five CHC abilities.
WJ-R (1989) Used modern Gf-Gc theory as the cognitive model for test development; included two measures of each of eight broad abilities. **WJ III NU (2001, 2007)** Used CHC theory as a "blueprint" for test development; included two or three qualitatively different narrow abilities for each broad ability; the combined Cognitive and Achievement batteries of the WJ III NU included 9 of the 10 broad abilities subsumed in CHC theory at the time.	**WJ IV (2014)** Uses expanded CHC theory (Schneider & McGrew, 2012) and introduces cognitive complexity in test development; changes Gsm to Gwm; adds attentional control (AC) under Gwm; added speed of lexical access (LA) under Glr; includes a new Gf-Gc composite; brings back Scholastic Aptitude Clusters; adds an Oral Language battery; provides adequate measurement of 10 broad CHC abilities across batteries.

(continued)

TABLE 27.4. *(continued)*

Test (year of publication) CHC and XBA impact	**Revision (year of publication)** CHC and XBA impact
SB:IV (1986)	**SB5 (2003)**
Used a three-level hierarchical model of the structure of cognitive abilities to guide construction of the test: The top level included a general reasoning factor or g; the middle level included three broad factors called Crystallized Abilities, Fluid-Analytic Abilities, and Short-Term Memory; the third level included more specific factors, including Verbal Reasoning, Quantitative Reasoning, and Abstract/Visual Reasoning.	Uses CHC theory to guide test development; increases the number of broad factors from four to five; includes a Working Memory factor, based on research indicating its importance for academic success.
DAS (1990)	**DAS-II (2007)**
No obvious impact.	Measures seven broad CHC abilities and also includes measures of certain narrow abilities not found on other major cognitive batteries (e.g., F6 or free-recall memory).

Note. formances, to test hypotheses regarding unusual patterns in test data, and so forth, crossing batteries is almost always necessary; therefore, cross-battery composites are helpful in understanding an individual's strengths and weaknesses. When cross-battery composites are necessary to represent broad or narrow abilities and processes, X-BASS provides the most psychometrically defensible approach to creating these composites (see Flanagan, Ortiz, & Alfonso, 2017, for details).

3. When assessment of a broad ability is desired, and the core battery does not contain at least two qualitatively different indicators of that broad ability, *supplement the core battery with at least two qualitatively different indicators of that broad ability from another battery*. For example, if an evaluator is interested in measuring visual processing (Gv), and the core battery has only one or no Gv subtests (or two Gv subtests that measure the same narrow ability), then the evaluator should select two qualitatively different indicators of Gv from another battery and use that Gv composite to supplement the core battery. This practice ensures that actual norms are used for interpreting broad-ability performance whenever they are available. Note that it is not always necessary to assess an ability broadly via two qualitatively different indicators. For example, the WISC-V has a Visual Spatial Index (VSI) that is comprised of two tests of Visualization (Vz). As such, the VSI is better described as a measure of the narrow Vz ability than a measure of the broad Gv ability. Based on the nature of the referral, a Vz composite may be sufficient. Unlike broad abilities, reliable and valid assessment of CHC narrow abilities very often requires crossing batteries. This is because most batteries do not contain two or more measures of the *same* narrow ability. When batteries are crossed to obtain information about narrow abilities, X-BASS may be used to generate theoretically and psychometrically defensible narrow-ability composites.

4. *Select tests from the smallest possible number of batteries* to minimize the effect of spurious differences between test scores that may be attributable to differences in the characteristics of inde-

pendent norm samples (McGrew, 1994). When tests are selected carefully and tailored to address well-defined referral concerns, it is typically not necessary to cross more than two or three batteries. That is, using selected tests from one or two batteries to augment the constructs measured by the core battery is typically sufficient to represent adequately the range of broad and narrow cognitive abilities and processes considered necessary based on referral concerns. However, when there is a need to follow up on aberrant score performances or test hypotheses related to unexpected performances, it is often necessary to select tests from additional batteries.

5. When constructing CHC broad- and narrow-ability clusters, *select tests that have been classified through an acceptable method, such as through CHC theory-driven factor analyses and expert-consensus content validity studies*. The most popular or widely used tests included in X-BASS have been classified through these methods (e.g., Flanagan, Alfonso, & Reynolds, 2013; Flanagan et al., 2006; Flanagan, Ortiz, & Alfonso, 2013) and cross-checked with the construct validity data reported in each test's technical and interpretive manual (Flanagan et al., 2017). Use of X-BASS ensures that this guiding principle is followed.

6. When crossing batteries, *select tests that were developed and normed within a few years of one another,* to minimize the effect of spurious differences between test scores that may be attributable to the so-called "Flynn effect" (Flynn, 1984, 2010). X-BASS includes approximately 135 cognitive, neuropsychological, achievement, language, and special-purpose tests, all of which were normed within 10–12 years of one another. Thus, use of X-BASS ensures that this guiding principle is followed.

7. *Establish ecological validity for test performances that are suggestive of normative weaknesses or deficits*. The finding of a cognitive weakness or deficit is largely meaningless without evidence of how the weakness manifests itself in activities of daily living, including academic achievement (Flanagan, Alfonso, & Mascolo, 2011; Mascolo, Alfonso, & Flanagan, 2014; see also Fiorello & Wycoff, Chapter 26, this volume). The validity of test findings is bolstered when clear connections are made between the cognitive weakness (as measured by standardized tests) and the educational impact of that weakness—for example, as observed in classroom performance and as may be gleaned from a student's work samples. To demonstrate, Table 27.5 includes information about (a) the major cognitive domains of functioning included in CHC theory; (b) the manifestations of deficits in these domains in general, as well as in specific academic areas; and (c) interventions and recommendations that can be tailored to an individual's unique learning needs when such weaknesses are found. In effect, the information in this table depicts the assessment–intervention connection. The key is understanding the manifestations of cognitive deficits for the individual (which provides ecological validity for test scores), which in turn provides a target for intervention. Once the target is identified, then the practitioner is in a better position to select interventions that are likely to minimize the effects of the deficit, allowing the student greater access to the curriculum and instruction.

CHC THEORY, NEUROPSYCHOLOGICAL THEORY, AND RESEARCH KNOWLEDGE BASES

To organize XBAs and interpret XBA data, practitioners should have knowledge of CHC theory or neuropsychological theory (or both) and the expansive research foundations supporting them. Meaningful and defensible interpretation of test data, whether from a single battery or from XBAs, requires knowledge of contemporary theory and research. Such information is critical in the early stages of assessment because it provides the foundation from which to specify the relations between manifest academic performance deficits and suspected underlying cognitive ability and neuropsychological processing deficits. Logical deductions and presuppositions that emanate from current theory and research allow for the formation and subsequent testing of a priori hypotheses.

SPECIFICATION OF A PRIORI HYPOTHESES

The definition of *a priori* as it is used in the XBA approach is found in *The American Heritage Dictionary of the English Language, Fifth Edition* (2018): "Proceeding from a known or assumed cause to a necessarily related effect; deductive." When case history data and current information are coupled with knowledge of contemporary theory and research (and perhaps with information from other fields, such as the literature on specific learning disabilities [SLD]), defensible connections among

TABLE 27.5. CHC Broad Abilities, Their Definitions, Manifestations of CHC Weaknesses, and Suggested Recommendations and Interventions

CHC broad ability	CHC broad-ability definition	General manifestations of the CHC broad-ability weakness	Specific manifestations of the CHC broad-ability weakness in academic areas	Recommendations/interventions
Fluid reasoning (Gf)	• Novel reasoning and problem solving • Processes are minimally dependent on learning and acculturation • Involves manipulating rules, abstracting, generalizing, and identifying logical relationships	***Difficulties with:*** • Higher-level thinking • Transferring or generalizing learning • Deriving solutions for novel problems • Extending knowledge through critical thinking • Perceiving and applying underlying rules or process(es) to solve problems	***Reading difficulties:*** • Inferential reading comprehension • Abstracting main idea(s) • ***Math difficulties:*** • Math reasoning (word problems) • Internalizing procedures and processes used to solve problems • Apprehending relationships between numbers ***Writing difficulties:*** • Essay writing and generalizing concepts • Developing a theme • Comparing and contrasting ideas	• Develop student's skill in categorizing objects and drawing conclusions • Use demonstrations to externalize the reasoning process • Gradually offer guided practice (e.g., guided questions list) to promote internalization of procedures or process(es) • Provide targeted feedback • Use cooperative learning • Use reciprocal teaching • Provide graphic organizers to arrange information in visual format • Use metacognitive strategies • Compare new concepts to previously learned (same vs. different) • Use analogies, similes, and metaphors when presenting tasks
Crystallized intelligence (Gc)	• Breadth and depth of knowledge of a culture • Developed through formal education and general learning experiences • Stores of information and declarative and procedural knowledge • Ability to communicate verbally and reason with previously learned procedures	***Difficulties with:*** • Vocabulary acquisition • Knowledge acquisition • Comprehending language • Fact-based/informational questions • Using prior knowledge to support learning	***Reading difficulties:*** • Decoding and comprehension ***Math difficulties:*** • Understanding math concepts and the "vocabulary of math" ***Writing difficulties:*** • Grammar (syntax) • Bland writing with limited descriptors • Verbose writing with repetitions • Inappropriate word usage ***Language difficulties:*** • Understanding class lessons • Expressive language—"poverty of thought"	• Provide an environment rich in language and experiences • Provide frequent practice with and exposure to words • Read aloud to children • Vary reading purpose (leisure, information) • Work on vocabulary building • Teach morphology • Use text talks
Auditory processing (Ga)	• Ability to analyze and synthesize auditory information	***Difficulties with:*** • Hearing information presented orally, initially processing oral information	***Reading difficulties:*** • Acquiring phonics skills • Decoding and comprehension • Using phonetic strategies	• Provide phonemic awareness activities • Emphasize sight word reading • Teach comprehension monitoring (e.g., "Does the word I heard/read make sense in

		• Paying attention, especially in the presence of background noise • Discerning the direction from which auditory information is coming • Foreign-language acquisition • Acquiring receptive vocabulary	***Math difficulties:*** • Word problems ***Writing difficulties:*** • Spelling • Note taking • Poor quality of writing	context?") • Enunciate sounds in words in an emphatic manner when teaching new words for reading or spelling • Use work preview/text preview to clarify unknown words • Provide guided notes during note-taking activities • Build in time for clarification questions related to "missed" or "misheard" items during lecture • Supplement oral instructions with written instructions • Shorten instructions • Use preferential seating • Localize sound source for student • Minimize background noise
Long-term retrieval (Glr)	• Ability to store information (e.g., concepts, words, facts) and fluently retrieve it later through association	***Difficulties with:*** • Learning new concepts • Retrieving or recalling information by using association • Performing consistently across different task formats (e.g., recognition vs. recall formats) • Speed with which information is retrieved and/or learned • Paired learning (visual–auditory) • Recalling specific information (words, facts)	***Reading difficulties:*** • Accessing background knowledge to support new learning while reading (associative memory deficit) • Slow to access phonological representations during decoding (RAN deficit) ***Math difficulties:*** • Recalling procedures to use for math problems • Memorizing and recalling math facts ***Writing difficulties:*** • Accessing words to use during essay writing • Specific writing tasks (compare and contrast; persuasive writing; conceptual) • Note taking ***Language difficulties:*** • Expressive—circumlocutions, speech fillers, "interrupted" thoughts, pauses • Receptive—making connections throughout oral presentations (e.g., class lectures)	• Provide repeated practice with and review of newly presented information • Teach memory strategies (verbal rehearsal to support encoding, use of mnemonic devices) • Use multiple modalities when teaching new concepts (e.g., pair written with oral information) • Limit the amount of new material to be learned; introduce new concepts gradually and with a lot of context • Be mindful of when new concepts are presented • Make associations between newly learned and prior explicit information • Use lists to facilitate recall (prompts) • Expand vocabulary to minimize impact of word retrieval deficits • Build in waiting time for student when fluency of retrieval is an issue • Use text previews to "prime" knowledge • Provide background knowledge first before asking a question to "prime" student for retrieval

(continued)

TABLE 27.5. *(continued)*

CHC broad ability	CHC broad-ability definition	General manifestations of the CHC broad-ability weakness	Specific manifestations of the CHC broad-ability weakness in academic areas	Recommendations/interventions
Processing speed (Gs)	• Speed of processing, particularly when required to pay focused attention • Usually measured by tasks that require rapid processing, but are relatively easy	***Difficulties with:*** • Efficient processing of information • Quickly perceiving relationships (similarities and differences between stimuli or information) • Working within time parameters • Completing simple, rote tasks quickly	***Reading difficulties:*** • Slow reading speed • Impaired comprehension • Need to reread for understanding • ***Math difficulties:*** • Automatic computations • Computational speed is slow despite accuracy • Slow speed can result in reduced accuracy due to memory decay ***Writing difficulties:*** • Limited output due to time factors • Labored process results in reduced motivation to produce ***Language difficulties:*** • Cannot retrieve information quickly—slow, disrupted speech, as cannot get out thoughts quickly enough • Is slow to process incoming information; puts demands on memory store, which can result in information overload and loss of meaning	• Provide repeated practice • Provide speed drills • Use computer activities that require quick, simple decisions • Provide extended time • Reduce the quantity of work required • Increase waiting times both after questions are asked and after responses are given
Visual processing (Gv)	• Ability to generate, perceive, analyze, synthesize, manipulate, transform, and think with visual patterns and stimuli	***Difficulties with:*** • Recognizing patterns • Reading maps, graphs, and charts • Attending to fine visual detail • Recalling visual information	***Reading difficulties:*** • Orthographic coding (using visual features of letters to decode) • Sight word acquisition • Using charts and graphs within a text in conjunction with reading • Comprehension of text involving spatial	• Capitalize on student's phonemic skills for decoding tasks • Teach orthographic strategies for decoding (e.g., word length, shape of word) • Provide oral explanation for visual concepts • Review spatial concepts and support comprehension through use of hands-on

		• Appreciation of spatial characteristics of objects (e.g., size, length) • Recognition of spatial orientation of objects	concepts (e.g., social studies text describing physical boundaries, movement of troops along a specified route) ***Math difficulties:*** • Number alignment during computations • Reading and interpreting graphs, tables, and charts ***Writing difficulties:*** • Spelling sight words • Spatial planning during writing tasks (e.g., no attention to margins, words that overhang a line) • Inconsistent size, spacing, position, and slant of letters	activities and manipulatives (e.g., using models to demonstrate the moon's orbital path) • Highlight margins during writing tasks • Provide direct handwriting practice • Use graph paper to assist with number alignment
Short-term memory (Gsm)	• Ability to hold information in immediate awareness and use or transform it within a few seconds	***Difficulties with:*** • Following oral and written instructions • Remembering information long enough to apply it Remembering the sequence of information • Rote memorization	***Reading difficulties:*** • Reading comprehension • Decoding multisyllabic words • Orally retelling or paraphrasing what one has read ***Math difficulties:*** • Rote memorization of facts • Remembering mathematical procedures • Multistep problems and regrouping • Extracting information to be used in word problems ***Writing difficulties:*** • Spelling multisyllabic words • Redundancy in writing (word and conceptual levels) • Note taking	• Provide opportunities for repeated practice and review • Provide supports (e.g., lecture notes, study guides, written directions) to supplement oral instruction • Break down instructional steps for student • Provide visual support (e.g., times table) to support acquisition of basic math facts • Outline math procedures for student, and provide procedural guides or flashcards for the student to use when approaching problems • Highlight important information within a word problem • Have student write all steps and show all work for math computations

academic skills, cognitive abilities, and neuropsychological processes can be made. For example, when a student presents with reading difficulties, CHC theory and its research base assist practitioners in identifying the most salient broad and narrow constructs that are related to reading achievement (e.g., short-term working memory, phonetic coding, lexical knowledge, naming facility). The neuropsychological research also supports these same reading ability–processing connections, placing additional focus on the process of attentional capacity as well as specific executive functions. Using this information, a practitioner can logically assume that if the student indeed has cognitive ability or neuropsychological processing deficits that are related to (or that are, in part, the presumptive causes of) reading difficulties, such deficits are likely to be found through an evaluation of the abilities and processes known to explain significant variance in reading achievement (Flanagan & Schneider, 2016). Note that although the practitioner has a suspicion that the individual's reading difficulties may be related to deficits in certain cognitive areas, the a priori hypothesis remains null, indicating that expected performance on any ability or processing test is *within normal limits* (WNL). This is discussed in more detail later.

ORGANIZING AN XBA UTILIZING SPECIFIC REFERRAL INFORMATION

Scenario 1: Cognitive–Achievement Relations

The first scenario relates to the need to evaluate the relationship between an individual's manifest performance (e.g., academic skills) and cognitive abilities and neuropsychological processes. This is often the situation in evaluations conducted in accordance with the Individuals with Disabilities Education Improvement Act of 2004 (IDEA; 2004), which seek to determine the presence of a disability that may be used to establish eligibility for special education programs and services. For example, if there are concerns with reading skills, practitioners should review current research that provides evidence linking cognitive abilities and neuropsychological processes to reading. Practitioners should then ensure that measures of these specific cognitive abilities and processes are included in the initial assessment.

Research on the relationships among cognitive abilities, neuropsychological processes, and specific academic skills has grown over the years (for summaries, see Flanagan, Ortiz, & Alfonso, 2013; Fletcher, Lyon, Fuchs, & Barnes, 2007; McDonough et al., 2017; McGrew & Wendling, 2010; Niileksela et al., 2016). Much of the recent research on cognitive–academic relationships has been interpreted within the context of CHC theory (e.g., Flanagan et al., 2011) and with specific instruments developed from CHC theory (e.g., McGrew & Wendling, 2010; Niileksela et al., 2016). In addition, statistical analyses, such as structural equation modeling, have been used to understand the extent to which specific cognitive abilities explain variance in academic skills above and beyond the variance accounted for by *g* (e.g., Floyd, McGrew, & Evans, 2008; Juarez, 2012; McGrew, Flanagan, Keith, & Vanderwood, 1997; Vanderwood, McGrew, Flanagan, & Keith, 2002). Finally, many valuable resources summarize the research on cognitive and neurobiological processes associated with specific academic skill deficits (e.g., Alfonso & Flanagan, 2018; Feifer & DeFina, 2005; Feifer & Della Toffalo, 2007; Flanagan et al., 2017; Fletcher et al., 2007; Fletcher-Janzen & Reynolds, 2008; Hale & Fiorello, 2004; Miller, 2010, 2013).

Scenario 2: Practical and Legal Considerations

Another scenario that illustrates the effect of referral concerns on test selection and organization in the context of XBA occurs when practical or legal considerations may constrain the evaluation in some way. With respect to practical considerations, it is unreasonable to expect that every practitioner has every published test or has expertise in administering, scoring, and interpreting all available tests. Therefore, decisions regarding test selection and organization will be directly influenced by this reality. For example, of the major cognitive batteries, the KABC-II may be considered the best one for testing a child who, after having exited an English as a second language (ESL) program in fifth grade, is nevertheless falling rapidly behind classmates in most academic areas. However, because the KABC-II does not measure certain abilities and processes important for understanding learning difficulties (e.g., working memory, processing speed, phonological processing), it will need to be supplemented with subtests from another battery (or batteries) with which the practitioner is familiar.

In similar fashion, with respect to legal considerations, there are times when federal or local regulations mandate that certain types of data be collected (e.g., IQ or global ability scores from cognitive batteries). Although this most often occurs in assessments that are conducted to gather data to inform decisions regarding special education eligibility, many states and districts no longer mandate global ability scores for SLD identification. However, in those locations where global ability is still mandated or encouraged, practitioners may find it necessary to obtain the required score even though they may not find it to be particularly informative. For example, instead of administering the WJ IV COG (which measures seven CHC broad cognitive abilities adequately), a practitioner may be required to administer the WISC-V, which measures six, precisely to obtain the Full Scale IQ (FSIQ). Then, if measurement of Ga is warranted, the WISC-V would need to be supplemented with tests from another battery, such as the Comprehensive Test of Phonological Processing—Second Edition (CTOPP-2). Although a WJ IV COG evaluation is more straightforward than the WISC-V/CTOPP-2 cross-battery, the evaluator in this case is constrained by the need to obtain the WISC-V FSIQ.

Scenario 3: Consideration of Examinee Characteristics

The third scenario in which decisions regarding test selection and organization may be highly subject to specific referral concerns involves testing individuals whose characteristics set them apart from the mainstream. For example, practitioners are often called on to assess the abilities of individuals who have sensory or perceptual impairments (e.g., deafness, blindness), who have fine motor impairments (e.g., individuals with cerebral palsy, tremors, seizure activity), or who come from culturally and linguistically diverse backgrounds. Obviously, if an individual is unable to manipulate objects because he or she cannot see or hold them, test selection and organization will be affected. Decisions about test selection and organization are not, of course, specific to conducting XBAs. An individual's unique characteristics must be considered before tests are selected for any evaluation. In the case of individuals who are culturally and linguistically diverse, the Culture–Language Test Classifications (C-LTC) can be utilized to make decisions that respond directly to issues of limited English proficiency or age- or grade-appropriate acculturative knowledge acquisition. This information and the ability to evaluate the validity of obtained results via the Culture–Language Interpretive Matrix (C-LIM) by using X-BASS allows practitioners the opportunity to construct and carry out XBAs that are tailored to specific referral concerns related to individual cultural and linguistic variables. (See Ortiz, Piazza, Ochoa, & Dynda, Chapter 25, this volume, for a discussion of the C-LTC and C-LIM.)

IMPLEMENTING THE XBA APPROACH STEP BY STEP

Practitioners should follow four general steps when conducting XBAs. Each step is described here.

Step 1: Select an Ability Battery

The first step of the XBA approach requires selecting a battery that is appropriate and responsive to various factors: age and developmental level of the examinee; acculturative experiences and background; developmental English-language proficiency of the examinee; the specific referral concerns; and so forth. As such, although a test like the WJ IV COG may be appropriate for a relatively bright and articulate seventh grader who is experiencing difficulties in reading comprehension, it may not be the best instrument of choice for a second grader who is an English-language learner (EL) and who is significantly behind classmates in all academic areas, even though the WJ IV COG provides the most comprehensive coverage of CHC abilities. The WJ IV COG may be less suitable for this scenario because it lacks manipulatives, relies exclusively on verbal instructions, and utilizes some tasks with high receptive language demands (e.g., Concept Formation). In the case of this second grader, a battery such as the KABC-II may be more appropriate because its language demands and cultural loadings are generally lower than those associated with the WJ IV COG.

Step 2: Identify Broad Abilities That Are and Are Not Measured by the Selected Battery; Identify Narrow Abilities and Processes That Need to be Measured

When examiners are interested in a comprehensive evaluation that samples functioning across a wide range of CHC broad abilities (approximately seven or more), nearly all batteries will need to be supplemented via XBA procedures. For example,

Table 27.6 shows that, on average, most major intelligence batteries have adequate representation of five broad CHC abilities. However, in most assessments of suspected SLD, it is desirable to measure abilities and processes across at least seven CHC domains. Therefore, most intelligence and cognitive batteries will need to be supplemented in a comprehensive evaluation for SLD.

Even when seven broad ability areas are measured in an initial assessment, it may be necessary to follow up on significant differences between scores within a broad-ability domain. For example, if an individual scores in the above-average range on a test of general sequential (deductive) reasoning and in the well-below-average range on a test of inductive reasoning, then the resulting Gf composite (reflecting average reasoning ability) is not particularly meaningful from a clinical perspective, even though it is a reliable and valid composite (Schneider & Roman, 2017). That is, the Gf composite in this example masks important information about the individual's reasoning strengths and weaknesses. In this case, it seems necessary to follow up on the inductive reasoning score, since it is suggestive of a weakness or deficit. Because an individual subtest score does not provide a solid basis upon which to render an interpretation of a weakness, another test of inductive reasoning

TABLE 27.6. Representation of Broad CHC Abilities on Selected Cognitive, Achievement, and Neuropsychological Batteries

Note. ✓, *adequately represented* (i.e., the battery contains at least two qualitatively different indicators [subtests] of the broad ability); U, *underrepresented* (i.e., the battery contains only one indicator of the broad ability, or two or more indicators of only one narrow ability subsumed by the broad ability); —, *not measured.* Gf, fluid reasoning; Gc, comprehension–knowledge; Gv, visual processing; Gsm, short-term memory; Glr, long-term storage and retrieval; Ga, auditory processing; Grw, reading and writing; Gq, quantitative knowledge; Gkn, domain-specific knowledge; Gp, psychomotor abilities; Gh, tactile abilities. There are four broad CHC abilities not included in this rapid reference (i.e., olfactory abilities [Go], psychomotor speed [Gps], reaction and decision speed [Gt], and kinesthetic abilities [Gk]). WISC-V, Wechsler Intelligence Scale for Children—Fifth Edition (Wechlser, 2014); WAIS-IV, Wechsler Adult Intelligence Scale—Fourth Edition (Wechsler, 2008); WPPSI-IV, Wechsler Preschool and Primary Scale of Intelligence—Fourth Edition (Wechsler, 2012); WJ IV COG and ACH, Woodcock–Johnson IV Tests of Cognitive Abilities and Tests of Achievement (Schrank, McGrew, & Mather, 2014); SB5, Stanford–Binet Intelligence Scales, Fifth Edition (Roid, 2003); DAS-II, Differential Ability Scales—Second Edition (Elliott, 2007); KABC-II, Kaufman Assessment Battery for Children—Second Edition (Kaufman & Kaufman, 2004); KTEA-3, Kaufman Test of Educational Achievement, Third Edition (Kaufman & Kaufman, 2014); WIAT-III, Wechsler Individual Achievement Test—Third Edition (Pearson, 2009); NEPSY-II (Korkman, Kirk, & Kemp, 2007); D-KEFS, Delis–Kaplan Executive Function System (Delis, Kaplan, & Kramer, 2001); DWNB, Dean–Woodcock Neuropsychological Battery (Dean & Woodcock, 2003).

should be administered. Most batteries do not have two measures of the same narrow abilities (see Table 27.3); therefore, it is often necessary to cross batteries to follow up on below-average score performances.

Finally, even when a battery contains adequate representation of seven main CHC domains and some narrow-ability domains, close inspection of the relations between the cognitive constructs measured by the battery and the referral concern may reveal that the battery does not include specific processes considered important to measure (e.g., orthographic processing in a reading referral or subitizing in a math referral). As such, crossing batteries to obtain information about specific narrow abilities and processes germane to referral concerns is often necessary. Following the XBA approach, X-BASS can be used to examine cross-battery data and create cross-battery composites that are psychometrically defensible, as is demonstrated later in this chapter).

Step 3: Administer and Score Selected Battery and Supplemental Tests

There are no unique administration or scoring instructions associated with XBAs to be followed, apart from those already specified by the test publishers. Practitioners should incorporate general testing and scoring considerations applicable to the use of standardized tests, as well as the specific guidelines provided by test publishers in the manuals of any tests that are used.

Step 4: Enter Scores into X-BASS

After all tests selected for an XBA have been administered, all subtest scaled and standard scores and composite standard scores should be calculated with the appropriate procedures (i.e., manual or hand scoring, computerized scoring). Having a summary of all scores will be very helpful, whether from the original protocol or from a computerized print out, and will facilitate data entry into X-BASS. Once all scores have been calculated, the examiner should open X-BASS, click on the "Start" tab from the "Welcome" screen, and enter demographic information. The individual's age will be calculated automatically; however, his or her grade must be entered manually. Note that it is important to enter the individual's grade for all analyses in X-BASS to run. After demographic data have been entered, click on the "Create New Record" tab and X-BASS will advance automatically to the "Test Index and Main Navigation" tab (or "Index" tab for short). From the index, the examiner clicks on the button corresponding to the battery for which there are scores to be entered. The program will then automatically go to the appropriate test tab, where the examiner may begin to enter data (e.g., WISC-V tab, WJ IV tab, KABC-II tab, WIAT-III tab).

After all initial data have been entered into X-BASS, scores are automatically analyzed to determine whether composites are cohesive or not cohesive and whether there is a need to follow up on any aberrant test performances, regardless of composite cohesion. This is an important point to be noted: Recommendations for follow up are independent of composite cohesion. Follow-up may well be warranted even in cases where the composite is cohesive, and in other cases, no follow up may be necessary even when the composite is not cohesive. Although there is some relation between the two, follow-up recommendations are made independently of cohesion (see Flanagan, Alfonso, Sy, Mascolo, & McDonough, 2018, for a discussion).

INTERPRETING TEST DATA

Test data must be interpreted in a manner that is both theoretically and psychometrically defensible. The XBA approach includes a set of interpretive guidelines that allows practitioners to interpret data from one or more batteries from CHC theory and research (and, in some instances, neuropsychological theory and research) via psychometrically defensible methods. Because the XBA approach represents an advance over traditional assessment practices in terms of both *measurement* and *meaning,* it has informed the interpretive approaches of widely used intelligence batteries (e.g., the WISC-V, WAIS-IV, and KABC-II; see Alfonso et al., 2005; Flanagan & Alfonso, 2017; Flanagan & Kaufman, 2009; Flanagan, Ortiz, & Alfonso, 2013; Lichtenberger & Kaufman, 2009).

Interpretation of XBA data adheres strictly to sound psychometric and statistical precepts that establish the basis for comparative evaluations of test performance, such as interindividual (or population-relative) analysis of cognitive strengths and weaknesses. Interpretation must not, however, be thought of as a separate or distinct endeavor from measurement. Rather, measurement and interpretation are related, and each influences the other in many ways. To interpret data properly, the manner in which measurement and interpretation are related must be specified. To this end, interpretation of test data is embedded in a broader conceptual framework for assessment that relies on the generation and testing of functional assumptions or hypotheses about expected performance. In general, both a priori and a posteriori assumptions are incorporated into the interpretive approach to control for confirmatory bias (explained in the next section). This part of the chapter begins with a discussion of a hypothesis-driven framework and its relationship to the iterative nature of measurement and interpretation. Next, specific guidelines are described that allow practitioners to make defensible interpretations of all data entered into X-BASS.

Hypothesis-Driven Assessment and Interpretation

Inherent in the XBA approach are the emphasis on conducting assessments within a broad, comprehensive framework and the recognition that measurement methods, however precise, might form only a part of the entire scope of assessment-related activities. When standardized testing is to be carried out, practitioners should adhere to guidelines based on a philosophy of hypothesis generation and hypothesis testing. Although psychometric data may seem to be rather objective, interpretation of such data is hardly an unambiguous exercise. Therefore, to reduce the chances of drawing incorrect inferences from test data on the basis of preconceived ideas, hypothesis-generating and hypothesis-testing approaches are necessary and critical components of XBA.

Confirmatory bias occurs when an examiner begins testing with preconceived notions regarding expected performance on a test. After the test is administered and the data are collected, the examiner reviews the data, looking specifically for patterns and results that support the preconception. In other words, the examiner becomes predisposed to seeing only those patterns in the data that support the prevailing assumption, and tends to minimize or reject data that are counter to the assumption (Sandoval, Frisby, Geisinger, Scheuneman, & Grenier, 1998). To reduce the tendency to see patterns of disability and dysfunction in data where in fact no such patterns exist, diagnostic interpretation should not begin with the presumption of preexisting deficits. Rather, interpretation of test data should be guided by the assumption that the examinee is not impaired and that his or her performance on tests (e.g., subtests, composites) will be within normal limits (WNL). The assumption of WNL performance represents the *null hypothesis,* which is evaluated to determine whether it should be retained or rejected in favor of an alternative hypothesis (i.e., performance is not WNL).

Adoption of the stance that performance will be WNL, until and unless convincingly contraindicated by the data, reduces the chance that examiners will view standardized test data only in a manner that corroborates the beliefs they had prior to testing. It is important to note that even when factors other than cognitive weakness or deficiency have been ruled out as the primary cause of observed difficulties (e.g., poor academic performance), it cannot be concluded automatically that an internally based disability is present (e.g., SLD). In every case, the null hypothesis must be expected and retained until the data suggest that such a position is no longer tenable or defensible. Notwithstanding, practitioners can and will entertain thoughts of dysfunction. After all, if standardized testing of a student is being contemplated, it is likely that the examiner has already been made aware of the possibility that a disability exists. However, a clear distinction must be drawn between the specific hypotheses that are to be evaluated and the opinions, conjecture, or suppositions of the examiner. Only the hypotheses specified a priori or a posteriori are actually tested and evaluated directly in light of the data; opinion and conjecture are not. Consequently, unless and until the data strongly suggest otherwise, the null hypothesis that performance is WNL must not be rejected, no matter how strong the examiner's belief, expectation, or desire to the contrary.

When the null hypothesis is rejected in favor of the alternative hypothesis, an examiner can be confident that (1) the data do not support the notion that performance is WNL and (2) performance is likely outside the range of normal limits. Accepting the alternative hypothesis, however, does not provide de facto support for the presence of a disability. The specific reasons for this level of performance should be investigated further and corroborated by additional data sources (e.g., review of school records, work samples, observations, diagnostic interviews). Likewise, failure to reject the null hypothesis does not provide de facto evidence that no disability is present. The range of normal limits encompasses 30 standard score points (SS = 85–115), which spans the below-average, average, and above-average ranges of ability. Performances in the below-average range (e.g., standard scores of 86, 87, 88) may very well be included as part of a constellation of findings that support the presence of a disability. As such, sole reliance on standard scores and cutoff points should be avoided in any diagnostic approach to determining disability, particularly SLD.

Integrating Hypothesis Testing and Data Interpretation

The next discussion is meant to assist practitioners in understanding the various stages of the XBA approach as they apply to interpretation. The assessment and interpretive process requires careful evaluation of case history information (e.g., educational records, progress-monitoring data, authentic measures of achievement, medical records); the inclusion of data from relevant sources (e.g., parents, teachers); and the framing of an individual's difficulties within the context of CHC or neuropsychological theory and research. No matter how compelling the results from the administration of a single ability battery or combination of batteries may appear, test data alone should not be used to make definitive diagnostic decisions.

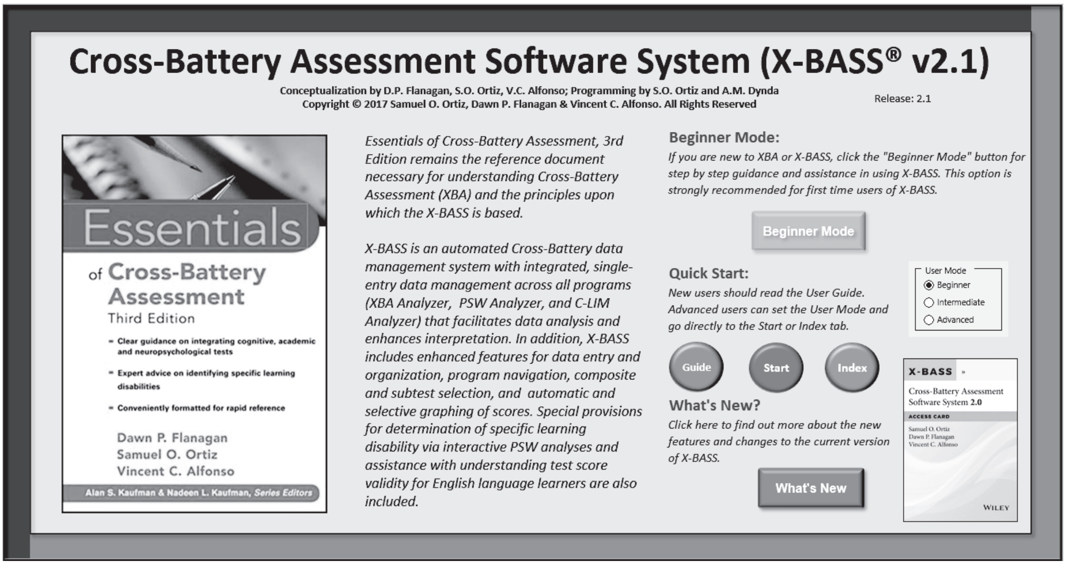
This stage is at the heart of the interpretive process. It is at this point that the examiner can accomplish several different levels of analysis. Such analysis includes evaluation of data yielded from a single battery (e.g., the WISC-V or WJ IV) and from more than one battery (i.e., XBA). Interpretations that are made within the context of the XBA approach are based on *inter* individual comparisons (i.e., population-relative comparison against same-age peers). Thus an individual's performance on both broad and narrow CHC abilities and neuropsychological processes is based on *between*-individual (or normative) comparisons rather than *within*-individual (or person-relative) comparisons, although the latter are certainly important to consider for intervention planning and are incorporated in X-BASS for the WISC-V, in particular.

In general, the current iteration of the XBA approach is based on a model of interpretation that reflects the integration of CHC and neuropsychological theory and research. With the emergence of the field of school neuropsychology (e.g., Fletcher-Janzen & Reynolds, 2008; Hale & Fiorello, 2004; Miller, 2007, 2010, 2013) came a logical extension for linking and integrating CHC theory and neuropsychological theories. Understanding how CHC theory and neuropsychological theories relate to one another expands the options available for interpreting cognitive test performance and improves the quality and clarity of test interpretation, as a much wider research base is available to inform practice (Flanagan, Alfonso, Ortiz, & Dynda, 2010, 2013; Flanagan, Fiorello, & Ortiz, 2010).

Although scientific understanding of the way the brain functions and how mental activity is expressed on psychometric tasks has increased dramatically in recent years, there is still much to be learned. All efforts to create a framework that guides test interpretation benefit from diverse points of view. For example, according to Fiorello, Hale, Snyder, Forrest, and Teodori (2008), "The compatibility of the neuropsychological and psychometric approaches [CHC] to cognitive functioning suggests converging lines of evidence from separate lines of inquiry, a validity dimension essential to the study of individual differences in how children think and learn" (p. 232). Their analysis of the links between the neuropsychological and psychometric approaches not only provides validity for both, but also suggests that each approach may benefit from knowledge of the other. For that reason, a framework that incorporates the neuropsychological and psychometric approaches to cognitive functioning holds the promise of increasing knowledge about the etiology and nature of a variety of disorders (e.g., SLD) and the manner in which such disorders are treated. This type of framework should not only connect the elements and components of both assessment approaches; it should also allow for interpretation of data within the context of either model. In other words, the framework should serve to translate the concepts, nomenclature, and principles of one approach into their counterparts in the other. For a detailed discussion on integrating neuropsychological and CHC theories, see Flanagan, Alfonso, and colleagues (2010).

X-BASS TUTORIAL

Upon opening X-BASS, a clinician can choose his or her User Mode (Beginner, Intermediate, Advanced). This program feature differentiates the amount of pop-up feedback and instruction provided to the clinician by the software. It is recommended that clinicians who are new to XBA or X-BASS choose Beginner Mode for step-by-step guidance (see Figure 27.2). Additionally, it is recommended that new users read the user "Guide" before beginning to analyze test data with X-BASS.



Cross-Battery Assessment Software System (X-BASS® v2.1)

Conceptualization by D.P. Flanagan, S.O. Ortiz, V.C. Alfonso; Programming by S.O. Ortiz and A.M. Dynda

Release: 2.1

Essentials of Cross-Battery Assessment, 3rd Edition remains the reference document necessary for understanding Cross-Battery Assessment (XBA) and the principles upon which the X-BASS is based.

X-BASS is an automated Cross-Battery data management system with integrated, single-entry data management across all programs (XBA Analyzer, PSW Analyzer, and C-LIM Analyzer) that facilitates data analysis and enhances interpretation. In addition, X-BASS includes enhanced features for data entry and organization, program navigation, composite and subtest selection, and automatic and selective graphing of scores. Special provisions for determination of specific learning disability via interactive PSW analyses and assistance with understanding test score validity for English language learners are also included.

Beginner Mode:

If you are new to XBA or X-BASS, click the "Beginner Mode" button for step by step guidance and assistance in using X-BASS. This option is strongly recommended for first time users of X-BASS.

Quick Start:

New users should read the User Guide. Advanced users can set the User Mode and go directly to the Start or Index tab.

User Mode
● Beginner
○ Intermediate
○ Advanced

What's New?

Click here to find out more about the new features and changes to the current version of X-BASS.

FIGURE 27.2. X-BASS Welcome tab.

The "Guide" button is located on the "Welcome" screen as well as subsequent tabs in X-BASS and may be printed by clicking on the "Print" button located in the "Guide" tab. When the user is ready to begin, he or she clicks on the blue Start button, through which the user will be transferred to the Start and Data Record Management tab. Here the student's name, birth date, grade, and date of testing are entered. Additionally, the clinician can indicate if the student is an ELL. When "ELL" is selected, X-BASS is programmed to perform alternative analyses that are specific to ELLs. When the clinician has finished entering the student's identifying information, he or she should click on Create New Record (see Figure 27.3).

The clinician will then be transferred automatically to the Test Index and Main Navigation tab. Here the clinician can choose from any of the major cognitive ability and academic achievement batteries for entering data (see Figure 27.4). From here, the clinician also can access the XBA-CHC Classifications tab, which contains all subtests from all batteries in X-BASS that have been classified according to their CHC broad- and narrow-ability domains, the IDEA-based academic categories related to SLD, and neuropsychological or "other" cognitive domains (see Figure 27.5). Additionally, the index and navigation tab provides access to analysis tabs, graphing tabs, score management tabs, indexes, and references, some of which are discussed below. However, this chapter is only intended to provide a brief overview of the use of X-BASS.

When a clinician is ready to enter test data, he or she clicks on the associated button on the index and navigation tab. This brings the clinician to the Data Analysis tab for the corresponding battery, where the student's scores can be entered. The clinician clicked on the WISC-V tab from the index and navigation tab and entered scores for the Verbal Comprehension Index (see Figure 27.6). If the student's scores are cohesive (as determined by X-BASS) or the composite is judged by the clinician to be a good representation of the examinee's ability in the cognitive domain (regardless of cohesion), the clinician can transfer the composite to the Data Organizer tab. This tab may be thought of as a holding tank for the best estimates of all abilities and processes that will be used in a pattern of strengths and weaknesses analysis (PSW-A). If the examinee's scores are not cohesive, then they may be transferred to the XBA and Test Composite Analyzer tab (XBA Analyzer for short), where they can be combined with a score or scores from another battery for further analysis of performance in that ability or processing domain. The way cohesion is determined in X-BASS is described in the "Guide." When follow-up testing is considered necessary for the lower score in a composite (most notably when the lower score is below average and the higher score is average or better), these scores are typically transferred to

1. ENTER NAME (if new case)

2. ENTER DATES/GRADE

3. CREATE NEW DATA RECORD

***Name of Examinee:**	Tommy	***Date of Evaluation:**	4/28/2017	Use mm/dd/yyyy If an error occurs, try yyyy/mm/dd.
Name of Evaluator:	Dr. McHouligan	***Date of Birth:**	11/4/2003	
Examinee's Age:	13 years 5 month(s)	***Examinee's Grade:**	8	PK,K,1-12,12+

Check box if examinee is current or former ELL ☐

DATA RECORD IS ACTIVE

To OPEN and activate a saved record from the database, select it from the dropdown menu on the right. Data records are listed in alphabetical order by first name. Once selected, all data associated with the record will be populated in the appropriate locations. Click the Index button at the upper right corner of this tab to begin reviewing and updating the saved data. The program can store and retrieve data for up to 500 cases.

OPEN SAVED DATA RECORD

Tommy

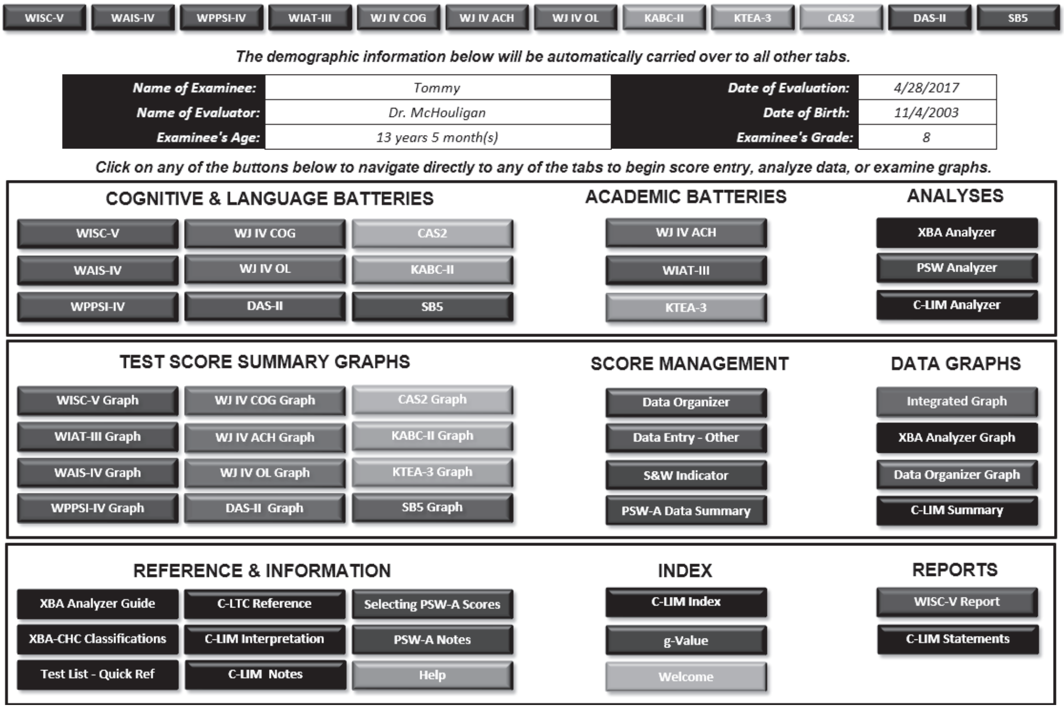
To SAVE or update the current data record, click the blue "Save Current Record" button and continue working. Frequent saves are recommended.

To EXPORT and save the current database (for importation to a newer version of X-BASS), click the "Export Current Database" button. This action creates a file that can be used by updated versions of X-BASS to automatically transfer and merge the current database for use with the new version.

To IMPORT a saved database (for use in a newer version of X-BASS), click the "Import Saved Database" button. Note that you must have already exported the previous database using the older version of X-BASS. Once the older database has been properly saved, use this button to import it.

To CLEAR all scores, selections, and tab data in current use from the program, click the "Clear Data/Reset Program" button. CAUTION: This action is not reversible, removes data in current use, and resets the program to default values. Unsaved data and information will be permanently erased.

FIGURE 27.3. X-BASS Start and Data Record Management tab.



The demographic information below will be automatically carried over to all other tabs.

Test Reference List - CHC, SLD & Neuropsych Classifications

Conceptualization by D.P. Flanagan, S.O. Ortiz, V.C. Alfonso; Programming by S.O. Ortiz and A.M. Dynda
Copyright © 2017 Samuel O. Ortiz, Dawn P. Flanagan & Vincent C. Alfonso. All Rights Reserved

All subtests are classified in one of the broad CHC domains according to narrow ability (blue buttons). In addition to their CHC classifications, subtests that correspond to areas of achievement, as defined in the IDEA categories for Specific Learning Disability, are also listed for reference by academic domain (purple buttons). Likewise, subtests that correspond to areas of neuropsychological or other cognitive functions not included under CHC theory, are also listed for reference by specific domain (tan buttons). Click on any button to scroll directly to the listings for that domain.

the XBA Analyzer where an alternative composite or composites may be calculated that included follow-up testing data. An example of how to conduct follow-up testing is included in the context of the case example below.

When data are transferred to the XBA Analyzer tab, and follow-up testing data are entered into this tab, X-BASS creates XBA composites, which can then be transferred to the Data Organizer and Score Summary tab (or Data Organizer tab for short). For the purpose of PSW analysis, the clinician should have a minimum of seven estimates of cognitive abilities and processes (i.e., referral-related broad and/or narrow abilities

CLINICAL JUDGMENT NEEDED

The VCI provides an estimate of Crystallized Intelligence (Gc). Gc refers to an individual's knowledge base (or general fund of information) that develops as a result of exposure to language, culture, general life experiences, and formal schooling. Word knowledge as measured by the Vocabulary subtest was Average, and the ability to reason with words as measured by the Similarities subtest was Low Average relative to same age peers. The difference between the scores that comprise the VCI is significant, however a difference of this size is considered common in the general population. This means that clinical judgment is necessary to determine whether the VCI is a good summary of Crystallized Intelligence. The individual's VCI of 92 (88-96) is classified as Average and is ranked at the 30th percentile, indicating performance as good as or better than 30% of same age peers from the general population. The difference between the VCI and the average of all five primary index scores is not significant and common in the general population. Overall, despite significant variation within the VCI, one or more of the individual's Crystallized abilities may facilitate learning, particularly the abilities that are at least average.

Gc:VL = 92

Because the difference between the scores that comprise the VCI is at least 1SD, and the lower score is indicative of a weakness or deficit, follow up on the lower score is considered necessary to determine if it is an accurate and valid representation of ability and:

- Consider whether IN or CO would provide useful additional information
- If IN and CO are administered, consider the new clinical composite, Verbal (Expanded Crystallized) Index (VECI)
- Consider whether the Gc clinical composites (e.g., Gc-Verbal Expression Low; Gc – Verbal Expression High) would provide useful additional information
- Consider whether there is a difference between Retrieval from Remote Long-term Storage (Vocabulary + Information) and Retrieval from Recent Long-term Storage (Delayed Symbol Translation + Recognition Symbol Translation)
- Consider task characteristics and response demands

FIGURE 27.6. WISC-V tab with Verbal Comprehension (Gc) Subtest Scaled Scores Entered.

within and across Gf, Gc, Gsm, Glr, Gv, Ga, and Gs) and at least one estimate of achievement (e.g., basic reading skills, reading fluency, math calculation, math problem solving), although the program allows for multiple estimates of achievement across eight areas corresponding to those listed in IDEA. Each estimate of cognitive ability, cognitive processing, and academic achievement should have been transferred to the Data Organizer tab. To conduct a PSW analysis, the clinician clicks the "Select All Checkboxes" button on the Data Organizer tab, which selects all scores that have been transferred to this tab for use in the analysis (see Figure 27.7).

Next, the clinician clicks on the S&W Indicator button, located at in the top right corner of the Data Organizer tab, where he or she is able to select whether a composite is a strength or weakness for the examinee. Typically, scores that are about 90 or higher are considered strengths and scores that fall below 90 are considered weaknesses. However, this is only one guideline that should be considered when designating scores as strengths or weaknesses. For some examinees scores in the upper 80s may be their highest scores and therefore are considered relative strengths for the examinee and should be designated as such. Another guideline for selecting cognitive strengths and weaknesses involves a consideration of whether the score represents an area that is likely facilitating or inhibiting learning and academic performance for the examinee. Thus, clinical judgment is sometimes necessary when determining a strength or weakness, especially when scores fall at or near common cutoff scores, such as 85 or 90. Figure 27.8 shows the S&W tab with all scores marked as either a strength or a weakness, which appear in green and red, respectively, in the actual software, although this and other figures are in black and white. The S&W Indicator tab was purposefully designed to allow for clinical judgment to avoid imposing cutoffs.

When strengths and weaknesses have been determined, the clinician may click on the PSW-A Data Summary button located at the top right of the S&W Indicator tab. The PSW-A Data Summary tab summarizes the data from the S&W Indicator tab (displaying strengths in green and weaknesses in red) and presents the g-value, Facilitating Cognitive Composite (FCC), Alternative Cognitive Composite (ACC), and Inhibiting Cognitive Composite (ICC), terms that are unique to the PSW model operationalized by X-BASS (see Figure 27.9).

Guidelines for Selecting Best Composite Scores for SLD Evaluation

The purpose of this tab is to organize composites and subtests to assist in the selection of those to be used for evaluation of the pattern of strengths and weaknesses in the PSW Analyzer. Test names and scores can not be entered into this tab directly. Rather, this tab provides a summary of test battery and XBA composites that were transferred from other tabs because they were considered the best estimates of CHC abilities, academic areas, and selected neuropsychological domains. Use this tab to select the composites and subtest scores you would like to use in PSW analyses by clicking on the check box to the right of each one in any domain for which there are data. You may select up to two composites for each of the CHC broad ability (e.g., Gc, Gf, Gsm) and neuropsychological (e.g., Executive Functions, Orthographic Processing) domains and up to three scores for each of the academic areas. Note that you may also click on the "Data Organizer Graph" to view or print the information on this tab. For more information on how to select the best scores for use in PSW analyses, click the button to the right.

After you have made your selections, click the "S&W Indicator" button to continue with additional steps for conducting PSW analyses.

CRYSTALLIZED INTELLIGENCE (*Gc*)

Indicate which composite(s) you wish to use for PSW analyses. No more than two scores can be selected for this domain.

Determination of Strengths and Weaknesses

Indicate whether the CHC domains (highlighted in blue) and neuropsychological domains (highlighted in beige) represent strengths or weaknesses for the individual. Determination of strengths and weaknesses is a judgment that is made by the evaluator based on what is known about the examinee. In general, ability and processing strengths facilitate learning and academic performance, whereas weaknesses inhibit learning and academic performance. Typically, scores that fall in the average range or higher likely facilitate learning and scores that fall below average or lower likely inhibit learning. Also, indicate whether the academic areas (highlighted in purple) represent strengths or weaknesses for the individual. Achievement standard scores that are about 90 or higher are considered strengths and scores that fall below 90 are considered weaknesses.

After you have made your selections, click the "PSW-A Data Summary" button to continue with the PSW analysis.

CHC Composites designated as strengths are used for computation of the g-Value and FCC (top oval in the DD/C model) and those designated as weaknesses are used for computation of the ICC (bottom left oval in the DD/C model). When a domain contains a strength and a weakness, the strength is used in calculation of the g-Value/FCC and the weakness is used in the calculation of the ICC.

1. g-Value: 0.78
The *g*-Value reflects overall cognitive ability based on the CHC abilities judged by the evaluator to be strengths. The *g*-Value is interpreted according to the *likelihood* that an individual possesses at least average overall cognitive ability.

2a. Facilitating Cognitive Composite (FCC) 104
Represents an individual's overall general ability (based on strengths) and is used to evaluate differences relative to a specific of pattern of cognitive and academic weaknesses.

2b. Alternative Cognitive Composite (ACC)
You may enter an alternative value if desired or when the FCC is not believed to be the best estimate of general ability .

3. Inhibiting Cognitive Composite (ICC) 75
Represents an aggregate of an individual's overall weaknesses and is used to evaluate consistency and the relationship between cognitive and academic weaknesses. If there is only one cognitive weakness, the ICC is not calculated.

Click to re-display pop up message regarding results of the current PSW analysis or when data are changed.

User Mode
○ Beginner
○ Intermediate
● Advanced

○ Score difference will be considered rare/infrequent when it occurs 5% of the time (very strict value, best for multiple comparisons or tests with low reliability)
● Score difference will be considered rare/infrequent when it occurs 10% of the time (default value, best for standard analyses with composites and reliable tests)
○ Score difference will be considered rare/infrequent when it occurs 15% of the time (very liberal value, increases false positive rate--not recommended)

4. Rarity/Frequency of Difference - FCC/ACC to Cognitive Weakness
Select base rate level for determining if the size of a difference occurs rarely or infrequently. The default value is 10%. A more conservative or liberal value may be selected. If multiple comparisons are made, a stricter value may be appropriate.

Areas of strength below are likely consistent with the individual's overall general ability.	ACHIEVEMENT/SLD DOMAINS	SCORE	Areas of weakness below may be used as academic deficits in the DD/C model.

Composites or subtest scores designated as weaknesses may be used to represent academic deficits in PSW-A analyses (bottom right oval in the DD/C model). Only one academic weakness at a time is evaluated relative to a cognitive weakness and general ability, but any area may be selected in turn to examine other patterns of strengths and weaknesses on the PSW Analyzer tab.

FIGURE 27.9. Pattern of Strengths and Weaknesses Analysis (PSW-A) Data Summary tab.

The *g*-value was developed to estimate the likelihood that the examinee has at least average ability to think and reason (or at least average overall ability) despite specific cognitive weaknesses. The higher the *g*-value, the greater the likelihood of at least average ability to think and reason.

The FCC is an aggregate of the abilities judged by the evaluator to be strengths for the individual, and when the FCC is calculated it means that the examinee has a sufficient breadth of cognitive strengths such that this composite is likely a very good proxy of *g* or general cognitive ability for the examinee. What is unique about the FCC as compared to estimates of overall ability on cognitive and intelligence batteries is that it does not include the examinee's areas of cognitive processing weakness; it is not attenuated by the cognitive processing weaknesses that are presumably interfering with the acquisition and development of the academic skill or skills in question.

The ACC, which is not used often, refers to any cognitive composite derived from an intelligence or cognitive ability battery that is a good estimate of general cognitive ability and considered a better estimate than the FCC. For example, if the *g*-value or FCC is reported by X-BASS in yellow, indicating that the examinee's scores did not demonstrate at least average ability to think and reason despite specific cognitive areas of weakness, then an ACC may be used in place of the FCC if it is judged by the clinician to provide a better estimate of overall cognitive ability as compared to the FCC.

The ICC is an aggregate of the abilities judged by the evaluator to be weaknesses for the individual. In nearly all cases, the PSW-A Data Summary tab does not require data entry. It is simply a summary of strengths and weaknesses for the examinee and reports his or her *g*-value, FCC, and ICC. After reviewing the information on this tab, the clinician clicks on the "*g*-Value tab" button at the top right to advance to this tab. Like the PSW-A Data Summary tab, the *g*-Value tab does not require data entry.

The *g*-Value tab provides information about the likelihood that the individual's pattern of strengths indicates at least average ability to think and reason; it also graphically displays the *g*-value and the scores that contributed to the FCC and ICC (see Figure 27.10). Note that higher *g*-values indicate increased likelihood of at least average ability to think and reason, with *g*-values above .60 indicating "very likely" and that any identified deficits are probably specific in nature. For more detailed information on the development and meaning of the *g*-value, FCC, and ICC, the clinician may go to the Test Index and Main Navigation tab (see Figure 27.4), locate the "Reference & Information" section, and click on the "PSW-A Notes" button.

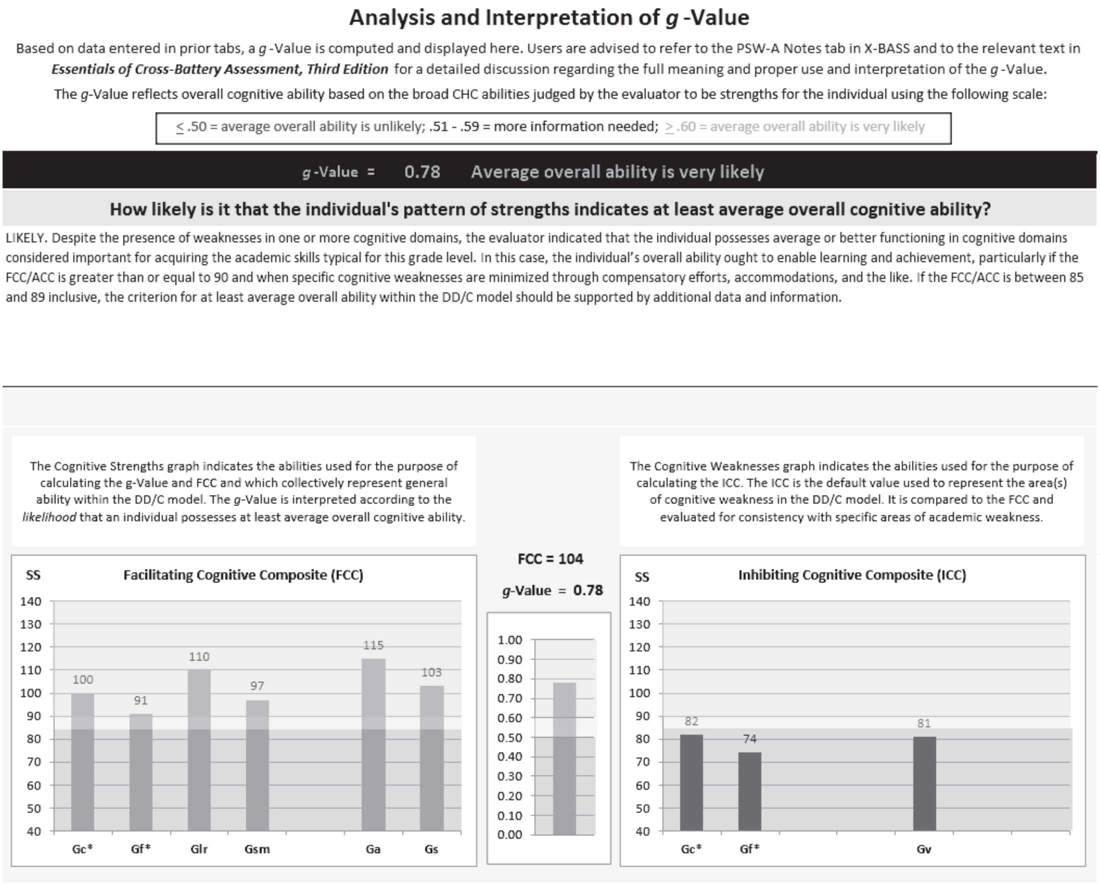
Last, the clinician clicks on the PSW Analyzer button at the top right of the *g*-Value tab, which takes the examiner to a tab labeled "Dual-Discrepancy/Consistency Model: PSW Analyses for SLD" (or PSW Analyzer for short). As shown in Figure 27.11, the tab automatically conducts the PSW analysis according to the DD/C method, which includes (1) a domain-specific cognitive ability weakness with at least average ability to think and reason, (2) unexpected underachievement, and (3) an empirical relationship between the domain-specific cognitive weakness and the academic weakness. The PSW Analyzer tab indicates whether each of these criteria are met through the use of statistical tests, regression analyses, base rate data, and corrections for false negatives. Additionally, the PSW Analyzer tab indicates whether both the cognitive and academic areas are considered weaknesses, and what the strength of the relationship is between the cognitive and academic areas (i.e., low, moderate, high), based on the research. (Again, see Flanagan et al., Chapter 22, this volume, for a more complete explanation of the DD/C method.) The case example below illustrates the use of X-BASS to assist in XBA and in informing SLD identification.

CASE EXAMPLE USING X-BASS FOR XBA AND PSW ANALYSIS

In the following section we summarize a case of a student who is having difficulties in math problem solving and reading comprehension. Use of the XBA and PSW components of X-BASS are highlighted.

Referral Concern

Tommy is a 13-year-old male student in an eighth-grade general education classroom. He was referred by his math teacher due to significant difficulties with math problem solving, such as formulating and reasoning about expressions and equations. In addition, his Language Arts teacher expressed concerns related to Tommy's reading comprehension, such as drawing inferences from text, distinguishing among the connotations of words that are similar in meaning, and understanding word relationships.



Analysis and Interpretation of *g* -Value

Based on data entered in prior tabs, a *g* -Value is computed and displayed here. Users are advised to refer to the PSW-A Notes tab in X-BASS and to the relevant text in ***Essentials of Cross-Battery Assessment, Third Edition*** for a detailed discussion regarding the full meaning and proper use and interpretation of the *g* -Value.

The *g*-Value reflects overall cognitive ability based on the broad CHC abilities judged by the evaluator to be strengths for the individual using the following scale:

≤ .50 = average overall ability is unlikely; .51 - .59 = more information needed; ≥ .60 = average overall ability is very likely

***g* -Value = 0.78 Average overall ability is very likely**

How likely is it that the individual's pattern of strengths indicates at least average overall cognitive ability?

LIKELY. Despite the presence of weaknesses in one or more cognitive domains, the evaluator indicated that the individual possesses average or better functioning in cognitive domains considered important for acquiring the academic skills typical for this grade level. In this case, the individual's overall ability ought to enable learning and achievement, particularly if the FCC/ACC is greater than or equal to 90 and when specific cognitive weaknesses are minimized through compensatory efforts, accommodations, and the like. If the FCC/ACC is between 85 and 89 inclusive, the criterion for at least average overall ability within the DD/C model should be supported by additional data and information.

The Cognitive Strengths graph indicates the abilities used for the purpose of calculating the g-Value and FCC and which collectively represent general ability within the DD/C model. The *g*-Value is interpreted according to the *likelihood* that an individual possesses at least average overall cognitive ability.

The Cognitive Weaknesses graph indicates the abilities used for the purpose of calculating the ICC. The ICC is the default value used to represent the area(s) of cognitive weakness in the DD/C model. It is compared to the FCC and evaluated for consistency with specific areas of academic weakness.

FCC = 104

***g*-Value = 0.78**

FIGURE 27.10. *g*-Value tab.

Choosing a Core Test Battery

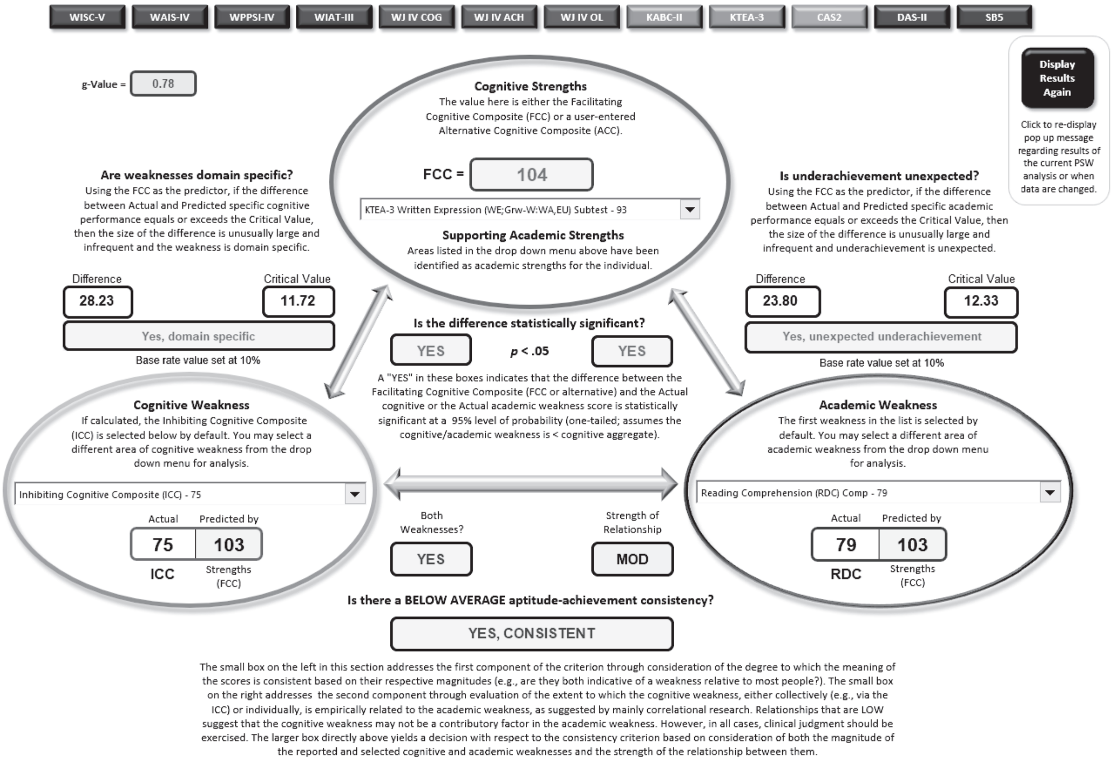
When an examiner is deciding on a core cognitive battery, the following considerations are necessary: referral concern, hypotheses based on the referral concern, age, developmental level, and cultural/linguistic background (e.g., English proficiency, level of acculturation, number of years in the United States). Regarding Tommy's case, there is evidence that fluid reasoning, crystalized intelligence, and short-term working memory are related empirically to both math problem solving and reading comprehension, as well as evidence that visual processing is related to higher-level math. There were no concerns about developmental delays; also, Tommy and his parents were born in the United States and speak only English at home, so cultural/linguistic differences are not involved. The WISC-V was chosen as the core battery for Tommy because it measures the main cognitive abilities and processes that are related empirically to his reported academic difficulties. When choosing an achievement battery, clinicians must consider which batteries most appropriately assess the areas of weakness. In regard to the current case, the Kaufman Test of Educational Achievement, Third Edition (KTEA-3) includes measures of math problem solving and reading comprehension that approximate task demands in the classroom. The WISC-V and KTEA-3 are also statistically linked.

Choosing Supplemental Test Batteries

An examiner who is deciding on supplemental tests must first identify which broad and narrow abilities and processes related to the referral concerns are not measured adequately by the core battery. It is helpful to have an understanding of the abilities and processes most closely associated with areas of academic concern when making this determination and when choosing supplemental tests. The cognitive–achievement relations research was summarized in Tables 22.5 through 22.7 in Chapter 22 (this volume).

In evaluations where the examiner wants to conduct a PSW analysis using X-BASS, a few pointers are in order. First, the PSW analysis requires estimates of performance in seven cognitive areas, namely Gf, Gc, Gwm, Glr, Ga, Gv, and Gs. Estimates in these seven cognitive areas are necessary for the calculation of the *g*-value, FCC, and ICC. Second, other areas of cognitive processing, such as executive functions and orthographic processing, may also be included in the PSW analysis, even though these estimates do not contribute the *g*-value, FCC, and ICC. Third, estimates of cognitive abilities and processes do not need to be *broad* estimates (i.e., comprised of two qualitatively different indicators of the cognitive area). For example, the areas of Ga and Gs are very often *narrow* estimates (i.e., comprised of two similar indicators). In the area of Ga, the estimate typically represents the narrow process of Phonetic Coding (especially in reading referrals); in the area of Gs, the estimate typically represents the narrow process of Perceptual Speed. It is up to the evaluator to determine what estimates are most relevant for the referral concerns—broad or narrow or, in some cases, both. Fourth, when there are strengths and weaknesses within a cognitive area (e.g., average Induction and below average General Sequential Reasoning in the area of Gf), both estimates (i.e., the strength and the weakness) should be used to represent Gf in the PSW analysis. Fifth, a cognitive area may be represented by a single subtest score in some instances, particularly when the subtest score is indicative of average or better performance. Examples are included in this case. Nevertheless, it is important to remember that single subtest scores make for poor measurement (Flanagan & Schneider, 2016). As such, before using a single (*average or better*) subtest score to represent a narrow cognitive area, converging data sources are necessary (e.g., data from previous evaluations, work samples, teacher reports).

Based on a review of the cognitive–achievement relations research and the requirements of a PSW analysis, Tommy's evaluator chose to use



g-Value = 0.78

Click to re-display pop up message regarding results of the current PSW analysis or when data are changed.

Cognitive Strengths

The value here is either the Facilitating Cognitive Composite (FCC) or a user-entered Alternative Cognitive Composite (ACC).

FCC = 104

KTEA-3 Written Expression (WE;Grw-W:WA,EU) Subtest - 93

Supporting Academic Strengths

Areas listed in the drop down menu above have been identified as academic strengths for the individual.

Are weaknesses domain specific?

Using the FCC as the predictor, if the difference between Actual and Predicted specific cognitive performance equals or exceeds the Critical Value, then the size of the difference is unusually large and infrequent and the weakness is domain specific.

Difference 28.23 Critical Value 11.72

Yes, domain specific

Base rate value set at 10%

Is underachievement unexpected?

Using the FCC as the predictor, if the difference between Actual and Predicted specific academic performance equals or exceeds the Critical Value, then the size of the difference is unusually large and infrequent and underachievement is unexpected.

Difference 23.80 Critical Value 12.33

Yes, unexpected underachievement

Base rate value set at 10%

Is the difference statistically significant?

YES $p < .05$ YES

A "YES" in these boxes indicates that the difference between the Facilitating Cognitive Composite (FCC or alternative) and the Actual cognitive or the Actual academic weakness score is statistically significant at a 95% level of probability (one-tailed; assumes the cognitive/academic weakness is < cognitive aggregate).

Cognitive Weakness

If calculated, the Inhibiting Cognitive Composite (ICC) is selected below by default. You may select a different area of cognitive weakness from the drop down menu for analysis.

Inhibiting Cognitive Composite (ICC) - 75

	Actual	Predicted by
	75	103
	ICC	Strengths (FCC)

Academic Weakness

The first weakness in the list is selected by default. You may select a different area of academic weakness from the drop down menu for analysis.

Reading Comprehension (RDC) Comp - 79

	Actual	Predicted by
	79	103
	RDC	Strengths (FCC)

Both Weaknesses? YES

Strength of Relationship MOD

Is there a BELOW AVERAGE aptitude-achievement consistency?

YES, CONSISTENT

The small box on the left in this section addresses the first component of the criterion through consideration of the degree to which the meaning of the scores is consistent based on their respective magnitudes (e.g., are they both indicative of a weakness relative to most people?). The small box on the right addresses the second component through evaluation of the extent to which the cognitive weakness, either collectively (e.g., via the ICC) or individually, is empirically related to the academic weakness, as suggested by mainly correlational research. Relationships that are LOW suggest that the cognitive weakness may not be a contributory factor in the academic weakness. However, in all cases, clinical judgment should be exercised. The larger box directly above yields a decision with respect to the consistency criterion based on consideration of both the magnitude of the reported and selected cognitive and academic weaknesses and the strength of the relationship between them.

FIGURE 27.11. PSW Analyzer tab: Inhibiting Cognitive Composite and Math Problem Solving.

the statistically linked WISC-V and KTEA-3 and supplement these batteries with selected subtests from the CTOPP-2 to assess phonological processing (which is not measured by the WISC-V and not measured well by the KTEA-3) as well as selected subtests from the KeyMath3 to assess math skills that are not measured on the KTEA-3. Testing hypotheses about aberrant score performances may require using subtests from additional batteries. The evaluation results and decisions made throughout the evaluation are described next.

Cognitive Test Data

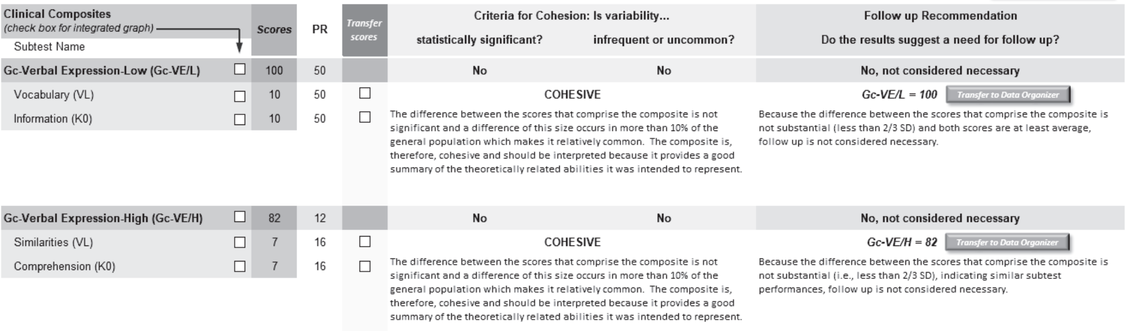
Crystallized Intelligence

Results from the WISC-V revealed an average score on Vocabulary (scaled score = 10) and a below average score on Similarities (scaled score = 8), both of which measure Lexical Knowledge. Together these scores yield a VCI of 92, suggesting that Tommy's Crystallized Intelligence (Gc), particularly his vocabulary knowledge, is average. These data are shown in Figure 27.4. However, Similarities includes a reasoning component, whereas Vocabulary does not. When these subtest scores are entered into X-BASS, the program shows that the difference between the two scores is statistically significant, but not unusual in the general population. This means that clinical judgment is necessary to determine if the VCI of 92 is a good representation of Tommy's Gc. X-BASS assists in determining this by indicating whether follow-up assessment is considered necessary for the lower score in the composite. In this case, the program recommends following up on the Similarities score performance. These decisions regarding composite cohesion and follow-up for the VCI are shown in Figure 27.4.

Tommy's evaluator chose to, but was not required (by XBA procedures) to, administer the remaining two Gc subtests on the WISC-V (i.e., Information and Comprehension), both of which measure the narrow ability of General (verbal) Information. Interestingly, Comprehension has a reasoning component, whereas Information does not. When all four Gc subtest scores are entered on the WISC-V tab, three *clinical composites* are generated based on actual norms provided by Pearson (see Flanagan et al., 2017). The first clinical composite, the Verbal-Expanded Crystallized Index (VECI; originally published in Raiford, Drozdick, Zhang, & Zhou, 2015) is made up of all four Gc subtests. The VECI was 91, which is considered cohesive with no need for follow-up. Psychometrically, the VECI is the best estimate of Tommy's Gc. Clinically, however, Tommy's evaluator believes that the VECI of 91 masks important information about his strengths and weaknesses, suggesting the need to explore why he demonstrated below average performance on two of the four Gc subtests.

Two additional clinical composites revealed that Tommy performed better on the Gc subtests that require low verbal expression (100) as compared to those that required high verbal expression (82) (see Figure 27.12). However, Tommy's expressive language has never been in question. Upon closer examination, it was clear that the subtests that required higher verbal expression were those that also involved reasoning (i.e., Similarities and Comprehension). Thus the composite of 82 could also be interpreted as an indication of Tommy's ability to reason with verbal information, an ability that is consistent with referral concerns.

In the area of Gc, the evaluator chose to report the VECI of 91 as the best estimate of Tommy's Gc. Additionally, the evaluator chose to report



Clinical Composites (check box for integrated graph) Subtest Name		Scores	PR	Transfer scores	Criteria for Cohesion: Is variability... statistically significant?	infrequent or uncommon?	Follow up Recommendation Do the results suggest a need for follow up?
Gc-Verbal Expression-Low (Gc-VE/L)	☐	100	50		**No**	**No**	**No, not considered necessary**
Vocabulary (VL)	☐	10	50	☐	COHESIVE		*Gc-VE/L = 100*
Information (K0)	☐	10	50	☐	The difference between the scores that comprise the composite is not significant and a difference of this size occurs in more than 10% of the general population which makes it relatively common. The composite is, therefore, cohesive and should be interpreted because it provides a good summary of the theoretically related abilities it was intended to represent.		Because the difference between the scores that comprise the composite is not substantial (less than 2/3 SD) and both scores are at least average, follow up is not considered necessary.
Gc-Verbal Expression-High (Gc-VE/H)	☐	82	12		**No**	**No**	**No, not considered necessary**
Similarities (VL)	☐	7	16	☐	COHESIVE		*Gc-VE/H = 82*
Comprehension (K0)	☐	7	16	☐	The difference between the scores that comprise the composite is not significant and a difference of this size occurs in more than 10% of the general population which makes it relatively common. The composite is, therefore, cohesive and should be interpreted because it provides a good summary of the theoretically related abilities it was intended to represent.		Because the difference between the scores that comprise the composite is not substantial (i.e., less than 2/3 SD), indicating similar subtest performances, follow up is not considered necessary.

FIGURE 27.12. WISC-V tab: Gc Clinical Composites.

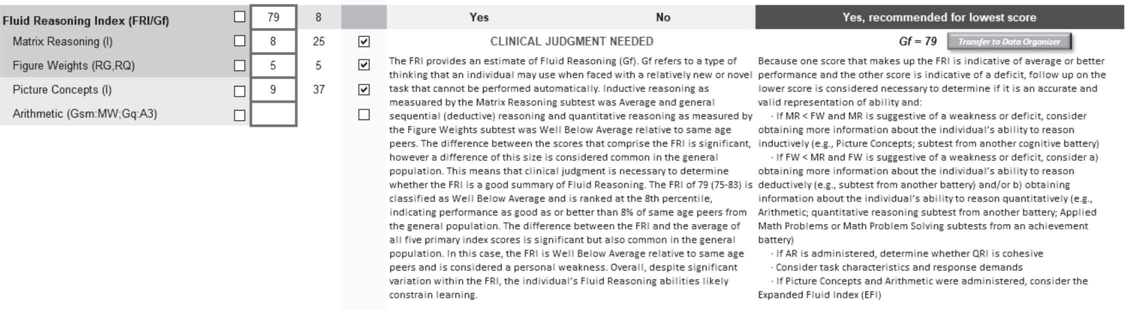
and use 100 and 82 (as depicted in Figure 27.12) to represent his stores of acquired knowledge and his ability to reason with that knowledge, respectively, in the PSW Analysis. As such, the evaluator clicked on the "Transfer to Data Organizer" buttons to the far right of each of these composites (see Figure 27.12) to represent his strength and his weakness in Gc in the PSW analysis.

Fluid Reasoning

Results from the WISC-V revealed an average score on Matrix Reasoning (scaled score = 8), a measure of Induction, and a well below average score on Figure Weights (scaled score = 5), a measure of General Sequential Reasoning and Quantitative Reasoning. Together, these scores yield an FRI of 79, suggesting that Tommy's Fluid Reasoning (Gf) is well below average. Tommy's evaluator was curious about what strategies he used to solve or attempt to solve the items on Figure Weights. She selected items that he got correct and incorrect and asked him how he solved them or attempted to solve them. Tommy's responses suggested that he did not use multiplication or attempt to solve any items mathematically. This information was consistent with the referral, past and current teacher reports, and math problem-solving worksheets. Nevertheless, the evaluator followed the recommendation in X-BASS to follow up on the lower score (Figure Weights), primarily because it was related to the main referral concerns. The UNIT2 Numerical Series subtest was administered to follow-up because it also measures quantitative reasoning but uses a different test format. Additionally, because Similarities was below average, presumably due to reasoning difficulties, the visual analog of this subtest was administered (i.e., Picture Concepts) to determine whether visual information (aided by verbal mediation) would lead to improved concept formation.

To analyze the four reasoning subtests scores, the evaluator checked the boxes next to each Gf subtest on the WISC-V tab, as shown in Figure 27.13, and then clicked on the "Transfer Scores to XBA Analyzer" button at the bottom of this tab (not shown in the figure). Once clicked, the program automatically advances to the XBA Analyzer tab where the Gf scores are displayed in the Gf section, as shown in Figure 27.14. Note that this tab analyzed the three Gf subtest scores from the WISC-V. Figure 27.14 shows that the Matrix Reasoning and Picture Concepts scores formed a cohesive Induction composite of 91 and the Figure Weights score was labeled as "divergent," meaning that it is substantially different from the other scores. Because the evaluator also gave the UNIT2 Numerical Series subtest, it was selected from the drop-down menu in the Gf section of the tab. After Tommy's score of 6 was entered, X-BASS displayed a four-subtest Gf XBA composite of 81 (see Figure 27.15). Psychometrically, 81 is the best estimate of Tommy's Gf. Clinically, the evaluator believes that this composite masks his strengths and weaknesses in the area of Gf; that is, Tommy's inductive reasoning is average, but his quantitative reasoning is well below average and consistent with referral concerns.

To further analyze Tommy's Gf scores, the evaluator clicked on the "Evaluate Score Configuration" button (which is seen in Figure 27.15). This button provides several options for score analysis. In the case of Tommy, the evaluator wanted to create two two-subtest composites: an Induction composite and a General Sequential/Quantitative Reasoning composite. When prompted by X-BASS, the evaluator chose that option. The results are found in Figure 27.16. This figure shows that Tommy's ability to



Fluid Reasoning Index (FRI/Gf)	☐	79	8

CLINICAL JUDGMENT NEEDED

The FRI provides an estimate of Fluid Reasoning (Gf). Gf refers to a type of thinking that an individual may use when faced with a relatively new or novel task that cannot be performed automatically. Inductive reasoning as measuared by the Matrix Reasoning subtest was Average and general sequential (deductive) reasoning and quantitative reasoning as measured by the Figure Weights subtest was Well Below Average relative to same age peers. The difference between the scores that comprise the FRI is significant, however a difference of this size is considered common in the general population. This means that clinical judgment is necessary to determine whether the FRI is a good summary of Fluid Reasoning. The FRI of 79 (75-83) is classified as Well Below Average and is ranked at the 8th percentile, indicating performance as good as or better than 8% of same age peers from the general population. The difference between the FRI and the average of all five primary index scores is significant but also common in the general population. In this case, the FRI is Well Below Average relative to same age peers and is considered a personal weakness. Overall, despite significant variation within the FRI, the individual's Fluid Reasoning abilities likely constrain learning.

Gf = 79

Because one score that makes up the FRI is indicative of average or better performance and the other score is indicative of a deficit, follow up on the lower score is considered necessary to determine if it is an accurate and valid representation of ability and:

· If MR < FW and MR is suggestive of a weakness or deficit, consider obtaining more information about the individual's ability to reason inductively (e.g., Picture Concepts; subtest from another cognitive battery)

· If FW < MR and FW is suggestive of a weakness or deficit, consider a) obtaining more information about the individual's ability to reason deductively (e.g., subtest from another battery) and/or b) obtaining information about the individual's ability to reason quantitatively (e.g., Arithmetic; quantitative reasoning subtest from another battery; Applied Math Problems or Math Problem Solving subtests from an achievement battery)

· If AR is administered, determine whether QRI is cohesive

· Consider task characteristics and response demands

· If Picture Concepts and Arithmetic were administered, consider the Expanded Fluid Index (EFI)

reason inductively with visual–spatial information is average (standard score = 91), while his ability to use quantitative reasoning to solve problems is well below average (standard score = 74).

Although the best estimate of Tommy's Gf is 81 based on the aggregate of the four Gf subtests, the examiner chose to use 91 and 74 (as depicted in Figure 27.16) to represent his ability to reason inductively with visual–spatial information and his ability to use reasoning processes that can be expressed mathematically, respectively, in the PSW Analysis. As such, the evaluator clicked on the "Transfer Comp(s) to Data Organizer" button in the Gf section on the XBA Analyzer tab (see Figure 27.16) to represent his strength and his weakness in Gf in the PSW analysis.

Score configuration and interpretation:

Two separate alternative composites have been formed using the four scores in this domain. The two highest scores were used to form one composite and the two lowest scores were used to forma a second composite. For any scores between 80-89 inclusive that may have been used to form one or both of the composites, additional data and information should exist to support their inclusion in the composite as representing a strength or weakness, particularly when the composites will be used in PSW analyses.

FIGURE 27.16. XBA Analyzer tab: New Score Configuration for Gf.

Visual Processing, Working Memory, and Processing Speed

Tommy's VSI of 81, WMI of 97, and PSI of 103 were cohesive and X-BASS indicated that there was no need to follow up in these areas, to which the examiner agreed. Each of these composites were transferred to the Data Organizer tab.

Long-Term Storage and Retrieval

Tommy scored in the average range on Naming Speed Literacy (scaled score = 104), a measure of naming facility, and in the above average range on Immediate Symbol Translation (standard score = 116), a measure of associative memory. Based on initial testing, the evaluator did not believe there was a need for further evaluation in the area of Glr. To create a Glr composite, the evaluator checked the boxes next to each subtest and transferred them to the XBA Analyzer tab. As may be seen in Figure 27.14, a Glr composite of 110 was computed automatically. From this tab (i.e., XBA Analyzer tab), the examiner transferred this score to the Data Organizer tab.

Auditory Processing

Typically, when reading is an area of concern, measures of Phonetic Coding are administered. These measures include tests of phonological processing and phonological memory and are associated with the acquisition and development of basic reading skills. However, Tommy has no difficulty with reading decoding or reading fluency, suggesting that Phonetic Coding is not an area of concern. To test this hypothesis, Blending Nonwords from the CTOPP-2 was administered. Tommy earned an above average score on this subtest (scaled score = 13, which converts to a standard score of 115). This score is consistent with parent and teacher reports, his history of reading achievement, and the evaluator's observations during testing. Therefore, there is no need to conduct additional testing in this area.

XBA has historically required that all cognitive constructs be represented by at least two measures (i.e., subtests). However, there are times when this requirement may lead to unnecessary testing, such as in this situation. To limit the amount of time spent on test administration in the area of Ga, the examiner used the "Other Test Data Entry" tab, as shown in Figure 27.17. On this tab the examiner may enter a single score *only if it is at least average and there are other compelling data sources to support at least average performance,* such as in the case of Tommy's Blending Nonwords score. As seen in Figure 27.17, the evaluator named the score "CTOPP-2 Blending Nonwords (with converging data)" and entered the converted score of 115. From this tab, the Ga score may be transferred to the Data Organizer tab.

In sum, after the assessment of cognitive abilities and processes, including follow-up assessment to explore aberrant score performances and to test specific hypotheses, nine estimates were transferred to the Data Organizer tab, covering the main seven cognitive areas that are necessary to conduct the PSW analysis. Most of these data were displayed earlier in Figure 27.7. The only other information necessary to conduct the PSW analysis

is at least one academic achievement score, although most practitioners gather data across many academic areas. Tommy's achievement data are discussed next.

Achievement Data

Selected subtests from the KTEA-3 were administered, including Reading Comprehension (standard score = 82; below average), Math Computation (standard score = 98; average), Math Concepts and Applications (standard score = 76; well below average), and Written Expression (standard score = 93; average). The KTEA-3 error analysis for Reading Comprehension showed that Tommy had difficulty on items that required drawing inferences from text. As such, the CELF-5 Reading Comprehension subtest was also administered to determine if Tommy had difficulty interpreting inferential information. On this subtest he earned a scaled score of 6 (well below average) and demonstrated much difficulty with inferential information.

To gather more data in math skills that are not measured (or measured in-depth) on the KTEA-3, the KeyMath3 Applied Problem Solving (APS) subtest was administered. Tommy obtained a scaled score of 7 on this subtest. He appeared to have the most difficulty with drawing inferences and conclusions to solve problems and using charts, tables, graphs, equations, and geometric representations to solve problems, which is consistent with his quantitative reasoning and visual processing weaknesses, respectively.

After the assessment of the academic skills most closely associated with the referral, two subtests were transferred to the Data Organizer tab from the KTEA-3 tab, namely Math Computation and Written Expression. Since the evaluator did more in-depth assessment of Reading Comprehension and Math Problem Solving, the KTEA-3 Reading Comprehension and Math Concepts & Applications subtest scores were transferred to the XBA Analyzer tab from the KTEA-3 tab. On the XBA Analyzer tab the evaluator used the drop-down menu in the Reading Comprehension section to select the CELF-5 Reading Comprehension subtest and then entered the scaled score of 6. X-BASS automatically calculated an XBA Reading Comprehension composite of 79 (see Figure 27.18), which the evaluator transferred to the Data Organizer tab.

In the Math Problem Solving section of the XBA Analyzer tab, the evaluator selected the KeyMath3 APS subtest from the drop-down menu and entered a scaled score of 7. X-BASS automatically calculated an XBA Math Problem Solving composite of 79, which the evaluator transferred to the Data Organizer tab (see Figure 27.19). In all, four achievement scores were transferred to the Data Organizer tab. Now that the evaluation is complete, all score have been entered, XBA composites have been calculated, and all estimates have been transferred to the Data Organizer tab, the evaluator is ready to begin the PSW analysis.

PSW Analysis

On the Data Organizer tab, the evaluator clicked on the "Select All Checkboxes" button to ensure that all cognitive and achievement estimates are used in Tommy's PSW analysis. Next, the evaluator marked each estimate as either a strength or a weakness on the Strengths and Weaknesses Indicator tab. Then X-BASS automatically calculated

Score configuration and interpretation:
The difference between the two scores is less than 1SD and, therefore, they form a composite that is considered cohesive and likely a good summary of the set of theoretically related abilities that comprise it. Interpret the composite as an adequate estimate of the ability that it is intended to measure.

FIGURE 27.18. XBA Analyzer tab: Reading Comprehension.

the g-Value, FCC, and ICC, as was shown earlier in Figure 27.9. Note that Tommy's WISC-V FSIQ is 87 and his FCC is 104. While both composites provide an estimate of overall cognitive ability, unlike the FSIQ, the FCC is not attenuated by Tommy's processing deficits. Note also that both estimates should be reported by the evaluator and the differences between them should be explained with respect to the composition of each composite. However, the FCC is the value used in the PSW analysis, unless the evaluator purposefully enters an alternative composite to replace the FCC.

Next, the evaluator advanced to the PSW-A tab, which displays the results of a PSW analysis using Tommy's data. Referring back to Figure 27.11, the top oval shows that Tommy's ability to think and reason is at least average (FCC = 104), despite specific cognitive processing weaknesses. The drop-down menu in the top oval lists academic areas that the evaluator indicated were strengths for Tommy. Individuals with SLDs often perform at or close to grade level (or at least average) in one or more academic skills and the top oval reflects this finding. The bottom left oval displays cognitive processing weaknesses. As may be seen in Figure 27.11, the program defaults to the ICC as the cognitive weakness in the bottom left oval. However, the oval contains a drop-down menu, where each area of cognitive processing weakness is listed and therefore any processing weakness may be selected in lieu of the ICC. The bottom right oval represents the academic weakness. This oval also contains a drop-down menu that lists each academic area that the evaluator marked as a weakness. The results in Figure 27.11 show that all criteria were met, indicating that Tommy displays a pattern of

FIGURE 27.19. XBA Analyzer tab: Math Problem Solving.

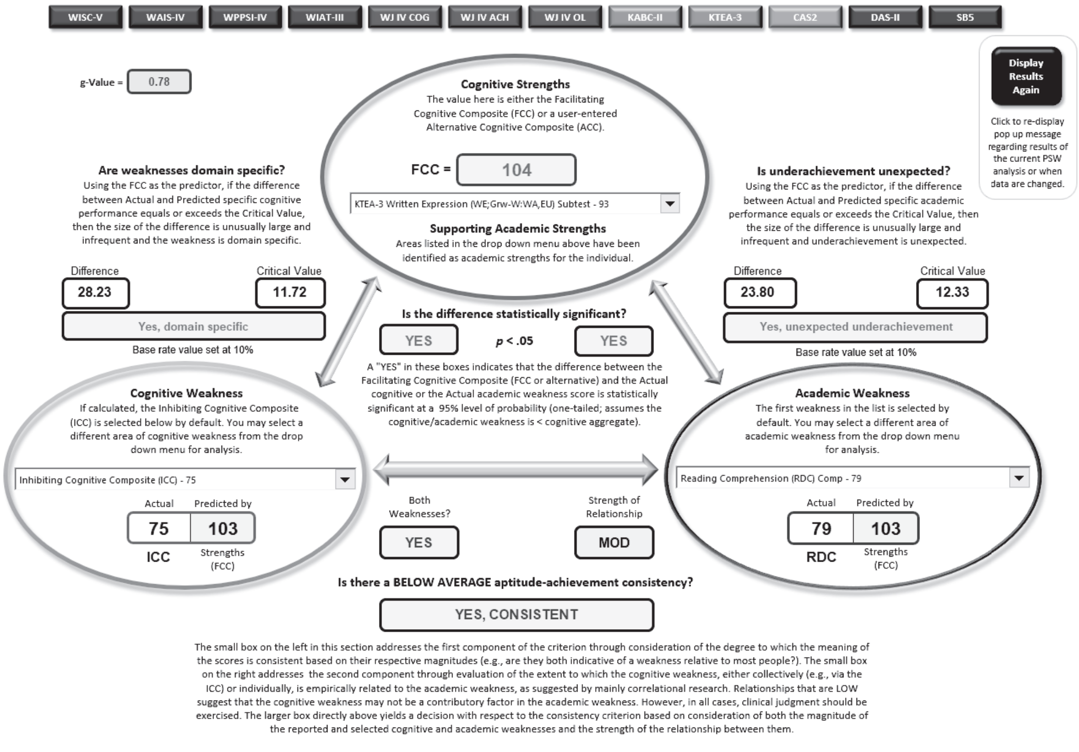
strengths and weaknesses that is consistent with an SLD in math problem solving.

Because reading comprehension was also an area of concern, the evaluator selected the Reading Comprehension composite from the drop-down menu in the bottom right oval and continued to use the ICC in the bottom left oval to represent Tommy's cognitive processing weaknesses (see Figure 27.20). Although X-BASS conducts the PSW analysis automatically each time a different cognitive or academic weakness is displayed in the bottom left or right oval, respectively, it is important to understand how the program conducts the analysis.

First, the program determines whether there is a statistically significant difference between the FCC and the cognitive weakness and the FCC and the academic weakness and reports either "yes" or "no" in the center of the three ovals. As seen in Figure 27.20, "yes" is displayed for both comparisons, meaning that these are reliable differences and are not likely due to chance. However, some statistically significant differences may be common in the general population. Therefore, base rate data are used to determine whether the differences are unusual.

Second, the program uses the FCC in a regression analysis to predict where the individual (in this case Tommy) was expected to perform in the selected areas of cognitive and academic weakness. The bottom ovals contain the actual scores alongside scores that were predicted based on the FCC. For example, the bottom right oval in Figure 27.20 shows that Tommy's "actual" reading comprehension score is 79 and his "predicted" reading comprehension score, based on the results of the regression analysis, is 103. Next, the difference between the actual and predicted scores are compared to a critical value to determine if that difference is unusual in the general population, meaning that the difference occurs in about 10% or less in the population. When the difference between the actual and predicted cognitive scores is unusual, the criterion of a "domain-specific" cognitive weakness is met. When the difference between the actual and predicted achievement scores is unusual, the criterion of "unexpected underachievement" is met. Figure 27.20 shows that both criteria were met.

Third, the program determines whether the pattern of strengths and weaknesses is marked by a "below average aptitude–achievement consistency." Consistency is determined by evaluating whether the cognitive and academic areas identified as weaknesses by the evaluator are actually weaknesses



g-Value = 0.78

Cognitive Strengths
The value here is either the Facilitating Cognitive Composite (FCC) or a user-entered Alternative Cognitive Composite (ACC).

FCC = 104

KTEA-3 Written Expression (WE;Grw-W:WA,EU) Subtest - 93

Supporting Academic Strengths
Areas listed in the drop down menu above have been identified as academic strengths for the individual.

Click to re-display pop up message regarding results of the current PSW analysis or when data are changed.

Are weaknesses domain specific?
Using the FCC as the predictor, if the difference between Actual and Predicted specific cognitive performance equals or exceeds the Critical Value, then the size of the difference is unusually large and infrequent and the weakness is domain specific.

Difference 28.23
Critical Value 11.72
Yes, domain specific
Base rate value set at 10%

Is underachievement unexpected?
Using the FCC as the predictor, if the difference between Actual and Predicted specific academic performance equals or exceeds the Critical Value, then the size of the difference is unusually large and infrequent and underachievement is unexpected.

Difference 23.80
Critical Value 12.33
Yes, unexpected underachievement
Base rate value set at 10%

Is the difference statistically significant?
YES $p < .05$ YES
A "YES" in these boxes indicates that the difference between the Facilitating Cognitive Composite (FCC or alternative) and the Actual cognitive or the Actual academic weakness score is statistically significant at a 95% level of probability (one-tailed; assumes the cognitive/academic weakness is < cognitive aggregate).

Cognitive Weakness
If calculated, the Inhibiting Cognitive Composite (ICC) is selected below by default. You may select a different area of cognitive weakness from the drop down menu for analysis.

Inhibiting Cognitive Composite (ICC) - 75

Actual	Predicted by
75	103
ICC	Strengths (FCC)

Academic Weakness
The first weakness in the list is selected by default. You may select a different area of academic weakness from the drop down menu for analysis.

Reading Comprehension (RDC) Comp - 79

Actual	Predicted by
79	103
RDC	Strengths (FCC)

Both Weaknesses? YES
Strength of Relationship MOD

Is there a BELOW AVERAGE aptitude-achievement consistency?
YES, CONSISTENT

The small box on the left in this section addresses the first component of the criterion through consideration of the degree to which the meaning of the scores is consistent based on their respective magnitudes (e.g., are they both indicative of a weakness relative to most people?). The small box on the right addresses the second component through evaluation of the extent to which the cognitive weakness, either collectively (e.g., via the ICC) or individually, is empirically related to the academic weakness, as suggested by mainly correlational research. Relationships that are LOW suggest that the cognitive weakness may not be a contributory factor in the academic weakness. However, in all cases, clinical judgment should be exercised. The larger box directly above yields a decision with respect to the consistency criterion based on consideration of both the magnitude of the reported and selected cognitive and academic weaknesses and the strength of the relationship between them.

FIGURE 27.20. PSW Analysis tab: Reading Comprehension.

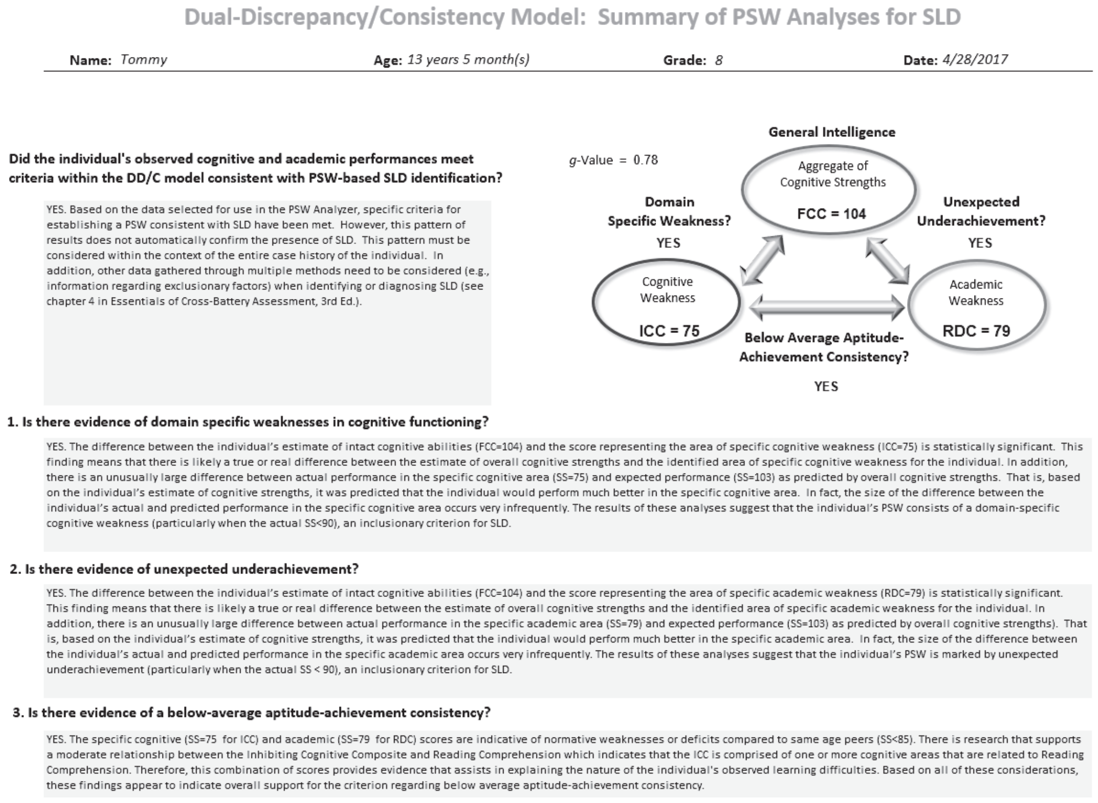
relative to the general population. For example, an evaluator may indicate that a score of 98 is a weakness for a very high-functioning individual. However, a score of 98 is not a weakness relative to most people. Figure 27.20 shows that Tommy's actual cognitive and achievement scores are weaknesses relative to most people. Specifically, the program reported "YES" to the question "Both Weaknesses?" Another component of consistency is an evaluation of the strength of the relationship between the cognitive and academic areas of weakness. The program shows that the combination of cognitive areas that make up the ICC has a moderate relationship to reading comprehension (displayed as "MOD" in Figure 27.20). Moreover, the combination of actual weaknesses and a moderate relationship indicates consistency, which is reported as "YES, CONSISTENT" in the PSW analysis (see Figure 27.20). The results in Figure 27.20 show that all criteria were met, indicating that Tommy displays a pattern of strengths and weaknesses that is consistent with an SLD in reading comprehension.

To assist the evaluator in interpreting the PSW analysis, X-BASS provides answers to the following questions and customizes them according to the individual's scores.

1. Did the individual's observed cognitive and academic performances meet criteria within the DD/C model consistent with PSW-based SLD identification?
2. Is there evidence of domain-specific weaknesses in cognitive functioning?
3. Is there evidence of unexpected underachievement?
4. Is there evidence of a below-average aptitude–achievement consistency?

A customized summary with answers to these questions may be printed and included as an appendix to a psychoeducational report. Figure 27.21 shows responses to these questions for Tommy.

As the case of Tommy reflects, the XBA approach has evolved significantly over the past 20 years. It is more sophisticated theoretically and psychometrically. It is now part of a software system (X-BASS) that provides a means of facilitating the approach and using XBA data to answer



Dual-Discrepancy/Consistency Model: Summary of PSW Analyses for SLD

Name: *Tommy* **Age:** *13 years 5 month(s)* **Grade:** *8* **Date:** *4/28/2017*

Did the individual's observed cognitive and academic performances meet criteria within the DD/C model consistent with PSW-based SLD identification?

YES. Based on the data selected for use in the PSW Analyzer, specific criteria for establishing a PSW consistent with SLD have been met. However, this pattern of results does not automatically confirm the presence of SLD. This pattern must be considered within the context of the entire case history of the individual. In addition, other data gathered through multiple methods need to be considered (e.g., information regarding exclusionary factors) when identifying or diagnosing SLD (see chapter 4 in Essentials of Cross-Battery Assessment, 3rd Ed.).

1. Is there evidence of domain specific weaknesses in cognitive functioning?

YES. The difference between the individual's estimate of intact cognitive abilities (FCC=104) and the score representing the area of specific cognitive weakness (ICC=75) is statistically significant. This finding means that there is likely a true or real difference between the estimate of overall cognitive strengths and the identified area of specific cognitive weakness for the individual. In addition, there is an unusually large difference between actual performance in the specific cognitive area (SS=75) and expected performance (SS=103) as predicted by overall cognitive strengths. That is, based on the individual's estimate of cognitive strengths, it was predicted that the individual would perform much better in the specific cognitive area. In fact, the size of the difference between the individual's actual and predicted performance in the specific cognitive area occurs very infrequently. The results of these analyses suggest that the individual's PSW consists of a domain-specific cognitive weakness (particularly when the actual SS<90), an inclusionary criterion for SLD.

2. Is there evidence of unexpected underachievement?

YES. The difference between the individual's estimate of intact cognitive abilities (FCC=104) and the score representing the area of specific academic weakness (RDC=79) is statistically significant. This finding means that there is likely a true or real difference between the estimate of overall cognitive strengths and the identified area of specific academic weakness for the individual. In addition, there is an unusually large difference between actual performance in the specific academic area (SS=79) and expected performance (SS=103) as predicted by overall cognitive strengths). That is, based on the individual's estimate of cognitive strengths, it was predicted that the individual would perform much better in the specific academic area. In fact, the size of the difference between the individual's actual and predicted performance in the specific academic area occurs very infrequently. The results of these analyses suggest that the individual's PSW is marked by unexpected underachievement (particularly when the actual SS < 90), an inclusionary criterion for SLD.

3. Is there evidence of a below-average aptitude-achievement consistency?

YES. The specific cognitive (SS=75 for ICC) and academic (SS=79 for RDC) scores are indicative of normative weaknesses or deficits compared to same age peers (SS<85). There is research that supports a moderate relationship between the Inhibiting Cognitive Composite and Reading Comprehension which indicates that the ICC is comprised of one or more cognitive areas that are related to Reading Comprehension. Therefore, this combination of scores provides evidence that assists in explaining the nature of the individual's observed learning difficulties. Based on all of these considerations, these findings appear to indicate overall support for the criterion regarding below average aptitude-achievement consistency.

FIGURE 27.21. Summary of PSW Analysis.

questions related to identification of SLD and whether XBA data gathered from cognitive tests yield scores that are likely consistent with an individual's cultural and linguistic background (for details, see Ortiz et al., Chapter 25, this volume). Table 27.7 highlights the many ways in which the XBA approach has evolved and contributed to the practice of conducting reliable, valid, and defensible psychoeducational evaluations.

SUMMARY

In this chapter, we have presented the XBA approach as a method that allows practitioners to augment or supplement any major ability test (e.g., cognitive, neuropsychological, academic, speech–language) to ensure measurement of a wider range of broad and narrow cognitive abilities in a manner that is consistent with contemporary theory and research, and that is predicated upon sound psychometric principles. The foundational sources of information upon which the XBA approach was formulated (i.e., CHC theory and the classifications of ability tests according to this theory), coupled with straightforward, step-by-step procedures, provide a systematic way to conduct a theoretically driven, comprehensive, and valid assessment of a wide range of cognitive abilities and processes. When the XBA approach is applied to the WISC-V, for example, it is possible to measure important abilities that would otherwise not be assessed (e.g., Ga) and to follow up on aberrant score performances and test hypotheses about unexpected variation within cognitive domains.

The XBA approach allows for the measurement of the major cognitive areas specified in CHC theory, with emphasis on those considered most critical on the basis of history, observation, response to intervention, and other available sources of data. The CHC classifications of a multitude of ability tests bring stronger content and construct validity evidence to the evaluation and interpretation process. With a strong research base, the XBA approach can aid practitioners not only in the comprehensive measurement of cognitive abilities and neuropsychological processes, but in the selective measurement of abilities and processes that are deemed to be most important with respect to suspected learning disabilities. Adherence to the guiding principles and steps of the XBA approach, as well as careful attention to specific referral concerns, results in the creation of highly individualized assessment batteries that are ideally suited for the intended purpose of assessment.

Through a case example, this chapter demonstrated the XBA approach and how to use X-BASS to facilitate the approach. Overall, this chapter showed (1) the value of crossing batteries to address referral concerns and inform decisions related to SLD identification; (2) the importance of understanding how identified areas of cognitive weakness manifest in real-world activities (e.g., in the classroom) and how this information informs intervention; and (3) how to use XBA data in a PSW analysis to inform SLD identification using X-BASS.

NOTE

1. CHC theory has been revised and updated in Chapter 3 of this book. Because the information contained in Chapter 3 is new, and because that chapter was written at the same time as this chapter, the classification system underlying the XBA approach as described here does not yet reflect some current refinements to the theory.

TABLE 27.7. Past and Present Contributions of the XBA Approach to Psychoeducational Evaluation

Source	Contribution
Flanagan, Genshaft, and Harrison (1997)	• First attempt at merging the Cattell–Horn Gf–Gc theory and Carroll's three-stratum theory (McGrew, 1997), which represented the foundation of cross-battery assessment (XBA). • First expert consensus study regarding the narrow abilities measured by intelligence tests (McGrew, 1997), an important component of XBA. • Introduction to the need for XBA and the assumptions and foundations as well as an operationalized set of XPA principles and procedures (Flanagan & McGrew, 1997).
McGrew and Flanagan (1998)	• Introduced a step-by-step approach to XBA in an attempt to improve upon the measurement of cognitive constructs. • Demonstrated how the XBA approach guarded against two ubiquitous sources of invalidity in assessment: construct-irrelevant variance and construct underrepresentation. • Provided worksheets for organizing assessments according to contemporary Gf–Gc theory and for conducting XBA. • Provided a review of the research on the relations between broad and narrow Gf–Gc abilities and academic (reading and math) and occupational outcomes. • Provided a desk reference of all the major intelligence tests, which provided important information for each subtest as a means of informing interpretation of XBA data (e.g., reliability, validity, standardization sample characteristics, test floors and ceilings, item gradients, variables influencing subtest performance, *g* loadings, broad and narrow abilities measured by subtests). • Provided the first comprehensive set of theory-based classifications of tests, in an attempt to further establish a Gf–Gc nomenclature for the field. • Highlighted the importance of joint or cross-battery confirmatory factor-analytic studies for understanding the Gf–Gc broad abilities underlying intelligence tests. • Provided the first set of systematic classifications of ability tests according to degree of cultural loading and degree of linguistic demand.
Flanagan, McGrew, and Ortiz (2000)	• Introduced the *integrated Cattell–Horn and Carroll Gf–Gc model* as the foundation for cross-battery assessment, based on analyses conducted by McGrew (e.g., McGrew, 1997). This integrated model was renamed *Cattell–Horn–Carroll (CHC) theory* shortly thereafter (see McGrew, 2005, for details). • Applied Gf–Gc theory to interpretation of the Wechsler scales. • Demonstrated that the Wechsler scales included redundancy in the assessment of certain constructs (e.g., Gc and Gv) and omitted measurement of other important constructs (e.g., Gf, Ga, and Glr). • Offered step-by-step XBA guidelines for augmenting a Wechsler scale, so that a broader range of cognitive abilities could be measured as deemed relevant and necessary vis à vis referral concerns. • Provided a set of worksheets for conducting XBA with the Wechsler scales.
Flanagan and Ortiz (2001)	• Used CHC theory as the foundation for XBA. • Expanded test classifications to include a variety of special-purpose tests, in addition to the major intelligence tests. • Included more comprehensive coverage of test interpretation. • Provided updated and improved XBA worksheets. • Expert consensus studies provided the basis for narrow-ability classifications of cognitive tests. • Refined classifications of ability tests according to degree of cultural loading and degree of linguistic demand.
Flanagan, Ortiz, Alfonso, and Mascolo (2002)	• Extended the XBA approach to achievement tests. • Included the largest expert consensus study of the narrow abilities underlying ability tests. • Provided an updated review of the literature on the relations between cognitive abilities and reading and math achievement. Review was expanded to include the area of written language. • Demonstrated how to use the XBA approach within the context of a CHC-based operational definition of SLD. • Provided a desk reference of achievement tests, which provided important information for each subtest (e.g., reliability, validity, standardization sample characteristics, test floors and ceilings, broad and narrow abilities measured by each subtest). • Included tables of the qualitative characteristics of individual achievement subtests from 48 batteries—information that informed test selection for XBA as well as interpretation.

(continued)

TABLE 27.7. *(continued)*

Source	Contribution
Flanagan and Kaufman (2004, 2009)	• Provided a CHC interpretive framework for the WISC-IV, thereby facilitating the use of this instrument in the XBA approach. • Included actual norms for seven CHC-based clinical clusters, including narrow-ability clusters that were incorporated into the XBA approach. • Automated the CHC-interpretation method for the WISC-IV (program included on CD that accompanied the book).
Flanagan and Harrison (2005)	• Detailed origins of the XBA approach and the theoretical and research foundation upon which it was based (McGrew, 1997, 2005). • Detailed the manner in which CHC theory and the XBA approach influenced test development (Alfonso, Flanagan, & Radwan, 2005). • Highlighted the XBA approach as an example of the current “wave” of intelligence test interpretation: application of theory (Kamphaus, Winsor, Rowe, & Kim, 2005).
Flanagan, Ortiz, Alfonso, and Mascolo (2006)	• Included variation in task characteristics of the subtests of over 50 achievement batteries—information that informed test selection for XBA as well as interpretation. • Updated CHC-based classifications of achievement tests. • Provided a desk reference of achievement tests, which provided important information for each subtest (e.g., reliability, validity, standardization sample characteristics, test floors and ceilings, broad and narrow abilities measured by each subtest). • Revised and refined the operational definition of SLD, and demonstrated how to use the XBA approach within the context of this definition. • Introduced *academic clinical clusters* according to the eight areas of SLD listed in IDEA 2004.
Flanagan, Ortiz, and Alfonso (2007)	• Introduced automated XBA worksheets in a program called the XBA Data Management and Interpretive Assistant (DMIA). • Introduced an automated Culture–Language Interpretive Matrix (C-LIM) program to evaluate whether test performance systematically declines as a function of increased culture and language demands for English language learners. • Introduced an automated program called the SLD Assistant. This program was intended to assist in determining whether an individual was of at least average overall intellectual ability, despite cognitive deficits in one or more specific areas. • Emphasized use of core tests (and supplemental tests as necessary) from a single battery, rather than selected components of a battery, as part of the assessment, because (1) current intelligence tests have better representation of the broad CHC abilities and use only two or three subtests to represent them; and (2) the broad abilities measured by current intelligence batteries are typically represented by qualitatively different indicators that are relevant only to the broad ability intended to be measured. • Greater emphasis placed on use of actual norms, rather than averages. Averages to be obtained under a selected few circumstances (e.g., narrow-ability level). • Expanded coverage of CHC theory to include abilities typically measured on achievement tests (e.g., Grw, Gq, Ga), providing additional information useful in the identification of SLD. • Addressed the “disorder in a basic psychological process” language of IDEA (2004). • Demonstrated how the XBA approach might be used to operationalize the “pattern of strengths and weaknesses” language of the federal regulations (U.S. Department of Education, 2005).
Flanagan, Alfonso, Ortiz, and Dynda (2010)	• Extended CHC classifications to neuropsychological instruments, thus expanding the range of instruments that might be used in the XBA approach. • Applied neuropsychological domain classifications to cognitive tests; this was intended to expand the interpretive options for XBA data. • Applied XBA principles to neuropsychological evaluation.
Flanagan and Harrison (2012)	• Expanded CHC theory to include 16 broad abilities and over 80 narrow abilities (Schneider & McGrew, Chapter 4). • Emphasized the relevance of the XBA approach for augmenting stand-alone batteries (e.g., McCallum & Bracken, Chapter 14).
Flanagan, Ortiz, and Alfonso (2013)	• Expanded coverage of CHC theory to include abilities not measured by most major intelligence and cognitive batteries (e.g., Gh, tactile abilities; Gk, kinesthetic abilities). • Incorporated and integrated all then-current intelligence batteries (i.e., WJ III, WPPSI-III, WISC-IV, SB5, KABC-II, DAS-II, and WAIS-IV), tests of academic achievement, and selected neuropsychological instruments.

(continued)

TABLE 27.7. *(continued)*

Source	Contribution
Flanagan, Ortiz, and Alfonso (2013) *(continued)*	• Provided a stronger emphasis on using actual norms when available. • Included more stringent guidelines for averaging subtest scores from the same or different batteries under specific circumstances. • Summarized current research on the relations between cognitive abilities and processes and academic skills, and placed even greater emphasis on forming CHC narrow-ability clusters, given their importance in understanding academic outcomes. • Revised the DMIA to incorporate and integrate all features of the XBA approach and to include interpretive statements. It also included tabs for all current intelligence batteries, major achievement tests (e.g., WJ III ACH), and co-normed (e.g., KABC-II and KTEA-II) or linked (WISC-IV and WIAT-III) batteries. Additionally, the DMIA now used a variety of criteria to determine cohesiveness of within-battery clusters. • Revised the SLD Assistant to include a psychometrically defensible analysis of an individual's pattern of strengths and weaknesses. • Revised and updated the C-LIM to include current cognitive tests, special-purpose tests, and selected neuropsychological instruments. The C-LIM now provided additional features for evaluating individuals based on varying levels of language proficiency, acculturative knowledge, and/or giftedness. The C-LIM also allowed for an examination of cognitive performance by the influences of language or culture independently. • Classified current cognitive batteries according to neuropsychological domains of functioning (e.g., sensory–motor, visual–spatial, speed and efficiency, executive). • Included examples of how the XBA approach could be used within the context of various state and district criteria for SLD identification. • Included guidelines for linking findings of cognitive weaknesses or deficits to intervention.
Cross-Battery Assessment Software System (X-BASS; Flanagan, Ortiz, & Alfonso, 2015, 2017)	• Integrated the three software programs from *Essentials of Cross-Battery Assessment*, third edition; improved upon the psychometrics of each program; and provided a means for allowing these programs to work together with the same set of data. • Used over 1,500 coefficients from the technical manuals of ability tests to calculate median reliabilities and intercorrelations that are used in formulas and analyses in the program. • Integrated the WISC-V interpreted system outlined in *Essentials of WISC-V Assessment* (Flanagan & Alfonso, 2017) and allowed for a customized summary report of findings for each examinee. • Incorporated the most psychometrically sophisticated pattern of strengths and weaknesses analysis currently available for assisting in making decisions about SLD. • Allowed for the software to be used with single-battery or cross-battery data. For example, if a single battery provides sufficient data for the PSW analysis, then the analysis will be conducted automatically. In most comprehensive evaluations for SLD, however, cross-battery data are gathered and therefore used in the PSW analysis in the software. • Includes a PSW interpretive summary report.
Flanagan & McDonough (2018)	• Includes the latest revisions and refinements to CHC theory (Schneider & McGrew, Chapter 3, this volume). • Emphasizes the relevance of the XBA approach for augmenting stand-alone batteries (e.g., McCallum & Bracken, Chapter 16, this volume). • Emphasizes the use of XBA data for a PSW analysis following the Dual Discrepancy/Consistency model (Flanagan et al., Chapter 22, this volume). • Demonstrates how to use X-BASS to facilitate use and interpretation of the XBA approach (Flanagan et al., Chapter 27, this volume).

CHAPTER 28

Linking Cognitive Abilities to Academic Interventions for Students with Specific Learning Disabilities

Nancy Mather
Barbara J. Wendling

An understanding of the relationships among cognitive abilities and achievement can help an evaluator make informed decisions regarding the choice of assessment tools, the type of diagnosis, the selection of accommodations, and the choice of instructional methodologies. In addition, cognitive assessment data are critical for the identification and understanding of specific learning disabilities (SLD). The definition of SLD indicates that a significant weakness exists in some aspect of basic psychological processing that is affecting learning and interfering with academic progress. Therefore, in this chapter we focus on (1) the cognitive abilities that are most commonly measured by various assessment instruments, (2) the ways these constructs relate to SLD, and (3) the possible instructional implications. We begin by discussing some general issues.

GENERAL ISSUES

In the current educational environment, psychologists and diagnosticians may encounter four general issues related to cognitive assessments of students with SLD: (1) the role of response to intervention (RTI), (2) the rationale for understanding the cognitive correlates of an academic area, (3) the need for and provision of differentiated instruction, and (4) the importance of establishing a *pattern of strengths and weaknesses* (PSW) for the determination of SLD.

The Role of RTI

The reauthorization of the Individuals with Disabilities Education Improvement Act of 2004 (IDEA 2004) eliminated the requirement of establishing an ability–achievement discrepancy for determining the presence of an SLD and offered other alternative procedures. One alternative approach permits the use of limited response to evidence-based instruction as *part* of the process. This process of documenting progress on interventions has been referred to as *response to intervention* (RTI). For those embracing an RTI model, the results from cognitive assessments may seem to be irrelevant for both identification and instructional planning. Another approach, which is often referred to as the *third method,* allows for the use of alternative research-based methods. This procedure is most often implemented by using a PSW approach to establish the presence of an SLD. Professionals implementing a PSW approach typically use both cognitive and academic assessments.

According to a Response to Intervention Adoption Survey (Spectrum-K12, 2011), 94% of schools surveyed reported implementing some level of RTI back in 2011. This represented an increase from 72% in 2009. Sixty-six percent of schools surveyed reported using RTI as part of the process for determining eligibility for special education—a 25% increase from 2010. As of 2013, 17 states required schools to use an RTI process to help determine which students are eligible for special education, and every state mentions RTI in their regulations (Hauerwas, Brown, & Scott, 2013). With the increase in districts implementing RTI and using RTI as part of the eligibility determination process, evaluation professionals have to consider the role of cognitive assessment. Does cognitive assessment add anything meaningful to the identification process or to instructional planning? Maybe it is not a question of either/or.

Most professionals supporting the role of cognitive assessment also encourage the use of RTI (e.g., Hale, Kaufman, Naglieri, & Kavale, 2006). Most practitioners agree that RTI has value as an instructional model of early intervention and prevention. The disagreement arises when professionals suggest that RTI be used as the sole identification or diagnostic model for determining the presence of SLD. Although an RTI process can help document whether a student is making adequate progress, this information is insufficient for the diagnosis of a disability.

RTI is not a diagnostic model, but rather focuses on analysis of groups or grade levels of students and treats them in the same manner: It is a "one-size-fits-all" approach (Wodrich, Spencer, & Daley, 2006). In contrast, special education is focused on addressing the needs of a specific individual; it is a "one-size-fits-one" approach. To design an individualized approach, an evaluator must first understand an individual's unique strengths and weaknesses. Thus many psychologists and diagnosticians are shifting their focus from the use of full-scale intelligence scores to a more in-depth analysis of an individual's specific abilities. Today's cognitive assessments, as well as the approaches to assessment, are more theory-based and more diagnostic, helping practitioners explore and document an individual's unique strengths and weaknesses.

Each of the methods for SLD identification has both positive and negative aspects, and skilled evaluators consider additional factors beyond test scores and RTI data. As Kovaleski and colleagues (2015) explained, "Knowledgeable practitioners also use clinical judgment to determine which approach is applicable for a given child or in a given school setting. While regulations and policies require school districts to implement a single approach, best practice may reside somewhere in the margins with a hybrid model" (p. 6). Professional judgment is used to (1) investigate a learning problem before testing is conducted; (2) modify a test selection plan during test administration; and (3) determine, after the initial assessment, whether additional testing is needed to clarify the nature of the learning problem (Schrank, Stephens, & Schultz, 2016).

For the results of cognitive tests to be useful, the focus must be on obtaining information that is relevant to academic performance and instruction. Even though a student may be deemed ineligible for certain services, all evaluations need to address the referral concerns and propose solutions. As Cruickshank (1977) noted, "Diagnosis must take second place to instruction, and must be a tool of instruction, not an end in itself" (p. 194). Within the field of SLD, the purpose of testing cognitive abilities is to determine a person's unique abilities and identify the underlying cognitive weaknesses that are often directly linked to the specific weaknesses in achievement. Therefore, it is important to identify the areas of strength and weakness, in order to individualize educational planning for students who do not respond adequately to intervention (Kavale & Flanagan, 2007). From the perspective of making an accurate SLD diagnosis, understanding *why* a student is not responding adequately does indeed matter, and the results from cognitive assessments often help to provide the necessary insights (Mather & Kaufman, 2006). As noted by McCloskey, Whitaker, Murphy, and Rogers (2012), "The nature of a tier 3 referral makes it imperative that the specific cognitive strengths and weaknesses of the student and their impact on learning and production be clearly specified" (p. 870). (See also McCloskey, Slonim, & Rumohr, Chapter 39, this volume).

Although these legal changes in identification procedures have created uncertainty and disequilibrium in the field, they have also led to a greater interest in understanding the relationships among cognitive abilities and achievement. Implementation of a simple discrepancy formula for SLD identification was inadequate for determining eligibility and insufficient for informing instructional planning. Although little research supports the use of IQ–achievement discrepancy, 67% of states still allow practitioners to use an ability–achievement discrepancy in identifying SLD (Maki, Floyd, & Roberson, 2015).

In today's educational world, professionals must assess, explore, and understand an individual's profile of cognitive, linguistic, and academic strengths and weaknesses to inform both eligibility determinations and instructional planning. Individualized education program (IEP) teams can make informed decisions about the educational program for a specific student by linking assessment to interventions (Maricle & Johnson, 2016). So, now more than ever, a need exists for understanding how various cognitive abilities are related to school achievement.

Understanding the Cognitive Correlates of Academic Areas

A growing body of research supports the usefulness of factor or specific ability scores in identifying the cognitive processing problems that specifically inhibit academic development (e.g., Cormier, McGrew, Bulut, & Funamoto, 2017; Fiorello, Hale, & Snyder, 2006; Flanagan, Ortiz, & Alfonso, 2013; McGrew & Wendling, 2010; Moats & Tolman, 2009). As examples in math achievement, weaknesses in number sense characterize many students with mathematical difficulties (Jordan, Fuchs, & Dyson, 2015). The most commonly studied cognitive abilities related to math achievement are working memory, processing speed, and general intelligence (Geary, Hoard, & Bailey, 2011; Peng, Wang, & Namkung, 2018). For example, research indicates that as working memory capacity increases, students become more effective in solving math word problems (e.g., Swanson, 2014; Zheng, Swanson, & Marcoulides, 2011). Also, researchers have identified fluid reasoning as an important correlate of math reasoning (e.g., Geary, Hoard, Byrd-Craven, Nugent, & Numtee, 2007; Hale, Fiorello, Kavanagh, Holdnack, & Aloe, 2007).

In reading, Adams (1990) found that a child's level of phonemic awareness in kindergarten was the best predictor of reading success in elementary school. Over the last two decades, numerous researchers have confirmed the importance of phonemic awareness to the development of basic reading skills (e.g., Berninger et al., 2006; Cooper, 2006; Cormier et al., 2017; Feifer, 2011; Shaywitz, Morris, & Shaywitz, 2008; Torgesen, 2002; Vellutino, Tunmer, Jaccard, & Chen, 2007). Others have described the relationship between slow rapid automatized naming (RAN) and poor reading (e.g., Berninger et al., 2006; Denckla & Rudel, 1974; Norton & Wolf, 2012; Swanson, Trainin, Necoechea, & Hammill, 2003; Torgesen, 1997; Wolf, Bowers, & Biddle, 2000). Still others have described the significant relationships between working memory and reading comprehension (e.g., Cooper, 2006; Swanson, 1999, 2000; Torgesen, 2002) and between fluid reasoning and reading comprehension (e.g., Cormier et al., 2017). In a recent study that explored the relationships between cognitive abilities and reading comprehension across a large sample of children ($N = 835$) in grades 1–5, the importance of specific cognitive abilities (e.g., auditory processing, long-term retrieval, fluid reasoning) varied across grade levels; however, vocabulary and general knowledge were significant at all levels (Decker, Strait, Roberts, & Wright, 2017).

In regard to reading development, similar difficulties have been observed in both children and adults. For example, in a meta-analysis of reading research, Swanson and Hsieh (2009) found that the cognitive processes of phonological skills, verbal memory, naming speed, and vocabulary all made significant contributions to reading disabilities in adults.

Early identification of students at risk for academic failure continues to be a primary goal of all educators. This desire for early identification fuels the research into the causes of academic failure and seeks to determine the predictive value of specific cognitive and linguistic factors that may be considered "precursors to manifest disabilities" (Fletcher et al., 2002, p. 51). Ideally, a predictor or subset of predictors will accurately differentiate between the children who will struggle with certain academic subjects and those who will not, so that intervention efforts can be initiated early in a timely fashion (Bishop, 2003). Researchers continue to document the relationships among specific cognitive, linguistic, and academic abilities, identifying prerequisite skills and delineating early indicators of risk.

Many investigators have encouraged the early assessment of cognitive abilities to identify children who are at risk for reading disabilities (e.g., Berninger et al., 2006; Fuchs et al., 2005; Hirsch, 2013; Torgesen, 2002). For example, Carroll, Solity, and Shapiro (2016) investigated which cognitive abilities were the best predictors of poor reading in later grades. As was expected, print knowledge, verbal short-term memory, phonological awareness, and rapid naming were all good predictors of later poor reading. In addition, weaknesses in visual search and auditory processing were present in a large minority of the poor readers. Nearly all of the poor readers had a deficit in at least one cognitive area upon school entry, but no single deficit characterized the majority of poor readers. Thus several relevant cognitive abilities can be assessed before students learn to read, such as phonemic awareness, RAN, and short-term memory; at-risk students can thereby be identified at a very young age—even before they experience reading difficulties. Exploring cognitive abilities can also help with establishing a PSW that is relevant to identifying an SLD, trying to understand why a student fails to make adequate progress, and/or planning the most effective instructional programs. The evolution and refinement of theory- and research-based tests measuring multiple abilities have given professionals the opportunity to gain a better understanding of an individual's unique characteristics.

Need for and Provision of Differentiated Instruction

Differentiated instruction is not a program, but a way of teaching. Because all students are not alike, a teacher plans varied approaches to address what individual students need to learn, how they will learn it, and how they will demonstrate what they have learned, thus increasing the likelihood that each student will learn as much as possible (Tomlinson, 2006). Responsive teaching is a simple definition of differentiated, prescriptive instruction. With the growing diversity of the U.S. population and the increased demand for accountability in education, the need to accommodate individual learners has intensified in general education.

Although educators widely embrace the concept of meeting individual students' needs, nearly 40% of new teachers (ones with 4 years or less of teaching experience) responding to the 2012 Schools and Staffing Survey did not feel adequately prepared to implement differentiated instruction (National Center for Education Statistics, 2012). This lack of teacher preparation stems in part from the failure of teacher training programs to integrate recommended methodologies and strategies into the required courses (Elksmin, 2001; Whitaker, 2001). To address these shortcomings, the U.S. Department of Education is drafting regulations for teacher preparation programs, with full implementation called for by 2020. (See *www.ed.gov/teacherprep*.)

Unfortunately, even in special education, many students with IEPs receive the same treatment goals and teaching strategies as their normally achieving peers (Reynolds & Lakin, 1987). To explore the implementation of differentiated instruction, Schumm, Moody, and Vaughn (2000) interviewed third-grade teachers who served students with SLD in inclusive classrooms. Overall, the teachers reported using whole-class instruction that included the same materials for all students, regardless of performance levels. All students were expected to read grade-level materials, even if they could not pronounce the words. Furthermore, students with SLD did not receive instruction directed at improving their word analysis skills. One teacher actually voiced strong opposition to providing instruction in word analysis, stating, "By the time they come to third grade they really should have those skills" (quoted in Schumm et al., 2000, p. 483). With undifferentiated instruction and minimal direct instruction in reading, the students with SLD made little academic improvement, and their attitudes toward reading declined as well.

Historically, the field of SLD has been based on the belief that children differ in their abilities and therefore should be taught and treated differently (Kavale & Forness, 1998; Whitener, 1989); this belief led to the requirement that an IEP must be developed for each student eligible for special education services. As Moats (2015) has noted, "Meeting the needs of students across the spectrum of academic ability . . . requires acceptance of diversity . . . To use one yardstick to measure student growth, one set of standards to drive what is taught, and one view of academic success is indefensible" (p. 22). A student who has difficulty memorizing information requires a different type of instruction than the student who memorizes facts easily. A student who works slowly needs more time than a student who works rapidly. A student who struggles to pay attention requires more novelty and structure than one who attends easily. In some cases, these marked differences in learning and behavior are neurologically based (Semrud-Clikeman et al., 2000; Shaywitz, 1998, 2003; Shaywitz et al., 2003). Clearly, for students with SLD, differentiated instruction that addresses their specific problems will be more effective than global approaches that do not (Aaron, 1997). Some believe that the lack of individualization in special education is a result of the current emphasis on and push for full inclusion. Hallahan and Cohen (2008) cautioned:

> Students with learning disabilities are not receiving special education, which is based on the core principles of intensive, relentless, structured, appropriately paced instruction in small groups with frequent monitoring of each student's progress. We believe

> that the diminution of special education for students with learning disabilities has occurred because of the well-meaning, but misinformed, overly zealous adoption of inclusive educational practices. (p. 3)

Determining a PSW

As mentioned previously, IDEA 2004 states that alternative research-based methods, such as a PSW approach, can be employed to determine eligibility for SLD services. Currently, however, there is debate about the effectiveness of various PSW methods for the identification of SLD. Proponents of using PSW methods state that identifying patterns of strengths and weaknesses helps explain low achievement, can inform instructional planning, and helps differentiate students with SLD from slow learners (Flanagan, Fiorello, & Ortiz, 2010; Naglieri & Otero, 2012; Schultz, Simpson, & Lynch, 2012). Others argue that current PSW methods do not reliably identify SLD (Kranzler, Floyd, Benson, Zaboski, & Thibodaux, 2016; Stuebing, Fletcher, Branum-Martin, & Francis, 2012; Taylor, Miciak, Fletcher, & Francis, 2017). Although one particular PSW method (e.g., Hale & Fiorello's [2004] concordance–discordance method, Flanagan et al.'s [2013] dual-discrepancy/consistency method, Naglieri's [2011] discrepancy–consistency method) may not always reliably identify individuals with SLD, helping practitioners explore significant intraindividual variations, or the differences among abilities, is precisely how intelligence tests can contribute to SLD determination and educational planning. To be most useful, the data collected from cognitive assessments must be combined with other forms of data, including achievement data, as well as the interpretive insights gained from the evaluator's clinical judgment (Schultz et al., 2012).

Assessments should then focus on understanding a person's information-processing capabilities, including the factors that can facilitate performance. As Gardner (1999) has suggested, in the study of human cognition, awareness of distinctive strengths is of critical importance. Evaluators must also understand the constraints (e.g., limited instruction, specific cognitive or linguistic weaknesses, limited cultural experiences, poor motivation) that affect performance, as well as the multidimensional impact of these constraints (Berninger, 1996). Because the various constraints affect different aspects of academic functioning, they can help inform the type and extent of accommodations and instruction needed. Interpreting intraindividual variations and determining how these differences affect performance then become the cornerstones for linking the results of cognitive ability tests to meaningful interventions. To do this in a valid manner, assessment professionals must know the existing research on the relationship between cognitive abilities and achievement, and must incorporate that knowledge into their decision-making process.

One basic concept underlying identification of SLD is that a student's difficulty does not extend too far into other domains. In other words, the problem is relatively specific, circumscribed, or domain-specific (Stanovich, 1999). This concept of specificity, a main tenet of SLD, is not new. For example, Travis (1935) observed that in some students, a striking disparity exists between achievement in one area and achievement in another. For example, a student may struggle with reading, but can easily comprehend material that is read aloud; or a student excels in reading and writing, but struggles with mathematical concepts and applications. These children, who do not achieve as well as would be expected in one or more areas of performance, may be regarded as having a "special defect or disability" (Travis, 1935, p. 43).

To maintain this concept of specificity, the academic problem is best described as a specific reading disability, math disability, or spelling disability that is associated with weaknesses in specific cognitive or linguistic processes. The first part of an evaluation is then to determine an initial domain-specific classification (Stanovich, 1999); the next part is to identify the specific cognitive processes that underlie the disorder (Robinson, Menchetti, & Torgesen, 2002). An SLD is caused by one or more inherent weaknesses in underlying cognitive processes (Robinson et al., 2002). The assessment process can then be viewed as an ability-oriented evaluation designed to help formulate the problem and then determine specific interventions (Fletcher, Taylor, Levin, & Satz, 1995).

COGNITIVE ABILITIES AND ACADEMIC PERFORMANCE

As noted previously, a growing body of research links certain cognitive and linguistic factors to the various domains of achievement. The relationships between certain cognitive abilities and academic performance are well established (e.g., phonemic awareness and decoding), whereas others are not (e.g., visual processing and reading).

Furthermore, some important cognitive constructs are commonly measured on many intelligence tests (e.g., vocabulary, reasoning, and working memory), whereas others are not (e.g., phonological awareness and RAN). Even though we discuss these cognitive abilities separately, Horn (1991) admonished that attempting to measure cognitive abilities in isolation "is like slicing smoke" (p. 198). Cognitive and academic abilities are interrelated, and various combinations of abilities are employed as an individual completes specific tasks. Therefore, when studying and diagnosing complex learning disorders, evaluators need to embrace a multiple-deficit approach (Carroll et al., 2016; McGrath et al., 2011; Pennington, 2006).

Consider the various skills required to take notes while listening to a lecture. The note taker must pay attention, have knowledge of the topic, understand the vocabulary, use memory to hold on to and paraphrase the important points, and then record these thoughts in writing. A student may struggle with note taking for any or all of these reasons. In addition, the prediction of performance for students with SLD may be improved when several factors are considered (Gregg, Davis, Coleman, Wisenbaker, & Hoy, 2004). For example, when combined, measures of working memory and language comprehension appear to provide the best prediction of reading comprehension ability (Daneman & Carpenter, 1980).

In some circumstances, something influences performance other than what a test was designed to measure. Stern (1938) noted: "It should never, of course, be supposed possible to test a definite, narrowly circumscribed separate capacity of thought with any one of these tests. Other abilities are always involved" (p. 315). He continued:

> Yet this is in no sense to be construed as a defect in the tests. On the contrary, they provide a favorable opportunity for observing the process of thinking in all its complexity. One must not be content to calculate the score for each performance. A completed test, which according to the system of scoring is thrown out as erroneous or deficient in performance, may very frequently result from the fact that *other* kinds of thinking than those expected have intervened, but which may have significance in terms of the subject's particular intellectual approach. (p. 316; original emphasis)

Thus Stern emphasized that intelligence tests are valuable beyond the mere production of scores because careful observation during performance and analysis of the psychological processes that led to the test answers can deepen an evaluator's insight into the structure and functioning of cognitive abilities. Accordingly, we reemphasize the value of forming, exploring, confirming, or rejecting diagnostic hypotheses that are based on test scores; careful, systematic observations of behavior; and prior history.

Vocabulary, Acquired Knowledge, and Language Comprehension

Unless they are designed primarily to measure nonverbal abilities, most intelligence batteries contain measures of vocabulary, acquired knowledge, and language comprehension. Often described as *crystallized intelligence, Gc, verbal or oral language abilities,* or *stores of acquired knowledge,* these abilities are highly correlated with achievement and are good predictors of academic success (Anastasi, 1988; Hirsch, 2013; Niileksela, Reynolds, Keith, & McGrew, 2016; Sinatra, Zygouris-Coe, & Dasinger, 2011). Ample evidence supports the finding that increasing a child's general knowledge and vocabulary before age 6 is the single highest correlate with later school success (Hirsch, 2013). Because most of the measures of crystallized intelligence rely on language, crystallized intelligence can be equated with verbal intelligence (Carroll, 1993; Hunt, 2000) and is often used as a key indicator of giftedness (Benbow & Lubinski, 1996; National Association for Gifted Children, 2010). These types of tests typically measure general aspects of cultural knowledge, rather than specialized knowledge specific to a domain, such as the rules for soccer. Because of the cultural and linguistic content of these tasks, evaluators must use caution when testing and interpreting the performance of individuals from different linguistic or cultural backgrounds, such as English-language learners (ELLs). Poor performance may be the result of limited exposure and/or opportunities, rather than a general weakness in word and world knowledge.

These linguistic abilities are related to most areas of academic performance across the lifespan. Verbal abilities and background knowledge have a strong and consistent relationship with reading (e.g., Beck & McKeown, 2007; Cooper, 2006; Cormier et al., 2017; Decker et al., 2017; Kintsch & Rawson, 2005; Nation, 2007; Perfetti & Stafura, 2014; Reynolds & Turek, 2012; Shaywitz et al., 2008), mathematics (Floyd, Evans, & McGrew, 2003; Gelman & Butterworth, 2005; Swanson & Jerman, 2006), and writing (Berninger, 2009; Cormier, Bulut, McGrew, & Frison, 2016; McCloskey, Perkins, & Van Divner, 2009; Stoeckel et al., 2013).

The most fully substantiated relationship is with reading comprehension and written expression. Decker and colleagues (2017) found that crystallized knowledge was a common cognitive contributor to reading comprehension across all of the elementary grades. Both reading comprehension and written expression depend on background knowledge, which enables a person to understand and create messages, interpret sentence structures, use verbal reasoning abilities, and employ a broad and deep vocabulary (McCardle, Scarborough, & Catts, 2001; Nation, Clarke, & Snowling, 2002). Words and the concepts they represent are thus the building blocks of literacy (Bell & Perfetti, 1994; Cunningham, Stanovich, & Wilson, 1990; Perfetti, Marron, & Foltz, 1996; Sinatra et al., 2011). In addition to vocabulary and background knowledge, researchers have identified other verbal abilities that are frequently weaknesses for individuals with reading comprehension difficulties: listening comprehension (Biemiller, 2003; Nation, Clarke, Marshall, & Durand, 2004), figurative language (Cain, Oakhill, & Lemmon, 2004), grammar (Nation & Snowling, 2000), and oral expression (Nation et al., 2004). Unlike other cognitive abilities, crystallized intelligence has been described as a maintained ability rather than a vulnerable ability because it continues to develop until midlife and does not decline with age as significantly as other cognitive abilities (Horn, 1991). On growth curves, the rate of growth for crystallized intelligence is much greater than for other abilities, and it shows a less rapid rate of decline (McGrew, LaForte, & Schrank, 2014).

Reasons for Differences in Performance

Some people will demonstrate a weakness on verbal ability tests because of language impairments, whereas others will have weaknesses due to limited experiences with language and/or a lack of educational experiences and opportunities (Carlisle & Rice, 2002). In addition, tests of general knowledge, vocabulary, and language comprehension most often reflect the culture and language of the norm group. Therefore, individuals from diverse cultural and/or linguistic backgrounds or from families of low socioeconomic status (SES) often obtain lower scores on measures of acquired knowledge. A child's language acquisition is influenced by the parents' attained level of education and the family's SES, as well as by exposure to early literacy and language activities (Hart & Risley, 1995).

Vocabulary access is influenced by three main factors: (1) familiarity with words, (2) the depth of conceptual understanding of those words, and (3) the ability to retrieve words as needed (Gould, 2001). A student may understand a word's meaning, but have difficulty using the word correctly when speaking. These word-finding or word-retrieving difficulties may also negatively influence performance on the verbal subtests found in many intelligence measures, particularly if the measure is timed. If a student obtains a low score on a vocabulary measure, the evaluator must determine whether that low score is a result of limited verbal knowledge, limited cultural experiences, or difficulty in retrieving verbal labels (a problem more closely linked to associative memory).

Implications for Achievement

Since many academic tasks require linguistic competence, individuals with low verbal abilities are likely to encounter academic difficulties in most areas and will need increased opportunities and experiences to improve linguistic abilities, including increasing the depth and breadth of their vocabulary and world knowledge. Early intervention that develops vocabulary knowledge is crucial to future academic success (Sinatra et al., 2011). Many children, especially those from low-SES communities, enter school with limits in their oral language. In general, students who have difficulty understanding or using spoken language will have difficulty with the aspects of reading, writing, and mathematics that depend on language-specific processes, such as reading comprehension, written expression, and math problem solving. These abilities require the integration of many skills. As an example, Moats and Daken (2008) explain the many components of written expression as follows:

> The ability to compose and transcribe conventional English with accuracy, fluency, and clarity of expression is known as basic writing skills. Writing is dependent on many language skills and processes and is often even more problematic for children than reading. Writing is a language discipline with many component skills that must be directly taught. Because writing demands using different skills at the same time, such as generating language, spelling, handwriting, and using capitalization and punctuation, it puts a significant demand on working memory and attention. Thus, a student may demonstrate mastery of these individual skills, but when asked to integrate

> them all at once, mastery of an individual skill, such as handwriting, often deteriorates. To write on demand, a student has to have mastered, to the point of being automatic, each skill involved. (p. 55)

Because reading comprehension and written expression share many of the same cognitive and linguistic processes, individuals frequently have difficulties in both areas. For example, a study of individuals with writing disabilities found that 75% of the sample also had reading difficulties (Katusic, Colligan, Weaver, & Barbaresi, 2009). As noted previously, both reading comprehension and written expression require vocabulary and background knowledge—in other words, they are built upon a solid foundation of oral language. Early deficits in vocabulary have been identified as a risk factor for later reading problems (Coyne, Simmons, Kame'enui, & Stoolmiller, 2004). A growing body of research illustrates the relationship between academic vocabulary interventions and improvement in comprehension (Lawrence, Rolland, Branum-Martin, & Snow, 2014; Lesaux, Kieffer, Kelley, & Harris, 2014; Townsend & Collins, 2009). Researchers have also established that the primary differences between individuals with good reading comprehension and those with poor reading comprehension are differences in verbal ability (Floyd, Bergeron, & Alfonso, 2006).

In discussing the reasons for reading comprehension failure, Perfetti and colleagues (1996) distinguished between the processes involved in comprehension (e.g., working memory and comprehension monitoring) and knowledge—which includes word meanings or vocabulary, as well as domain knowledge (i.e., the concepts specific to a domain, such as physics, biology, or history). Clearly, knowledge is an important component underlying reading comprehension that contributes to individual differences in reading (Hannon & Daneman, 2001; Oslund, Clemens, Simmons, Smith, & Simmons, 2016). A person's level of acquired knowledge, including domain knowledge obtained through life experiences, school, or work, is highly predictive of academic performance. Breadth and depth of knowledge and a robust oral vocabulary suggest that the person will excel on tasks involving language-learning abilities, whereas limited knowledge and a poor vocabulary suggest that the person will struggle.

In the simple view of reading (Gough & Tunmer, 1986), reading ability equals the product of decoding and linguistic comprehension. The equation used to represent this simple view is $R = D \times C$. Within this model, decoding is measured by the ability to pronounce pseudowords, and linguistic comprehension is assessed by a test of listening comprehension. If either decoding or linguistic comprehension is impaired, reading performance is compromised. Within this framework, Gough and Tunmer proposed three types of reading disabilities: inability to decode (dyslexia), inability to comprehend (hyperlexia), or both ("garden-variety" poor reader). The results of a large-scale study support the simple view of reading with poor reading comprehension associated with inadequate decoding, vocabulary, or both (Spencer, Quinn, & Wagner, 2014). In the absence of poor word recognition skills, a language-based problem is at the core of reading comprehension difficulties (Oakhill & Cain, 2016; Spencer et al., 2014).

Individuals with specific reading disabilities, or dyslexia, typically have verbal abilities that are more advanced than their decoding skills. Essentially, what distinguishes individuals with reading disabilities from other poor readers is that their listening comprehension ability is higher than their ability to decode words (Rack, Snowling, & Olson, 1992). Listening comprehension is frequently cited as a good predictor of reading comprehension (Aaron & Joshi, 1992; Cooper, 2006; Hammill, 2004). Thus measures of verbal abilities, including listening comprehension, can be used to provide the best estimates of how much poor readers would profit from written text if their deficient decoding skills were resolved (Stanovich, 1999). Caution is needed, however, because measures of verbal ability and listening comprehension may underestimate potential for achievement among students with attention or language-processing problems, as well as among students for whom English is a second language (Berninger & Abbott, 1994; Fletcher et al., 1998).

Beyond third grade, individuals with good verbal ability and good reading skills acquire knowledge and new vocabulary primarily through reading. In contrast, individuals with good verbal ability but poor reading skills are much more likely to learn new vocabulary through oral discussions (Carlisle & Rice, 2002). Unfortunately, since reading rather than listening is used to acquire more complex syntax and abstract vocabulary, poor readers tend to fall behind good readers on verbal tasks as they progress through school. Since many intelligence tests include vocabulary measures, a poor reader's relative standing on the verbal scores may decline when compared to that of normally achieving peers. As a result, poor language contributes to a lower ability score, as well as to poor reading (Fletcher et al., 1998; Strang, 1964).

Thus reading experience influences verbal intelligence test scores. In addition, cognitive and academic tests assess many of the same underlying abilities (e.g., vocabulary, general information) (Aaron, 1997). Older students with reading difficulties may have depressed performance on measures of verbal intelligence and reading because of limited experiences with text. Several decades ago, Strang (1964) summarized this problem as follows:

> Intelligence tests are not a sure measure of innate ability to learn. They measure "developed ability," not innate or potential intelligence. Previous achievement affects the test results. The poor reader is penalized on the verbal parts of the test. The fact that his store of information is limited by the small amount of reading he has done also works against him. (p. 212)

For students with reading disabilities, limited print exposure contributes to reduced knowledge and vocabulary, and these deficiencies are likely to increase over time (Vellutino, Scanlon, & Lyon, 2000). This phenomenon has been referred to as the "Matthew effect," which is described in sociology when discussing economic inequality as "the rich get richer and the poor get poorer" (Stanovich, 1986; Walberg & Tsai, 1983). Limited reading alters the course of development in education-related cognitive skills (Stanovich, 1993). In other words, a reading difficulty leads to less time spent reading, which in turn contributes to lower verbal ability and knowledge. The relationship between good reading skills and the development of reading-related cognitive abilities has been described as the "virtuous circle" (Snowling & Hulme, 2011). On the other hand, the "vicious circle" includes students who fail to develop reading skills, tend to avoid reading, and do not develop reading-related and cognitive abilities, all of which limits both cognitive and academic development (Pulido & Hambrick, 2008).

Verbal ability has also been identified as a strong predictor of math performance (Hale, Fiorello, Kavanagh, Hoeppner, & Gaither, 2001) and has been linked to early math achievement, especially to the development of number concepts (Carey, 2004; Gelman & Butterworth, 2005). The importance of verbal ability for math performance appears to increase with age and is most likely related to the increased linguistic demands of complex problem solving (Fuchs et al., 2006, 2008; Geary, 1994; McGrew & Wendling, 2010). Individuals with a math disability tend to score lower on verbal ability measures than typical age peers (Proctor, Floyd, & Shaver, 2005) and have limited oral language abilities (Fuchs et al., 2008). In addition, individuals with low verbal ability often experience problems in both math and reading, whereas those with more intact verbal abilities have problems that are more specific to math.

Interventions for Limited Verbal Ability

An individual with limited knowledge or vocabulary is likely to experience difficulty acquiring new knowledge or vocabulary, unless the new information is connected to prior knowledge (Beck, Perfetti, & McKeown, 1982). Instruction needs to build on prior knowledge and may need to be modified so that it occurs at the individual's language level. One finding from a meta-analysis of the impact of vocabulary instruction was that students with reading difficulties who received vocabulary instruction benefited three times as much as those who did not (Elleman, Lindo, Morphy, & Compton, 2009).

The National Reading Panel (NRP, 2000) found that individuals with limited vocabulary benefit from a variety of approaches, and that no one single approach is best for everyone. Some of the most effective instructional approaches for building vocabulary include both direct and indirect methods, such as reading aloud to students, providing explicit vocabulary instruction, and encouraging wide reading. Ideally, an individual's home and school environments are language-rich, with many opportunities and experiences to reinforce learning. A variety of strategies can be used to help students understand the nature of related words and concepts, such as semantic feature analysis, word webs, and graphic organizers. One important way language develops is through social interactions with more knowledgeable language users (Vygotsky, 1962). As teachers and students work together to attain educational goals, they can model the process of learning by talking about these processes as they perform tasks. Thus modeling and thinking aloud are useful for promoting language development. Research has also focused on the importance of developing academic vocabulary by emphasizing orthographic and morphological instruction (Nagy & Townsend, 2012; Townsend, Bear, Templeton, & Burton, 2016; Uccelli, Phillips Galloway, Barr, Meneses, & Dobbs, 2015). To further aid instruction, Gardner and Davies (2014) have identified the highest-frequency words within specific disciplines (the language of math, history, science, etc.). Swanson, Vaughn, and Wexler (2017) described numerous strategies for enhancing the vocabulary knowledge of adolescents.

A reciprocal relationship exists between learning to read and learning to write (Ehri, 2000), so instruction is more effective when these skills are taught in an integrated manner (Clay, 1982). Reading has been referred to as "language by eye," and writing as "language by hand" (Berninger, 2000; Berninger & Graham, 1998), further connecting the two achievement domains. As discussed, individuals with limited verbal ability will struggle primarily with reading comprehension and written expression. Although these individuals may experience success with lower-level skills, such as spelling or handwriting, their limits in language will interfere with the acquisition of higher-level skills, including vocabulary development, reading comprehension, sentence formulation, and written expression. Thus instruction should focus on increasing vocabulary, as well as both declarative and procedural knowledge (Perfetti & Stafura, 2014).

Although math is considered a less "verbal" achievement area, its demands on language and acquired knowledge are quite significant. Math requires knowledge of content-specific concepts and vocabulary, as well as the ability to understand story or word problems. Supporting the role of verbal ability in math, difficulty with math problem solving has been associated with deficient oral language abilities (Fuchs et al., 2008). In addition, conceptual knowledge of numbers and their relationships is another important correlate of math achievement (Hecht, Close, & Santisi, 2003). Explicit instruction, concrete examples, and guided practice are important for developing math vocabulary and concepts. The concrete–representational–abstract teaching sequence is beneficial for individuals struggling with mathematics. In this teaching sequence, the concrete level involves the use of objects or manipulative devices; the representational level involves visual representations, such as tallies or pictures; and the abstract level involves the use of actual numbers and equations.

Phonological Processing

Phonological awareness, another component of oral language, is important to an understanding of reading, writing, and even math disabilities. *Phonological awareness* refers to the ability to attend to various aspects of the sound structure of speech, whereas *phonemic awareness* refers to the understanding that words can be divided or segmented into phonemes, the individual speech sounds. The importance of phonological processing for promoting reading and spelling achievement has been extensively documented (e.g., Ehri, 1998; Fletcher, Lyon, Fuchs, & Barnes, 2007; Niileksela et al., 2016; Perfetti, 2011; Shaywitz, 2003; Snow, Burns, & Griffin, 1998; Torgesen, 1998; Uhry, 2005). Rack, Snowling, and Olson (1992) hypothesized that phonological awareness underlies the establishment of the graphemic memory store that is required for written language. Supporting this hypothesis, others have found that poor phonological processing interferes with the development of phoneme–grapheme mapping (Kilpatrick, 2015; Noble & McCandliss, 2005). Because phonological awareness abilities are known to be prerequisites for success in word reading and spelling, they should be assessed early, especially in cases where a child is developing slowly in word identification or spelling skill.

The role of phonological processing in math achievement is not as well documented as it is for reading, although phonological processing appears to correlate with math achievement (e.g., Hecht et al., 2003; McGrew & Wendling, 2010; Rasmussen & Bisanz, 2005). Geary (2007) found that individuals with comorbid reading and math difficulties often display phonological processing problems. Some researchers suggest that it plays a role in forming and encoding accurate phonological representations of math facts in working memory (Logie, Gilhooly, & Wynn, 1994; Swanson & Jerman, 2006). Peng and colleagues (2018) found that weaknesses in phonological processing and attention were more severe in younger students than older students with math disabilities.

Reasons for Differences in Performance

Cultural and linguistic differences have an impact on the development of phonological awareness. Individuals who have had limited exposure to the sounds of the English language, have limited oral language, have not been read to during the preschool years, and/or come from low-SES homes may have difficulty discriminating, rhyming, and manipulating speech sounds. They may also have difficulty repeating nonwords, which measures both phonemic sensitivity and phonological short-term working memory capacity (Schrank, Decker,

& Garruto, 2016). Older students may have mastered the more rudimentary skills of rhyming, blending, and segmenting but may still have difficulty with tasks involving the manipulation of sounds (e.g., deleting, substituting; Kilpatrick, 2015).

Implications for Achievement

A weakness in phonological processing as a common factor among individuals with early reading problems has been substantiated by an impressive body of research (e.g., Ehri, 1998; Fletcher & Foorman, 1994; Shaywitz et al., 2008; Stanovich & Siegel, 1994; Torgesen, 2002; Vellutino et al., 2007). Phonological processes are critical for the development of reading and spelling skills (Adams, 1990; Goswami & Bryant, 1990; Gough, 1996; Perfetti, 2011). Results from longitudinal studies suggest that 75% of children who struggle with reading in third grade will still be poor readers at the end of high school, primarily because of problems in phonological awareness (Francis, Shaywitz, Stuebing, Shaywitz, & Fletcher, 1996; Lyon, 1998). Individuals with poor phonological abilities typically make less progress in basic word-reading skills and spelling than normally achieving peers. Even spelling problems in young adults often reflect specific problems in the phonological aspects of language (Moats, 2001, 2010).

Numerous findings have documented the neurobiological basis of reading disabilities (Ashkenazi, Black, Abrams, Hoeft, & Menon, 2013; Richlan, Kronbichler, & Wimmer, 2011; Shaywitz, 2003; Wandell, Rauschecker, & Yeatman, 2012). The evolution of functional magnetic resonance imaging technology has made it possible to discover exactly which parts of the brain are engaged during phonological tasks. Good readers engage both the front and back of the left side of the brain as they perform reading tasks, whereas poor readers appear to rely primarily on the front part of the brain. Research has also documented that effective instruction in reading creates changes in brain behavior during reading (Shaywitz, 2003); this finding further emphasizes the extreme importance of implementing high-quality early intervention.

Some children who show phonologically-based reading difficulties also exhibit difficulties in the retrieval of math facts (Ashcraft, 1987, 1992; Geary, 2007; Light & DeFries, 1995). Phonological processing is a persistent weakness in individuals with math fact fluency deficits (Chong & Siegel, 2008). Speech sound processes are used when solving math computations—for example, when counting (Bull & Johnston, 1997; Geary, 1993). Several studies have implicated phonological processing as an underlying cause of individual differences in math problem solving as well (Furst & Hitch, 2000; Gathercole & Pickering, 2000; Geary & Brown, 1991; Swanson & Sachse-Lee, 2001).

Interventions for Limited Phonological Processing

Research results indicate a causal and reciprocal relationship between phonological awareness and reading; gains in one lead to gains in the other (e.g., Castles & Coltheart, 2004; Hulme, Snowling, Caravolas, & Carroll, 2005; Muter, Hulme, Snowling, & Stevenson, 2004). Because children with poor phonological awareness can be identified before they begin learning to read (Hulme & Snowling, 2009; Wise & Snyder, 2001), early intervention is possible. Poor phonological awareness has been described as the single best predictor of risk of early reading failure (Uhry, 2005), so early evaluation is essential. The NRP (2000) identified phonemic awareness as one of the five key components to effective reading instruction. The most important early phonological ability for reading is *blending* (the ability to push together sounds), whereas the most important early ability for spelling is *segmentation* (the ability to break apart the speech sounds in a word). Explicit, sequenced, multisensory instruction at the appropriate level, delivered by highly trained teachers to groups of six or fewer, appears most effective for increasing phonological awareness (Wise & Snyder, 2001). Individuals with limited phonological processing should be exposed to a language-rich environment that includes daily practice with sounds, words, and language. Generally, phonemic awareness instruction should begin with easier tasks such as rhyming, and move to more complex tasks such as segmenting and manipulating sounds (e.g., Anthony & Francis, 2005; Kilpatrick, 2015). Reading aloud to individuals with a weakness in phonological processing and providing audio books can be two beneficial accommodations.

Once a student has learned to blend and segment sounds orally, explicit, systematic, synthetic phonics instruction is needed. This type of instruction involves the direct teaching of the relationships among the phonemes (speech sounds) and the graphemes (letters and letter strings that represent the phonemes). For students who struggle with reading, direct instruction in phoneme–

grapheme connections results in improved word reading (Jenkins & O'Connor, 2001; NRP, 2000).

Short-Term Memory and Working Memory

Two types of memory are discussed briefly in this section: *short-term memory,* or *memory span,* and *working memory.* The relationship between short-term memory and working memory has been described in three different ways: (1) the two as similar constructs; (2) working memory as a subset of short-term memory; and (3) short-term memory as a subset of working memory (Engle, Tuholski, Laughlin, & Conway, 1999). For purposes of this discussion, we address these constructs as being related but distinct.

Short-term memory is a limited-capacity system that requires apprehending and holding information in immediate awareness. It is more narrowly defined as consisting of tasks requiring storage but not a great deal of processing (Gathercole & Alloway, 2008). Most adults can hold seven pieces of information (plus or minus two) at one time. Short-term memory can be thought of as the "use it or lose it" memory. When new information requires a person's short-term memory, the previous information held is either stored or discarded. Common short-term auditory memory span tasks include sentence repetition tasks and repeating digits or words in a serial order. Research has documented the importance of memory span to achievement (Carroll et al., 2016; Flanagan et al., 2013), as well as to the development of verbal abilities (Engle et al., 1999). Memory span also appears to be significantly related to reading recognition (Swanson & Zheng, 2013); basic writing skills, particularly spelling (Berninger, 1996; Lehto, 1996); and math problem solving (Geary, 1993, 2007).

Working memory has been described as a brain-based function in which plans can be retained temporarily as they are being formed, transformed, or executed (Miller, Galanter, & Pribram, 1960). Similarly, Baddeley (1990) described working memory as a system for temporarily storing and manipulating information while executing complex cognitive tasks that involve learning, reasoning, and comprehension. Jensen (1998) described it as the "mind's scratchpad." More recently, working memory has been described as a broader, more complex construct that refers to a dynamic system for temporary storage and manipulation of information and includes the attentional control processes (Unsworth, 2016). An example of a common working memory task is listening to numbers in a forward sequence and then restating the numbers in a reversed order. Working memory shows a strong connection to fluid intelligence and reasoning ability (Chuderski & Necka, 2012; Kane & Engle, 2002; Kyllonen & Christal, 1990), whereas memory span does not (Engle et al., 1999).

Strong connections exist between working memory and most areas of academic performance, making working memory useful in identifying individuals at risk for many types of learning problems (Gathercole & Alloway, 2008). As examples, significant correlations have been found between working memory and reading comprehension (e.g., Berninger, Raskind, Richards, Abbott, & Stock, 2008; Cain, Oakhill, & Bryant, 2004; Cooper, 2006; Fletcher et al., 2007; Shaywitz & Shaywitz, 2008), language comprehension (King & Just, 1991), vocabulary acquisition (Daneman & Green, 1986; Gathercole & Baddeley, 1993), spelling (Ormrod & Cochran, 1988), math computation (Andersson, 2008; Ashcraft & Kirk, 2001; Passolunghi, Mammarella, & Altoè, 2008; Swanson & Jerman, 2006), and math problem solving (Fuchs et al., 2008; Geary, 2007; Logie et al., 1994; Peng et al., 2018). Children who have both reading and math disabilities often have difficulty on tasks involving working memory (Evans, Floyd, McGrew, & Leforgee, 2002; Floyd et al., 2003; Reid, Hresko, & Swanson, 1996; Szucs, 2016; Wilson & Swanson, 2001), as do children who only have difficulties in math. Szucs (2016) found that individuals with reading and math difficulties had verbal working memory deficits, whereas those with difficulty in math only had visual–spatial working memory deficits. Working memory deficits have been identified as the primary characteristic of individuals with a math disability (e.g., Bull, Espy, & Wiebe, 2008; Chong & Siegel, 2008; Geary, 2004; Peng et al., 2018; Rotzer et al., 2009).

Reasons for Differences in Performance

Several factors can influence performance on working memory tasks. Working memory has several different facets: the capacity of primary memory, the small set of items a person is currently working on; attentional control abilities, the set of attentional processes that aid in the ability to maintain focus in the presence of internal and external distractions; and secondary memory abilities, the ability to retrieve and reactivate information that could not be actively maintained in primary memory (Unsworth, 2016). Thus low performance on working memory tasks can arise from a variety of reasons.

If an individual lacks automaticity or efficiency in performing a particular task, or has poor attentional control, performance on memory tasks may be impaired. Language proficiency is a factor for some types of memory span tasks, such as sentence repetition. Knowledge of syntax and vocabulary helps facilitate performance on sentence repetition tasks, placing individuals with different or limited linguistic backgrounds at a distinct disadvantage. Because most memory tasks present the stimulus briefly and only once, performance can also be affected by attention or anxiety. For example, individuals with high math anxiety demonstrate smaller working memory spans when performing math-related tasks (Ashcraft & Kirk, 2001), and stress in general has a negative impact on working memory capacity (Klein & Boals, 2001). Moreover, attention and working memory are closely related; this has been substantiated by a meta-analysis of 26 studies, which concluded that individuals with attentional problems also manifested limits in working memory (Martinussen, Hayden, Hogg-Johnson, & Tannock, 2005). In one study, over 74% of individuals diagnosed with attention-deficit/hyperactivity disorder (ADHD) were found to have working memory deficits (Brown, Reichel, & Quinlan, 2009).

Implications for Achievement

Memory deficits are characteristic of individuals with SLD (Gathercole, Lamont, & Alloway, 2006; Swanson & Zheng, 2013). Individuals with limited memory abilities may (1) appear inattentive, (2) have difficulty following directions or recalling sequences (e.g., months of the year), (3) have trouble memorizing factual information, (4) have difficulty following a lecture or a class discussion, (5) have trouble taking notes, or (6) struggle to comprehend what has been stated or read. For reading comprehension to occur, an individual must decode the words to obtain meaning. If decoding is labored, then fluency is reduced, and greater demands are placed on working memory, diminishing comprehension.

In math, weaknesses in short-term or working memory may contribute to difficulties in retrieving basic facts or solving algorithms. Individuals with math disabilities appear to have difficulty holding information in their minds while completing other processes. Both verbal short-term working memory and visual–spatial short-term working memory have an impact on math performance (Szucs, 2016). Individuals with specific math disabilities often have difficulty in attentional control or logical problem solving (Geary, 2013). These individuals may understand the rules, but forget the numerical information or have trouble following the steps of an algorithm in order. They know fewer facts and forget them more quickly than other children do. Difficulties in learning basic number facts do not necessarily mean that a person has poor memory. Limited knowledge can also result from insufficient exposure, poor instruction, or attentional weaknesses, rather than specific math disabilities (Robinson et al., 2002).

In contrast, above-average performance on memory tasks can indicate good attention. If information can be dealt with quickly, then the limited-capacity system of short-term memory will not be overloaded, and more attention can be directed to higher-level tasks. Good working memory facilitates proficiency in higher-level abilities, such as reading comprehension, math problem solving, and written expression.

Interventions for Limited Short-Term Memory or Working Memory

Individuals with limited short-term memory or working memory often benefit from practice, review, and specific instruction in memory strategies. For example, the use of chunking strategies, mnemonics, and verbal rehearsal of information can help improve performance. The more routines are practiced, the more automatic these tasks become. Automaticity is especially important for activities that require rapid, efficient responses, such as pronouncing words or responding quickly to math facts. For individuals with memory difficulties, explicit instruction in the academic area of concern is essential. For example, in mathematics, explicit, direct instruction of core numerical relations is beneficial (Geary, 2013).

As a basic principle, students who struggle with memory are helped and supported by effective instruction. For all areas of achievement, teachers should review prerequisite information and previously learned skills, provide distributed practice over time, and introduce new skills carefully and systematically. Validated instructional techniques to improve academic performance include (1) providing demonstration and modeling of the skill to be learned, using a think-aloud procedure; (2) incorporating guided practice with immediate corrective feedback; (3) requiring independent practice to promote mastery; (4) setting goals; and (5) monitoring progress.

At times, accommodations may be necessary. To accommodate individuals with memory difficulties, oral directions need to be short—or, better yet, written down. In addition, oral instructions can be supported with visual cues, such as demonstrations, pictures, or graphic representations. Accommodations for memory difficulties often involve reducing the amount of information that must be memorized. For example, a teacher can provide a student with a fact chart or calculator, rather than requiring memorization of math facts; prepare a specific study guide that highlights the information to be learned; or have the student maintain a personal dictionary of words the student commonly misspells.

Some students will require specific accommodations, such as the use of audio books, permission to record lectures, and/or the provision of lecture notes. In addition, individuals who struggle with tasks involving memory need to understand how their difficulties with memory affect their learning, so that they can request specific accommodations when needed.

Long-Term Storage and Retrieval and RAN

Long-term storage and retrieval constitutes another type of memory process that involves associative memory or the process of storing and retrieving information. This aspect of memory would be similar to what Unsworth (2016) has referred to as *secondary memory*. Problems with this process can influence how effectively new information is stored, as well as how efficiently it is retrieved. Long-term storage and retrieval is not to be confused with the actual information being stored or recalled, which is considered to be crystallized or verbal intelligence. Word-finding difficulties (discussed below) are related to problems with the retrieval process.

Associative memory, a narrow ability of long-term storage and retrieval, appears to be an important ability at the early stages of reading (Cormier et al., 2017; Evans et al., 2002; Flanagan et al., 2013; McGrew & Wendling, 2010), as well as math development (Floyd et al., 2003; McGrew & Wendling, 2010). Acquisition of basic reading or math skills requires the individual to associate pairs of information, such as phonemes (speech sounds) and graphemes (a letter or letters that represent the speech sound), and store this information for later use. This ability to form, store, and retrieve sounds and symbols, as well as to store and retrieve lexical knowledge, is important to early reading development (Cooper, 2006; Hammill, 2004; Perfetti, 2007). The acquisition of alphabetic knowledge (phoneme–grapheme correspondence) can be described as a visual–verbal paired-associate learning task (Hulme, 1981; Manis, Seidenberg, Stallings, et al., 1999). Research indicates that paired-associate learning (PAL) accounts for unique variance in reading, independent of the influence of phonological awareness (Hulme, Goetz, Gooch, Adams, & Snowling, 2007; Windfuhr & Snowling, 2001). These findings suggest that difficulties in storing and recalling associations may affect the development of early reading skills. Warmington and Hulme (2012) explain that "recent research suggests that visual-verbal PAL may be a unique cross-modal associative learning mechanism that is specific to the creation of mappings between visual (orthographic) and phonological stimuli" (p. 46).

Both letter sound knowledge and letter name knowledge have also been identified as strong predictors of reading attainment (Adams, 1990; Muter, Hulme, Snowling, & Taylor, 1997). These aspects of literacy development require the ability to form associations between visual and verbal representations, store those associations, and retrieve them later as needed. Knowledge of the letter patterns, or orthography of a language, plays an important role in developing reading skill (Perfetti, 2011). In addition, several studies have reported that individuals with dyslexia have difficulties associating verbal labels with visual stimuli (Holmes & Castles, 2001; Vellutino, 1995).

The same basic memory problem that results in common features of reading disabilities, such as difficulties in retaining phoneme–grapheme correspondences and retrieving words from memory, may also contribute to the fact retrieval problems of many children with math disabilities. Conceivably, a weakness in the long-term storage and retrieval process is a core difficulty that helps explain the high comorbidity of reading and math disabilities (Robinson et al., 2002). Geary (2007) has hypothesized that individuals with both reading and math disabilities have a common memory problem that affects decoding and math fact learning. Associative memory may be that common memory deficit.

Naming facility, another narrow ability of long-term storage and retrieval, has also been identified as a key predictor of early reading achievement (e.g., Berninger et al., 2006; Scarborough, 1998; Wolf et al., 2000). Carroll (1993) classified naming facility as a narrow ability of long-term storage and retrieval that is sometimes referred to as the *speed of lexical access,* or the efficiency with which individuals retrieve and pronounce letters or words.

As noted earlier, this type of naming facility has been referred to as RAN (Denckla & Rudel, 1974). On RAN tasks, a person is typically shown a randomized array of several objects, colors, letters, or digits (6–8 in a row, with a total of 30–50), and is asked to name the stimuli as quickly as possible. Unlike other long-term retrieval tasks, these measures are timed, and the person must name the symbols as quickly as possible. Although RAN has been the focus of extensive research in recent years, use of this type of assessment began with the original work of Geschwind (1965) and Denckla and Rudel (1974). Since these early reports, results from many studies have demonstrated a connection between poor RAN and poor reading skill (e.g., Hammill, 2004; Perfetti, 1994; Torgesen et al., 1999; Wagner, Torgesen, Laughon, Simmons, & Rashotte, 1993; Wolf, 2007; Wolf & Bowers, 1999). Phonemic awareness and RAN appear to account for independent variance in later reading scores and relate to distinct aspects of reading development (Manis, Seidenberg, & Doi, 1999). RAN is more strongly related to reading fluency than to the reading of isolated words (Protopapas, Altani, & Georgiou, 2013).

To attempt to refine explanations of reading failure, Wolf and Bowers (1999) proposed a theory referred to as the *double-deficit hypothesis.* According to this theory, three major subtypes of poor readers exist: (1) ones with phonological deficits, (2) ones with naming speed deficits, and (3) ones with a combination of the two. Wolf and Bowers have hypothesized that RAN tasks tap nonphonological skills related to reading, such as the processes involved in the serial scanning of print. Presumably, children who are slow to name symbols are slower to form orthographic representations of words (Bowers, Sunseth, & Golden, 1999)—abilities related to the visual aspects of reading. If common letter patterns are not recognized easily and quickly, orthographic pattern knowledge, and subsequently reading rate, will be slow to develop (Bowers & Wolf, 1993; Kilpatrick, 2015).

Some evidence also suggests that RAN differentially predicts reading, based on the level of reading skill. For example, Meyer, Wood, Hart, and Felton (1998) found that RAN tasks had predictive power only for poor readers. Manis, Seidenberg, and Doi (1999) and Abu-Hamour (2009) summarized what existing research suggests about RAN: (1) RAN appears to be independent of phonology and to contribute independent variance to word identification and comprehension; (2) its independent contribution appears larger with younger children and individuals with more severe reading disabilities; (3) RAN is more closely related to reading irregular words than to reading phonically regular nonsense words; (4) it appears to be more closely related to tasks involving orthography than to tasks involving phonology; and (5) RAN is related to both the accuracy and speed of reading words, but the relationship is stronger with speeded measures. In addition, pause time is significantly correlated with both reading accuracy and reading fluency measures, whereas articulation time is not (Georgiou, Parrila, & Kirby, 2006; Georgiou, Parrila, Kirby, & Stephenson, 2008). Thus RAN tasks seem to be measuring the speed in which an individual can retrieve and name visual symbols.

Reasons for Differences in Performance

As with other measures of memory, tasks measuring long-term storage and retrieval may be affected by attention or anxiety. Individuals with math disabilities have difficulty learning basic facts and then, once facts are stored, have difficulty accessing them (Geary, 1993; Miller & Mercer, 1997); these problems suggest difficulties in the storage and retrieval process, which appear to be similar to the word retrieval difficulties common in individuals with reading disabilities. Another problem noted in the retrieval process is the inability to inhibit the recall of related but unnecessary information when one is trying to retrieve a specific answer. For example, an individual may recall that 9 is the answer to 4 + 5, but may also recall 6, the number following the 4-5 sequence, or 20, the product of 4 × 5. Thinking of these extraneous facts slows down the process of getting to the correct answer and increases the chance for error.

Word retrieval difficulties can also impede the effortless retrieval of numbers, letters, and words. German (2001) described three types of word-finding errors as "slip of the tongue" (recalling the wrong word), "tip of the tongue" (unable to recall the word), and "twist of the tongue" (mispronouncing the target word). An individual who manifests word-finding difficulties is not necessarily lacking "knowledge," but may be unable to retrieve and express that knowledge on demand. Higbee (1993) distinguished between *available* and *accessible* information. Available information is known and stored; accessible information is available information that is retrievable. When known information cannot be recalled, a word-finding difficulty is present.

Like word retrieval difficulties, differences in performance on RAN tasks can be attributed to a variety of cognitive and linguistic processes. Wolf and colleagues (2000) describe serial naming speed as similar to reading because it involves a "combination of rapid, serial processing, and integration of attention, perceptual, conceptual, lexical, and motoric subprocesses" (p. 393). A person may have slow naming speed because of any one, or several of, the multiple processes underlying these tasks. Students with reading disabilities as well as those with ADHD can have impairments in RAN (de Jong, Licht, Sergeant, & Oosterlaan, (2012).

Morris and colleagues (1998) have described this specific subtype of reading disability as a "rate deficit." Students are impaired on tasks requiring rapid serial naming, but not on measures of phonological awareness. Conceivably, rapid sequential processing is common to naming speed, processing speed, and reading speed, and slow naming speed reflects a global deficit in the rapid execution of a variety of cognitive and linguistic processes (Kail, Hall, & Caskey, 1999). Whatever RAN measures, it may be partially subsumed under the rubric of processing speed (Denckla & Cutting, 1999).

Implications for Achievement

High performance on associative storage and retrieval tasks suggests that an individual will be successful in learning new information and recalling stored information. Long-term storage and retrieval help an individual store, retrieve, and demonstrate knowledge. Low performance on tasks measuring this ability suggests that the individual will experience difficulty storing new information and recalling previously learned information. These individuals may have difficulty acquiring phoneme–grapheme knowledge, memorizing math facts, and completing fill-in-the-blank tests that require the precise recall of specific information.

Presently, more is known about RAN than about other associative memory abilities. The best predictive measures of early reading achievement appear to be a combination of letter identification, phonological awareness, and RAN (Adams, 1990; Bishop, 2003; NRP, 2000). In addition, children with weaknesses in both RAN and phonemic awareness appear to be the most resistant to reading intervention (Wolf & Bowers, 1999). Results from one study indicated that low RAN scores were the single best predictor of treatment resistance among second-grade students (Vaughn, Linan-Thompson, & Hickman, 2003). Children with only naming speed deficits (no weaknesses in phonological awareness) are characterized by problems in word identification, fluency, and comprehension (Wolf et al., 2000). Although future research is likely to confirm the exact processes involved in RAN tasks, students with naming deficits appear to have a poorer prognosis for reading success than do other subgroups (Korhonen, 1991). Denckla (1979) described these students as a "hard-to-learn" group. Naming speed deficits persist into adolescence and adulthood (e.g., Denckla & Rudel, 1974; Vukovic, Wilson, & Nash, 2004), making them an important marker for identifying reading problems in older individuals.

The double-deficit theory attempts to explain two cognitive correlates of reading failure—poor phonological awareness and slow naming speed—but these are not the only tasks that differentiate poor readers from good readers. For example, Ackerman, Holloway, Youngdahl, and Dykman (2001) found that poor readers scored lower than typically achieving peers on orthographic tasks, attention ratings, and arithmetic achievement. Wolf (1999) also acknowledged the importance of using multidimensional models for explaining reading difficulties, stating that

> this new conceptualization of reading disabilities was ironically, named too quickly. To be sure, double deficit captures the phenomenon of study—that is, the importance of understanding the separate and combined effects of two core deficits—but it fails miserably in redirecting our simultaneous attention as a field to the entire profile of strengths and limitations manifest in children with reading disabilities. Only when we develop truly multi-dimensional models of deficits and strengths will our diagnostic and remedial efforts be best matched to individual children. (p. 23)

Thus more attention has recently been paid to identifying the multiple cognitive deficits that can be found in individuals with reading disabilities (Carroll et al., 2016; McGrath et al., 2011; Pennington, 2006). The research on which and how many cognitive abilities are involved is critical for informing reliable diagnoses of dyslexia (Tamboer, Vorst, & Oort, 2016). In addition, reading disabilities and math disabilities have been associated with different cognitive profiles: In one study, whereas reading was more associated with slow RAN and poor verbal memory, mathematics was more associated with poor temporal processing and visual–spatial memory (Moll, Gobel, Gooch, Landerl, & Snowling, 2016).

Interventions for Deficits in Long-Term Storage and Retrieval and RAN

Individuals with difficulties in associative memory and retrieval will require repeated opportunities and more practice to learn new information. Carroll (1989) suggested that the degree of learning results from the ratio of the time spent learning to the amount of time that was needed for learning. In other words, students who have trouble retaining associations require more time to learn. The strategies that may be most useful include limiting the amount of information presented at one time, and using multisensory and meaning-based instructional approaches that help a student make connections and retain new learning. Examples of approaches include verbal rehearsal, active learning, use of manipulatives, and real-life projects. Smith and Rivera (1998) found that demonstration plus a permanent model was an effective strategy for helping children master computational mathematics, especially learning math skills and organizing and remembering the sequences of multistep algorithms. In addition, techniques that activate the emotional center of the brain by using humor, dramatizations, or movement can enhance learning (Leamnson, 2000). The most effective strategies help a learner to form associations between new and learned information by activating prior knowledge, so that the learning of new information occurs in the context of what the learner already knows (Marzano, 1992).

Another helpful method to facilitate recall is instruction in the use of mnemonic strategies. For example, the *keyword* method involves associating new words with visual images, to help students recall word meanings and learn new vocabulary (Mastropieri, 1988). Three steps are used: *recoding, relating,* and *retrieving.* For recoding, students change the new vocabulary word into a known word, the keyword, which has a similar sound and is easily pictured (e.g., the word *apex* changed to *ape*). For relating, students associate the keyword with the definition of the new vocabulary word through a mental image or a sentence (e.g., a picture of an ape sitting on top of a mountain). For retrieving, students think of the keyword, remember the association, and then retrieve the definition (e.g., the tip or summit). A more specific program that addresses the challenges imposed by RAN deficits is RAVE-O (Reading through Automaticity, Vocabulary, Engagement, and Orthography) (Wolf, 2010). This program emphasizes expansion of vocabulary and building fluency through rapid recognition of the most frequent orthographic patterns in the language.

Visual Processing

Visual–spatial tasks, because they are inherently less verbal in nature, are commonly included in intelligence tests. Carroll (1993) described broad *visual–spatial ability* as including the narrow abilities of *spatial relations, visualization, visual memory, closure speed, spatial scanning,* and a number of others that are not typically included on intelligence tests. Thus a wide range of these abilities exists, and they emphasize the processes of image generation, storage, retrieval, and transformation (Lohman, 1994).

Results from current research do not indicate a strong relationship between visual–spatial abilities and reading or writing (Ackerman et al., 2001; Cormier et al., 2016, 2017; McGrew & Wendling, 2010; Nation et al., 2002; Swanson & Berninger, 1995). This is not to say that such abilities are unimportant to academic success. Clearly, spelling some words involves an ability to retrieve a visual orthographic image of the word to spell it correctly, but the types of visual–spatial tasks on intelligence measures have little relationship with spelling competence (Liberman, Rubin, Duques, & Carlisle, 1985; Sweeney & Rourke, 1985; Vellutino, 1979). This lack of correlation may be due to the types of visual–spatial tasks traditionally included on intelligence tests, such as manipulating patterns, assembling objects, or noting visual details in pictures, that differ from the visual–orthographic processing abilities required for efficient reading and spelling. Visual–spatial abilities are often three-dimensional in nature, and should therefore not be confused with the orthographic processing that includes the visual representations and spelling patterns of the writing system (Berninger, 1990). Orthographic processing is the awareness of the visual representations of language and is one of the two major skills required for printed word recognition; the other being phonological processing (Mather & Wendling, 2012). Orthographic processing is often measured through the reading and spelling of exception or irregular words.

Visual–spatial thinking abilities do appear, however, to be related to math achievement (De Cruz, 2012; Geary, 1994, 2007; Hegarty & Kozhevnikov, 1999; Lubinski, 2010; Moll et al., 2016; Rourke, 1993; Strawser & Miller, 2001). Estimation skills, representations of magnitude, and visualizing a mental number line are dependent on visual–spatial systems (Dehaene, Spelke, Pinel, Stanescu, & Tsivkin, 1999; Pinel, Piazza, Le Bihan, & Dehaene, 2004; Zorzi, Priftis, & Umiltá, 2002). Visual processing is frequently a weakness in individuals with math disabilities (Hale et al., 2008; McLean & Hitch, 1999; Proctor et al., 2005), and difficulties in visual memory and visual–spatial working memory have been noted (Fletcher, 1985; McLean & Hitch, 1999; Moll et al., 2016). Geary (1993) identified a visual–spatial disorder subtype of math disability, characterized by difficulties with spatial representations (e.g., alignment) as well as place value errors. Several researchers have found a relationship between math and specific spatial abilities (Assel, Landry, Swank, Smith, & Steelman, 2003; Osmon, Smertz, Braun, & Plambeck, 2006). Still others have suggested that visual–spatial abilities are related to performance on higher-level mathematics, but not to basic math skills (Flanagan et al., 2013). The results from research that explores the relationship between spatial ability and STEM domains (science, technology, engineering, and mathematics) indicates that spatial ability has importance above and beyond the influence of mathematical and verbal abilities in identifying individuals with aptitude for STEM (Wai, Lubinski, & Benbow, 2009).

Reasons for Differences in Performance

Visual processing tasks can measure an array of narrow abilities, so identifying a person's specific weakness(es) is an important prerequisite to understanding performance. For example, an individual may have strengths in visual memory of objects, but weaknesses in spatial relations. Other factors, such as speed of performance on timed visual–spatial tasks, attention, motivation, and working memory, can influence performance. Problems in visual–motor coordination can also affect performance on timed visual–spatial tasks that involve the use of manipulatives, such as moving and assembling blocks or puzzle pieces, or drawing with a pencil.

Implications for Achievement

Except for math, research has not documented a significant relationship between visual processing and reading or writing achievement. Therefore, it would be erroneous to conclude that a student with high scores on visual–spatial tasks would benefit from a sight word approach to teaching reading, or that a student with low scores would benefit from a phonics approach to reading instruction. Many individuals, including those in clinical groups, demonstrate average scores on visual–spatial tasks with simultaneous low achievement. For example, visual processing scores do not differentiate between college students with and without SLD (McGrew & Woodcock, 2001). In many children with reading disabilities, visual–spatial skills are better developed than other abilities (Fletcher et al., 1995). Furthermore, in a review of over 6,000 clinical cases representing 21 different clinical groups, visual processing was generally not impaired (Schrank, Miller, Wendling, & Woodcock, 2010). For example, individuals with autism were found to have little difficulty with visual–spatial tasks, which is consistent with other research (Corbett, Carmean, & Fein, 2009). These findings provide further evidence that visual processing abilities remain relatively intact in clinical groups, and therefore are not good predictors of academic performance in reading or writing.

Interventions for Limited Visual Processing

Research indicates that spatial reasoning skills can be improved with training (Uttal et al., 2013). Although more research is needed on whether improved spatial skills lead to improved achievement, some studies indicate that this is the case. For example, one study of 6- to 8-year-olds found improvement in calculation accuracy immediately after 40 minutes of spatial training (Cheng & Mix, 2014). Another study found improved math achievement in first graders after 6 months of pattern training (Kidd et al., 2013).

In general, students with visual processing deficits benefit when interventions are highly concrete and as verbal as possible. The most effective methods are highly structured and provide external guidance—methods employed in explicit instruction. Expectations may need to be simplified, broken down, or modified. Teaching a student how to use self-talk to reinforce routines or procedures can help with the completion of simple as well as more complex tasks. Rourke (1995) recommended using a "part-to-whole" verbal teaching approach by presenting information in a logical sequence, one step at a time, so that the student can pay attention to details.

Teaching specific learning strategies, such as the use of imagery, graphic organizers, and puzzles, may significantly improve less skilled individuals' performances on visual–spatial tasks. Another strategy, verbal labeling, uses language to describe visual forms as they are manipulated and represented spatially (Kibel, 1992). For individuals with strengths in visual–spatial abilities, teachers may enhance the students' performance by instruction with pictures, diagrams, or graphic organizers. These individuals often excel in tasks such as visualizing and drawing three-dimensional objects.

Processing Speed

Schneider and McGrew (2012) have defined *processing speed* "as the ability to perform simple, repetitive cognitive tasks quickly and fluently" (p. 119). They indicate that once a person knows how to do a task, processing speed becomes an important predictor of skilled performance. From an information-processing perspective, speediness and automaticity of processing underlie efficient performance (Kail, 1991; Lohman, 1989). Processing information quickly frees up limited resources so that higher-level thinking can occur. Slow processing speed may be characterized as a domain-general deficit because it underlies performance in many areas and is not specific to any one area or disability. For example, slow processing speed characterizes individuals with dyslexia, math disabilities, as well as those with ADHD (Eden & Vaidya, 2008; Peng et al., 2018), although children with reading disabilities appear to have more significant weaknesses than those with ADHD (Shanahan et al., 2006).

Perceptual speed is a narrow ability of processing speed; Carroll (1993) described it as the ability to search for and compare visual symbols. Perceptual speed is strongly related to reading achievement (Cormier et al., 2017; McGrew, Flanagan, Keith, & Vanderwood, 1997; McGrew & Wendling, 2010), math achievement (Fiorello & Primerano, 2005; Floyd et al., 2003; McGrew & Hessler, 1995; McGrew & Wendling, 2010; Peng et al., 2018), and writing achievement (Cormier et al., 2016; Floyd, McGrew, & Evans, 2008; McGrew & Knopik, 1993; Williams, Zolten, Rickert, Spence, & Ashcraft, 1993). Thus the ability to process symbols rapidly is strongly related to academic performance and success.

Speed of processing has been identified as a primary process in reading (Joshi & Aaron, 2000), and many researchers have emphasized the importance of speed constructs in early reading acquisition (e.g., Berninger et al., 2006; Kintsch & Rawson, 2005; Shaywitz et al., 2008; Torgesen et al., 1999). In studies investigating the differences between typically achieving readers and those with reading disabilities, processing speed was slower for the students with reading disabilities (Kruk & Willows, 2001; Pammer, Lavis, Hansen, & Cornelissen, 2004) on both linguistic and nonlinguistic tasks (Shanahan et al., 2006). Research results have indicated a relationship between perceptual speed and word reading (e.g., Apel, 2009; Berninger, 1990; Urso, 2008), as well as basic writing skills and composition (Berninger, 2009; Cormier et al., 2016; Floyd et al., 2008).

In the area of math, processing speed was found to be the best predictor of arithmetic competence in 7-year-olds (Bull & Johnston, 1997). In addition to reading, various researchers have identified speed-related issues for individuals with math disabilities: counting speed (Geary, 1993, 2007), numerical processing fluency (Swanson & Jerman, 2006), and efficiency in executing simple cognitive tasks during math fact tasks (Fuchs et al., 2006).

Reasons for Differences in Performance

When an evaluator is examining a person's performance on processing speed tasks, several additional factors need to be considered. Because most tasks used to measure processing speed are visual in nature (often involving rapid searching of symbols or shapes), the individual's vision and visual processing may be a factor. Motivation and attention are factors to consider as well. Processing speed tasks are typically timed and clerical in nature. Some individuals may have difficulty maintaining attention, and some may not be motivated to complete a relatively simple task quickly. Personality style can also affect performance on speeded tasks, as can cultural differences. Some cultures do not value speeded performance as an important behavioral attribute. Age can also influence performance; some younger students do not understand the concept of working quickly for a certain amount of time, whereas older adults may not care. In general, individuals who are reflective will work more slowly, carefully reviewing their options before responding. Some gifted individuals exhibit a relative weakness on speeded tasks because they reflect and check answers before making a decision. In contrast, individuals who are impulsive may work quickly and carelessly.

Implications for Achievement

Limited processing speed suggests that a person may process information slowly, thus creating a "bottleneck" that affects new learning or skilled performance on tasks that are known. When information is well known, it can be processed more automatically; when information is new, the processing is more effortful. However, even after a task is learned, individuals can differ in the speed and fluency with which they perform those tasks (Ackerman, 1987). Schneider and Shiffrin (1977) made a distinction between *automatic* and *conceptual* processing. The automatic processes require little attentional resources, whereas the conceptual processes are controlled and require the application of knowledge and strategies. Processing speed appears to be most closely related to the lower-order academic tasks that become increasingly automatic with repeated practice, such as reading words quickly, knowing multiplication facts, or spelling words with accuracy. Two consistent findings have emerged from the research on individuals with SLD: (1) Individuals both with and without SLD exhibit a range of responses on a variety of speeded tasks, and the intercorrelations between different speeded tasks often differ for both groups; and (2) individuals with SLD typically obtain lower scores than typically achieving individuals on a variety of speeded tasks (Ofiesh, Mather, & Russell, 2005).

Thus the issue of extended time has particular relevance for students with SLD. Weis, Dean, and Osborne (2016) have suggested that when making a recommendation for extended time, evaluators should include "(a) history of reading disability, special education, or previous reading accommodations, (b) a current diagnosis of reading disability or disorder, (c) objective evidence of current limitations in reading, and (d) test data suggesting the need for additional time" (p. 486). A further consideration is whether an exam is attempting to measure an individual's knowledge and/or the speed in which they can demonstrate this knowledge. In considering the provision of time accommodations on exams, Kelman and Lester (1997) advised educational authorities to consider whether or not speed is a genuine academic virtue in the particular context. If not, the test should be untimed. In the very few cases where speed is judged to be necessary, no one should be provided with accommodations. As noted by Weis and colleagues (2016), it seems desirable to remove construct-irrelevant barriers for all students, not just those with SLD.

Interventions for Limited Processing Speed

Individuals with limited processing speed often require specific accommodations, particularly when an academic area is compromised as well. These individuals may need extended time, as well as shortened directions and assignments. In addition, copying activities should be limited or eliminated. If slow processing of language is also involved, it may be necessary to increase "wait" time so that an individual has more time to think and respond. In order to suggest appropriate interventions or accommodations, the evaluator must first determine whether the person's processing speed deficit is due to limits in speed, accuracy, or both. For example, some individuals work slowly but accurately, whereas others may work quickly but inaccurately. If performance is slow and accurate, a student may benefit from extra time or shorter assignments. If the student works quickly but makes numerous errors, extra time may not be appropriate or beneficial.

Use of explicit instruction in the relevant academic area is also recommended. Often instructional interventions designed to increase rate and fluency in the academic area of concern are beneficial. For example, repeated practice to build automaticity, speed drills, and computer programs that focus on increasing rate or making decisions quickly may improve the performance of individuals with slow processing speed (Klingberg, 2009; Mahncke, Bronstone, & Merzenich, 2006).

Fluid Reasoning

Fluid reasoning involves the ability to solve novel problems via inductive or deductive reasoning and to transfer or generalize learning. Intelligence tests typically include fluid reasoning tasks, such as matrices, sequences, or analogies. Research has documented the relationship between fluid reasoning and reading comprehension (Cormier et al., 2017; Floyd et al., 2006; McGrew, 1993; Nation et al., 2002), math achievement (Fiorello & Primerano, 2005; Flanagan et al., 2013; Floyd et al., 2003; Fuchs et al., 2006; Geary, 1993, 2007; Hale et al., 2007; Proctor, 2012; Rourke & Conway, 1997), and writing achievement (Cormier et al., 2016; Floyd et al., 2008).

Some individuals with SLD tend to have difficulties in abstracting principles from experiences (Geary, 1993; Swanson, 1987), and some appear to struggle with making generalizations (Ackerman & Dykman, 1995). Unfortunately, little is known about the breadth, depth, and developmental course of children's generalization capabilities (Pressley & Woloshyn, 1995), but a growing body of research indicates that poor inferential reasoning is one cause of reading comprehension problems (Wise & Snyder, 2001). For individuals with math disabilities, research indicates that fluid reasoning is frequently impaired (Geary, 2007; Proctor et al., 2005). These inferential reasoning difficulties then interfere with an individual's ability to "classify an event as belonging to a category" (Bruner, 1971, p. 93), and thereby affect success at mathematical problem solving. A deficit in fluid reasoning may affect the development of other cognitive abilities, especially in the domain of acquired knowledge (Blair, 2006).

Reasons for Differences in Performance

Performance on fluid reasoning tasks may vary for many reasons. One reason for variation is how effectively a student employs strategies. Results from one study indicated that high achievers are more attentive and use more effective strategies (e.g., talking through a task) that help them learn and practice the task at hand, whereas low achievers use less effective strategies for task completion (e.g., guessing, carelessness, attending to inappropriate contextual clues; Anderson, Brubaker, Alleman-Brooks, & Duffy, 1985). Another reason for differences in performance is mental flexibility, or the ability to shift cognitive gears. Individuals who have mental flexibility are able to anticipate what is expected on a task and change the approach when needed, resulting in more successful outcomes (Kronick, 1988). In contrast, individuals with rigid cognitive styles may be unable to use their knowledge except when the context closely resembles the original learning situation (Westman, 1996). Semrud-Clikeman (2012) explored the role of inattention in individuals with ADHD, combined type, and those with primarily the inattentive type. She found that both groups performed significantly more poorly on fluid reasoning tasks than the control group. Performance can also vary, depending on the type of reasoning task. Some tasks require reasoning with language (e.g., analogies), whereas others require nonverbal problem solving and mathematics (e.g., matrices).

Implications for Achievement

Individuals with limited fluid reasoning may require instruction at a reduced level of difficulty—in other words, a modification to instruction rather than an accommodation. These individuals often experience difficulty with higher-level thinking tasks and may struggle with comprehending what they read, solving math problems, or expressing themselves in writing. They may display rigidity when attempting new things and continue to apply a strategy that does not work. Even after learning a skill, they may not be able to apply that skill in a new context.

On the other hand, individuals with high performance on fluid reasoning tasks are likely to succeed in higher-level thinking tasks, such as those involved in reading comprehension, math reasoning, or written expression. They will typically display mental flexibility when approaching problem-solving tasks, shift strategies to accomplish their goals, and demonstrate self-regulation.

Regarding math instruction, reasoning and seeing patterns are at the heart of mathematics. These abilities help the student make connections between new learning and prior knowledge. In some instances, math instruction is too focused on rules and procedures. Effective instruction must help students develop conceptual understanding. Math concepts and connections must be taught explicitly, and students must be actively engaged to understand and acquire mathematical concepts (Richland, Stigler, & Holyoak, 2012).

Interventions for Limited Fluid Reasoning

Students benefit from opportunities to develop their metacognitive and higher-order thinking skills. Such opportunities may include engaging in reflective discussions about lessons, comparing and contrasting concepts, or using thought journals. Teaching students to use self-questioning techniques, identify main ideas and themes, classify and categorize objects, attend to organizational cues, and implement strategies can lead to significant gains in inferential skills. Specific strategy instruction has proven to be effective in improving the performance and achievement of students with SLD (e.g., Deshler, Ellis, & Lenz, 1996; Pressley & Woloshyn, 1995; Swanson, 2001). This type of instruction appears to be more effective for higher-order, conceptual tasks than for lower-order tasks (Deshler et al., 1996), but the strategies must be taught explicitly and practiced (Klauer, Willmes, & Phye, 2002).

Higher-level thinking skills (e.g., analyzing, comparing, evaluating, synthesizing) require the brain to use multiple and complex systems of retrieval and integration (Lowery, 1998). Experiential learning appears to activate the area of the brain responsible for higher-order thinking (Sousa, 1998). Therefore, instruction that combines physical activities with problem-solving tasks can help connect the motor cortex with the frontal lobes, where thinking occurs, and can thus increase memory and learning (Kandel & Squire, 2000). Learning can be demonstrated in multiple ways, such as dramatizations, experiments, visual displays, music, or inventions. Effective instructional principles include strategies to activate prior knowledge, activities that actively engage learners, and provision of explicit instruction.

CONCLUSION

Cognitive assessment is not only relevant, but essential, for the accurate identification of individuals with SLD. As research continues to increase our knowledge of the relationships among cognitive abilities and achievement, more and more evaluators are taking advantage of that knowledge and applying it to their evaluation practices. Although the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013) subsumes all types of SLD under the category of specific learning disorder, distinct cognitive profiles exist that are relevant to the selection of accommodations and interventions (Poletti, Carretta, Bonvicini, & Giorgi-Rossi, 2018).

Interestingly, the research on cognitive–achievement relationships connects comprehensive evaluations to RTI in a way suggesting that they both provide useful data. Advocates of RTI talk about cognitive markers when discussing the need for early screening to identify children at risk for academic difficulties. For example, phonemic awareness, RAN, and vocabulary are often mentioned as predictors of early reading skill; number sense, processing speed, and fluid reasoning are discussed as predictors of math achievement. When an evaluator is establishing a PSW that suggests the presence of an SLD, the focus is on a student who is experiencing academic difficulties. RTI allows for early identification and intervention. Comprehensive evaluations enable us to understand why a student is struggling or not making sufficient progress. If a student fails to respond to intervention, and the results of a comprehensive evaluation indicate that the student has a processing deficit that affects academic performance, both the definitional criteria for SLD and the SLD eligibility criterion of limited response to evidence-based instruction have been addressed, resulting in a balanced model that promotes diagnostic accuracy (Hale et al., 2006).

In discussing the assessment of intellectual functioning, Wasserman (2003) indicated that one of applied psychology's biggest failures of the last century was that intellectual assessments were not systematically linked to effective interventions. Fortunately, progress is being made to correct this. First, research continues to identify and clarify the cognitive correlates and predictors of achievement. This information provides an early warning system that can lead to timely interventions and prevent or ameliorate future learning problems. Second, most modern intelligence tests measure a broad array of abilities that reflect the findings of current research, streamlining the process of gathering diagnostic information. Third, the principles of effective instruction are known, and educators are responsible for implementing evidence-based instruction. Finally, progress is being made in linking evaluation results to evidence-based interventions. As Monroe noted back in 1935, "In all remedial work, the teacher should start first with the child and then find the appropriate method. Fit the method to the child, not the child to the method" (p. 227). Ultimately, all psychologists and educators share the same goal: to provide the best educational experiences and opportunities for each and every student.

CHAPTER 29

The Kaufman Test of Educational Achievement, Third Edition, Wechsler Intelligence Scale for Children—Fifth Edition, and Wechsler Intelligence Scale for Children—Fifth Edition Integrated

Integrating Data for a Comprehensive Evaluation of Specific Learning Disability

Jaclyn Danielle Morrison
Jennie Kaufman Singer
Susan Engi Raiford

In 2015, an estimated 2.4 million U.S. students received special education services under the category of specific learning disability (SLD). This group represents about 35% of the national special education population, now more prevalent than any other disability type permissible by the Individuals with Disabilities Education Improvement Act (IDEIA, 2004; Kaufman, Kaufman, Drozdick, & Morrison, 2018; Maki, Burns, & Sullivan, 2017). Recent research has shown that the intellectual profile of children with SLD differs from that of typically developing children. In general, students with SLD demonstrate average overall intelligence (referred to as general cognitive ability, or *g*) but present isolated weaknesses in specific cognitive abilities that directly support academic learning (Toffalini, Giofre, & Cornoldi, 2017).

School psychologists play an essential role in maximizing the learning potential of these students, as emphasized by the National Association of School Psychologists (NASP) in a 2011 position statement, "Expertise in Specific Learning Disabilities is an essential area of specialization for all school psychologists" (p. 4). Reasonably, school psychologists spend most of their time conducting psychoeducational assessments to inform decisions regarding special education eligibility (Bramlett, Murphy, Johnson, Wallingsford, & Hall, 2002; Filter, Ebsen, & Dibos, 2013).

Despite the steadily increasing prevalence of SLD and the growing body of research investigating the underlying mechanisms, the field of school psychology continues to lack cohesive guidelines on how to best to assess students with suspected SLD. Major challenges stem from the lack of a universally accepted SLD definition, diagnostic methods that vary across disciplines and regional boundaries, overlapping nomenclature that creates confusion (e.g., What is the difference between a cognitive ability and a cognitive process?), and consistent debates among experts and researchers who advocate disparate approaches for test interpretation and linking data to intervention. In light of advancements in both theoretical and applied psychometrics, it is necessary for school psychologists to reexamine their own professional practice in the identification and intervention of students with SLD.

The main purpose of this chapter is to synthesize current research on SLD diagnosis and interventions, geared specifically for school psychologists working in the U.S. school system. A large focus is placed on the Kaufman Test of Educational Achievement, Third Edition (KTEA-3; Kaufman & Kaufman, 2014a, 2014b), a valuable tool for assessing a student's reading, writing, mathematics, and oral language skills as part of a comprehensive SLD evaluation. We begin with a review of the KTEA-3, including the underlying test theory and structure, psychometric properties, and the various quantitative, norm-referenced scores available. Next, we highlight the KTEA-3 interpretative options that go beyond the standard profile analysis to investigate a student's intra-individual processing strengths and weaknesses. These qualitative methods include task and demands analyses and the unique KTEA-3 Error Analysis system. We then present a comprehensive summary of recent research using the KTEA-3 with specific clinical groups. Finally, we conclude with a discussion of issues specifically related to the assessment of SLD by school psychologists within the educational paradigm. An appendix to the chapter provides an interpretive case study that demonstrates the synthetization of achievement and cognitive data to inform special education eligibility decisions and intervention design.

KTEA-3 THEORY AND STRUCTURE

The KTEA-3 (Kaufman & Kaufman, 2014a, 2014b) is an individually administered diagnostic test of academic achievement for children and youth from ages 4 through 25, or from prekindergarten (PK) through grade 12. The KTEA-3 offers a wealth of information that can be used for multiple purposes in educational, clinical, and research settings alike. It is an effective tool for identifying academic strengths and weaknesses; making eligibility, placement, and diagnostic decisions; planning individualized instruction; monitoring academic progress; measuring a student's response to intervention; and conducting research. Although there are other popular standardized measures available, the KTEA-3 is the only achievement test that offers a systematic and norm-referenced system for error analysis (Flanagan, Mascolo, & Alfonso, 2017). These procedures allow the clinician to look beyond standardized scores and identify specific skill and processing weaknesses to target for intervention.

The KTEA-3 offers two versions: a Brief Form (Kaufman & Kaufman, 2015) and a Comprehensive Form (Kaufman & Kaufman, 2014a). The Brief Form is used to screen for weaknesses in three core academic areas (reading, writing, and math), while the Comprehensive Form assesses a fourth academic area (oral language) and additional skills in reading-related and cross-domain areas. The Comprehensive form offers two versions (A and B), which makes it useful for progress monitoring with a reduced potential for practice effects. The six subtests on the Brief Form were taken directly from the Comprehensive Form B, which allows practitioners to extend a screening assessment without the need to re-administer subtests. The Comprehensive Form (hereinafter referred to simply as the KTEA-3) is the focus of discussion in this chapter, but administration and scoring rules for mirrored subtests are identical.

The KTEA-3 represents a substantial revision of the Kaufman Test of Educational Achievement—Second Edition (KTEA-II; Kaufman & Kaufman, 2004b), updated with valuable modifications that enhance the clinical utility of the test. Changes from the previous version include updated norms (new PK norms), a decrease in the lower age limit from 4 years, 6 months (4:6) to 4 years, 0 months (4:0), the addition of four new subtests, improved content coverage of existing subtests and items, simplified administration procedures, and enhanced artwork. The KTEA-3 is based on a clinical model of development that advocates for both interpersonal and intrapersonal analysis.

The content of the KTEA-3 was developed with strong guidance from curriculum experts and practicing professionals. Items were designed to resemble popular textbooks and to include skills that align with state standards when possible. The breadth and depth of content coverage enhance interpretation and provide critical information for diagnostic and instructional decision making. The KTEA-3 measures all areas of SLD identified in IDEIA 2004 (e.g., Oral Expression, Listening Comprehension, Basic Reading Skills, Reading Comprehension, Reading Fluency Skills, Written Expression, Mathematics Calculation, and Mathematics Problem Solving), as well as the areas of impairment provided by the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association, 2013). Administration, scoring, and interpretive procedures offer optimal flexibility for designing an individualized battery that allows examiners to administer a single subtest or any combination of subtests specific to the referral concerns.

Like the two previous versions, the KTEA-3 includes a comprehensive criterion-referenced error analysis system that has been carefully developed over time. Curriculum experts in all academic areas helped to define the specific skills that are measured by each subtest and the types of errors that students are likely to make. The test developers also conducted a literature review on instructional theory and practice, consulted with practicing clinicians, and analyzed actual errors made by students during the data collection phases. This optional interpretive process allows an examiner to compare a student's error patterns with those of a normative group to determine specific skill deficits.

COMPOSITES AND SUBTESTS

The KTEA-3 includes 19 subtests that can be grouped into three core composites, 10 supplemental composites, and a global Academic Skills Battery (ASB) composite. The three core composites include Reading, Math, and Written Language. The 10 supplemental composites are organized into three subgroups: Reading-Related composites, which include Sound–Symbol, Decoding, Reading Fluency, and Reading Understanding; Oral composites, which include Oral Language and Oral Fluency; and Cross-Domain composites, which include Comprehension, Expression, Orthographic Processing, and Academic Fluency. Not all subtests and composites are available for all ages and grades. Most notably, different subtests contribute to the ASB for students in PK, kindergarten (K), and those in grades 1–12+. Figure 29.1 illustrates the composites and subtests that contribute to the ASB by age. The descriptions below provide specific details about the composites (task requirements, age ranges, etc.), followed by subtest specific explanations.

Core Composites

- *Academic Skills Battery (ASB).* This composite provides a measure of overall academic achievement in Reading, Math, and Written Language. Unlike the global score offered on the KTEA-II (the Comprehensive Achievement Composite, or

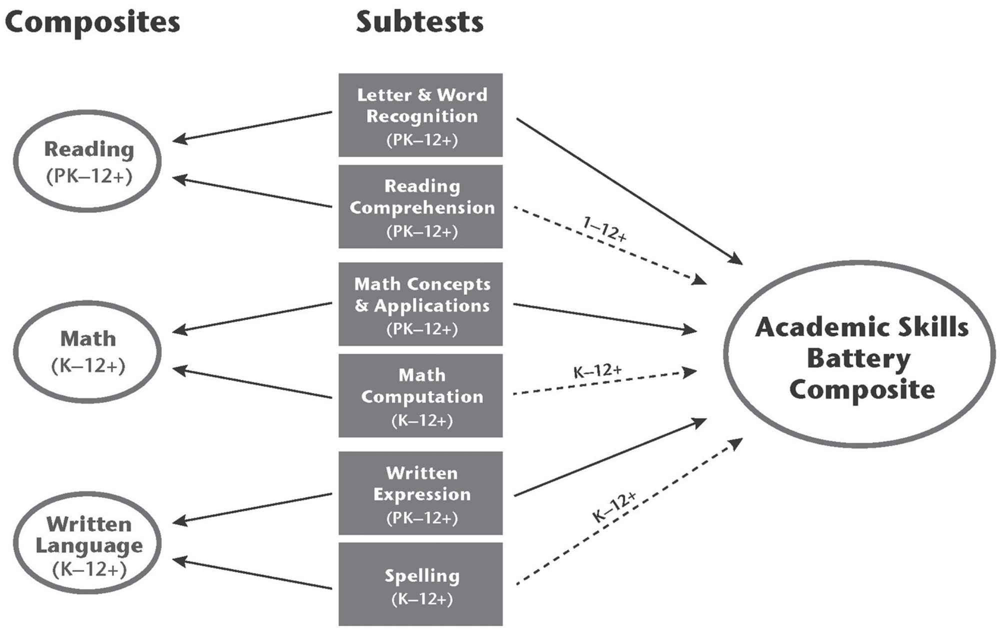

FIGURE 29.1. Core composite structure of the KTEA-3. Figure found in the *Manual for the Kaufman Test of Educational Achievement, Third Edition (KTEA™-3)*. Copyright © 2014 by NCS Pearson, Inc. Reproduced with permission. All rights reserved. "KTEA" is a trademark, in the US and/or other countries, of Pearson Education, Inc. or its affiliates(s).

CAC), the ASB does not include Oral Language skills. Results of joint confirmatory analyses conducted with the KTEA-II and the Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004a) revealed that the Oral Language subtests were excellent measures of crystallized intelligence, but not directly related to any core academic skill; in other words, oral language is better conceptualized as a foundational skill that is essential for building academic skills, rather than as an academic skill in and of itself (S. B. Kaufman, Reynolds, Liu, Kaufman, & McGrew, 2012). The ASB covers all three core academic areas for all ages, but different subtests contribute to the score for PK, K, and grades 1–12+.

- *Reading (grades PK–12+; ages 4–25).* This composite provides a measure of overall reading ability, including basic reading skills and reading comprehension. Weak scores may indicate deficits in basic reading skills, language comprehension, or both. Subtests: Letter and Word Recognition; Reading Comprehension.
- *Math (grades K–12+; ages 5–25).* This composite provides an overall measure of math achievement, including math computation and problem-solving skills. Subtests: Math Computation; Math Concepts and Applications.
- *Written Language (grades K–12+; ages 5–25).* This composite provides a measure of achievement in expressive written language. Subtests: Written Expression; Spelling.

Supplemental Composites

Reading-Related

- *Sound–Symbol (grades 1–12+; ages 6–25).* This composite measures phonological processing and decoding skills. Weak scores may indicate deficits in phonological, orthographic, and/or morphological awareness, as well as the phonological loop of working memory. A phonological core deficit is a common underlying cause of dyslexia. Subtests: Phonological Processing; Nonsense Word Decoding.
- *Decoding (grades 1–12+; ages 6–25).* This composite measures broad basic reading skills, including recognizing regular, irregular, and nonsense words. Weak scores may indicate deficits in phonological, orthographic, and or morphological awareness; long-term storage and retrieval; receptive vocabulary; and the phonological loop of working memory. Subtests: Letter and Word Recognition; Nonsense Word Decoding.
- *Reading Fluency (grades 3–12+; ages 8–25).* This composite provides a measure of reading automaticity across a range of speeded conditions, including real and nonsense words, words in isolation and in context, and both oral and silent responses. Subtests: Silent Reading Fluency; Word Recognition Fluency; Decoding Fluency.
- *Reading Understanding (grades 1–12+; ages 6–25).* This composite measures comprehension of written narrative containing literal or inferential information, and the ability to identify or infer the meaning of words. Low scores may indicate weakness in vocabulary knowledge, the ability to comprehend written passages, or both. Subtests: Reading Comprehension; Reading Vocabulary.

Oral

- *Oral Language (grades PK–12+; ages 4–25).* This composite measures the ability to comprehend literal and inferential information from oral narratives, to describe a picture orally, and to name words fluently in a sematic category. Low scores may indicate difficulties with oral expression in the areas of fluency, pragmatics, or grammar, or with comprehending formal speech. Subtests: Associational Fluency; Listening Comprehension; Oral Expression.
- *Oral Fluency (grades PK–12+; ages 4–25).* This composite measures verbal fluency and automaticity with tasks that require naming pictured objects or words in a semantic category, as quickly as possible. Also known as *rapid automatic naming (RAN)*, this ability is well supported in research as a predictor of reading and spelling difficulties. Low scores may indicate weak word retrieval difficulty or deficits in long-term memory. Subtests: Associational Fluency; Object Naming Facility.

Cross-Domain

- *Comprehension (grades PK–12+; ages 4–25).* This composite provides a measure of receptive language skills in both written and oral modalities. Low scores may indicate a receptive language deficit and/or weakness in verbal working memory, inattention, or distractibility. Subtests: Reading Comprehension; Listening Comprehension.
- *Expression (grades PK–12+; ages 4–25).* This composite measures expressive language skills in both written and oral modalities. Low scores

may indicate an expressive language deficit and/or weakness in grammar, verbal working memory, and self-monitoring. Subtests: Written Expression; Oral Expression.

- *Orthographic Processing (grades 1–12+; ages 6–25).* This composite measures the ability to form, store, recognize, and retrieve orthographic representations. Low scores may indicate poor orthographic memory; difficulty learning phoneme–grapheme correspondences; or weakness in phonological processing, auditory verbal working memory, and/or cognitive efficiency. Subtests: Spelling; Letter Naming Facility; Word Recognition Fluency.

- *Academic Fluency (grades 3–12+; ages 8–25).* This composite assesses the ability to perform rudimentary academic tasks quickly and accurately, while maintaining focus under time pressure. This information helps to determine the impact of automaticity on academic performance. Low scores may indicate weaknesses in automaticity and processing speed. Additionally, pairwise comparisons can help determine whether slow performance is a function of a skill deficit versus an emotional factor such as anxiety or low motivation. Subtests: Writing Fluency; Math Fluency; Decoding Fluency.

Subtest Descriptions

Basic Reading

- *Letter and Word Recognition (grades PK–12+; ages 4–25).* The student identifies letters and pronounces words of gradually increasing difficulty. The initial items assess knowledge of letter names and sounds, followed by easy word items including high-frequency, phonetically regular words that can be read by using principles of phonological decoding. As the difficulty level increases, the proportion of irregular words increases; this ensures that the subtest measures word recognition (reading vocabulary) in addition to decoding skills.

- *Nonsense Word Decoding (grades 1–12+; ages 6–25).* The student reads invented words of increasing difficulty. This task primarily measures phonological decoding.

Reading Understanding

- *Reading Comprehension (grades PK–12+; ages 4–25).* On this untimed measure of silent reading comprehension, the item types vary depending on the difficulty level. The easiest items require matching a symbol or word with its corresponding picture. Subsequent items ask the student to read a simple instruction and respond by performing an action. On later items, the student reads passages of increasing difficulty and answers literal or inferential questions about them. The most difficult items require rearranging five sentences into a coherent paragraph and answering related questions.

- *Reading Vocabulary (grades 1–12+; ages 6–25).* Newly designed for the KTEA-3, this subtest measures contextual reading vocabulary by requiring the student to determine the meaning of words that are embedded in the context of a sentence. On early items, the student is required to point to one of three words that have the same meaning as a picture or target word. For remaining items, the student reads a sentence (silently or aloud) and then points to the word in the sentence that has the same meaning as a target word.

Reading Fluency

- *Word Recognition Fluency (grades 1–12+; ages 6–25).* The student reads a list of real words aloud as quickly as possible for two 15-second trials.

- *Decoding Fluency (grades 3–12+; ages 8–25).* The student reads a list of invented words aloud as quickly as possible for two 15-second trials.

- *Silent Reading Fluency (grades 1–12+; ages 6–25).* New to the KTEA-3, this subtest was designed to measure both reading fluency and literal comprehension. The student silently reads simple sentences and indicates whether each is true or false by marking “yes” or “no” in the response booklet, completing as many items as possible within a 2-minute time limit.

Language Processing

- *Phonological Processing (grades PK–12+; ages 4–25).* The student responds orally to items that require manipulation of sounds. The subtest is separated into five sections of phonemic awareness tasks: Blending, Rhyming, Sound Matching, Deleting Sounds, and Segmenting.

- *Object Naming Facility (grades PK–12+; ages 4–25).* The student names pictured objects as quickly as possible for two short trials.

- *Letter Naming Facility (grades K-12+; ages 5-25):* The student names upper- and lowercase letters as quickly as possible for two short trials.

Math

- *Math Concepts and Applications (grades PK–12+; ages 4–25).* The student is required to respond orally to items that require the application of various mathematical principles to real-life situations. Skills measured include number concepts, operation concepts, time/money, measurement, geometry, fractions/decimals, data investigation, and higher math concepts.
- *Math Computation (grades K–12+; ages 5–25).* The student writes answers to as many math calculation problems as possible. Skills measured include simple counting and number identification; addition, subtraction, multiplication, and division operations; fractions and decimals; square roots and exponents; and algebra.
- *Math Fluency (grades 1–12+; ages 6–25).* The student writes answers to as many addition, subtraction, multiplication, and division problems as possible within a 60-second time limit.

Written Language

- *Written Expression (grades PK–12+; ages 4–25).* Students in grades PK and K are required to trace, copy, and write letters, words, and sentences from dictation. Older students are required to complete writing tasks in the context of a grade-appropriate story format with items that include writing sentences from dictation, adding punctuation and capitalization, filling in missing words, completing sentences, combining sentences, writing compound and complex sentences, and retelling a story in essay format.
- *Spelling (grades K–12+; ages 5–25).* On early items, the student writes single letters that represent sounds. On subsequent items, the student writes regular and irregular words from dictation at increasing difficulty levels.
- *Writing Fluency (grades 2–12+; ages 7–25).* In the response booklet, the student writes one sentence for each picture presented and completes as many items as possible within 5 minutes.

Oral Language

- *Listening Comprehension (grades PK–12+; ages 4–25).* The student listens to either a sentence read by the examiner or a recorded passage played from the audio files on the flash drive, and then responds orally to comprehension questions (literal and inferential) asked by the examiner.
- *Oral Expression (grades PK–12+; ages 4–25).* For each item, the student orally responds with a complete sentence that describes a picture presented in the stimulus book. Harder items require the student to use one or two target words in each response, while the most difficult items require the student to begin each response with a target word or phrase.
- *Associational Fluency (grades PK–12+; ages 4–25).* Within a 60-second time limit, the student says as many words as possible that belong to a given semantic category.

PSYCHOMETRIC PROPERTIES

Standardization Sample

Standardization of the KTEA-3 was conducted with an age-norm sample of 2,050 examinees (ages 4:0–25:11) and a grade-norm sample of 2,600 students (grades PK–12). All age levels included a range of 120–160 examinees, apart from age 4 (sample of 100) and ages 19–20 and 21–25 (each with a sample of 75). Each grade level was represented by 150–200 students, and the cumulative sample was split into semesters, with approximately half tested in the fall and the other half in the spring. The normative sample was closely matched to the 2012 American Community Survey of the U.S. Census Bureau along the variables of age/grade, sex, parental education level, geographic region, and special group designation. Approximately 8–10% of the norm samples at each grade or age group included students with one of more of the following educational classifications: SLD in reading and/or writing, SLD in math, language disorder, attention-deficit/hyperactivity disorder (ADHD), mild intellectual disability, and academic giftedness. To account for the KTEA-3 parallel forms, approximately half of the norm sample was administered Form A, and the remaining half was administered Form B. Data were collected by 490 examiners in 48 states between August 2012 and July 2013.

Reliability

For both Forms A and B, the internal-consistency reliability of the KTEA-3 Comprehensive Form is strong. For all grade levels and age ranges, reliabilities are in the .90s for the ASB composite (.97–.99), as well as the Reading (.92–.97), Math (.95–.98), Written Language (.91–.97), and Reading-Related

(.92–.99) composites. The Oral Language composite has a mean reliability of .86, while the Cross-Domain composites have a mix of reliabilities in the .80s and .90s.

Alternate-form reliabilities were calculated by administering both versions of the KTEA-3 (Forms A and B) to a sample of 306 children. The average time elapsing between administrations was 7.5 days. The values for the alternate-form reliabilities are comparable to the high internal-consistency reliability values. The ASB composite has very high consistency values across time and forms (mid-.90s). The Reading, Math, and Written Language composites have alternate-form reliabilities in the high .80s to mid-.90s. The Decoding and Reading Fluency composites also have alternate-form reliabilities in the high .80s to mid-.90s. These strong values suggest that the KTEA-3 alternate forms will be useful in reducing practice effects.

The Written Expression and Oral Expression subtests require subjective judgment in scoring because examinees' responses can vary significantly. As such, these subtests are most susceptible to differences in scoring among examiners. The interrater reliability was calculated as the percentage of agreement between trained scorers for all double-scored cases in the norm sample, weighted by the number of protocols scored. Agreement rates were calculated for both forms combined. There were 10 scorers for Oral Expression and 13 for Written Expression, each scoring approximately 300 protocols. Interrater agreement was 90% for Oral Expression and 95% for Written Expression, which supports the reliability of the KTEA-3 scoring criteria. Although other KTEA-3 subtests also require some degree of selective judgment in scoring (i.e., Reading Comprehension, Listening Comprehension, Writing Fluency, and Associational Fluency), their respective agreement rates were consistently high (≥98%).

Validity

There is strong evidence supporting the interpretation of KTEA-3 scores for their intended purpose. Revisions of the KTEA-3's content were based on careful consideration of examiner feedback, school curriculum guidelines, and expert and panel reviews, as well as on special-group studies conducted with clinical populations. The KTEA has a history of strong theoretical and empirical evidence of its validity based on response processes. Further evidence collected during the development of the KTEA-3 included consultation with experts in the field, extensive literature reviews, and empirical and qualitative evaluations. Results continue to indicate that the KTEA-3 items are measuring the constructs as expected.

The internal structure of the KTEA-3 also shows evidence of strong construct validity. Correlations among the Reading, Math, Written Language, Sound Symbol, Decoding, and Reading Fluency composites are mostly within the .70s and .80s across groups. The Oral Language and Oral Fluency composites correlate with the other composites at lower levels (.40s to .50s). These lower correlations are expected, given that language processes are considered to constitute a foundation for building academic skills, rather than an academic skill area in and of themselves.

Additional confirmatory factor analysis was conducted to investigate the relationship between the KTEA-3 composites and subtests in a more systematic way than simply investigating intercorrelations. Confirmatory factor analysis was applied to the six subtests that make up the ASB composite, plus the additional three Oral Language subtests. Results support the validity of composite structure through a four-factor model with constructs related to the domains of reading, mathematics, written language, and oral language. The final model had good fit statistics, and all subtests had high loadings on all factors.

Parkin (2018) recently investigated the factor structure of the KTEA-3 reading, writing, and oral language measures to test for invariance across grade levels. Results of his analyses suggest that the factors analyzed demonstrated the same amount of variance across grade levels and are associated with each other to the same degree across groups. Parkin's findings support the use of the KTEA-3 across grade levels for interpretation of both its core academic composites and supplemental cross-domain composites related to comprehension, expression, and decoding. This research also suggested that subtests could contain systematic variance for multiple abilities. Performance on Reading Comprehension, for example, may reflect a general reading ability and a comprehension ability. Spelling might be a summative score reflecting general writing skill and decoding (Parkin, 2018).

The KTEA-3 demonstrates evidence of concurrent validity when compared to other similar measures of academic achievement. Correlations were calculated with the KTEA-3 Comprehensive Form and the KTEA-3 Brief Form, as well as the

Wechsler Individual Achievement Test—Third Edition (WIAT-III; Pearson, 2009), the Woodcock–Johnson III Tests of Achievement (WJ III ACH; Woodcock, McGrew, & Mather, 2001), and the Clinical Evaluation of Language Fundamentals—Fourth Edition (CELF-4; Semel, Wiig, & Secord, 2003). Like the KTEA-II composites, the KTEA-3 composites show correlations with the WIAT-III and WJ III ACH in the mid- to high .80s; correlations between most of the total achievement scores range from the high .80s to .95. The CELF-4 Formulated Sentences was used to evaluate the validity of the new KTEA-3 Oral Expression subtest. They show a correlation of .64, which supports the validity of the new KTEA-3 subtest.

Correlation studies were also conducted with tests of cognitive ability, including the KABC-II (Kaufman & Kaufman, 2004a), the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007), and the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014). Correlations between the KTEA-3 core composites and the global scales of the KABC-II, DAS-II, and WISC-V range from .49 to .82. KTEA-3 composites generally correlate highest with measures of crystallized, fluid, and learning ability.

ADMINISTRATION AND SCORING

Subtest Selection

A key asset of the KTEA-3 is the flexibility for practitioners to individually design assessments that are specific to each student. If only one domain of academic functioning is of concern, an examiner may choose to administer a single subtest or any combination of subtests in the relevant academic domain. If multiple domains need to be measured, then all age-appropriate subtests can be administered to obtain the desired composite score(s). The KTEA-3 manual (Kaufman & Kaufman, 2014b, p. 21) provides suggestions for designing an initial battery based on the referral concerns, but the examiner is encouraged to take a fluid assessment approach by modifying the battery as data are collected that confirms or refutes initial theories and hypotheses.

Administration Considerations

The administration of subtests on standardized tests typically follows a strict sequential format that is predetermined by the test publishers. Another aspect of the KTEA-3's flexible design is that the order of subtest administration is mostly left to the examiner's discretion. There are two sets of subtests that must follow a sequence (Letter and Word Recognition must be given before Word Recognition Fluency, and Nonsense Word Decoding must be given before Design Fluency), but other subtest administration guidelines offered in the KTEA-3 stimulus book and record form are mostly suggestions. Administration times can vary, depending on the subtests selected for administration, the examiner's testing style, and examinee-related factors (such as personality, mood, and rapport with the examiner). In general, each of the core academic composites takes 10–35 minutes to administer; obtaining the ASB composite varies from approximately 15 minutes for the youngest children to 85 minutes for students in grade 3+.

As in other standardized tests of achievement, the KTEA-3 items are ordered by difficulty, with the easiest items being administered first. Grade-based starting points are listed on the record form and on the first page of a subtest's directions in the stimulus book. The KTEA-3 subtests include fewer sample, teaching, or practice items than are typically seen in many standardized cognitive tests. Only eight subtests direct the examiner to record time during administration: Six subtests enforce time limits (Writing Fluency, Reading Fluency, Math Fluency, Word Recognition Fluency, Decoding Fluency, and Associational Fluency), while two require completion time (Object Naming Facility and Letter Naming Facility). On certain subtests, the examiner may be encouraged or required to record oral responses, depending on the depth of information needed for scoring. If an examiner chooses to apply error analysis procedures, verbal responses may need to be recorded verbatim. For a subtest-by-subtest review of administration, see Breaux and Lichtenberger (2016).

Scoring Methods

Q-Global™

The KTEA-3 offers convenient digital scoring through Q-global™, Pearson's web-based scoring platform. Benefits of digital scoring include efficient organization of student information and test data, instantaneous calculation of scores, and assorted options for generating reports that can be downloaded and customized. Additionally, Q-global offers features that are not available through hand scoring, but provide information that is exceptionally valuable within the context of a comprehensive SLD assessment. These features include:

- A pattern of strengths and weaknesses (PSW) discrepancy analysis.
- Intervention statements and teaching objectives, based on patterns of errors in the student's performance and skill deficits aligned with the Common Core State Standards.
- Recommended interventions for the home environment, which include fun and engaging educational activities that family members can use to strengthen a child's basic academic skills at home.

Hand Scoring

Examiners may also score the KTEA-3 by hand. All forms and normative data required for hand scoring are preloaded onto a flash drive that is included as part of the test kit. Detailed instructions for hand scoring are provided in the KTEA-3 manual (Kaufman & Kaufman, 2014b).

Types of Scores

The KTEA-3 yields several types of derived scores that practitioners can use to inform their clinical judgment. Analyzing different types of scores helps an examiner to understand a student's test performance in a systematic and meaningful way. Standard scores, percentile ranks, grade and age equivalents, and growth scale values (GSV) are all available. Age-based norms are available for all ages (4:0–25:11), and grade-based norms are available for all grade levels (PK–12). Grade-based norms are separated by trimester: fall (for students assessed in August through November), winter (for students assessed in December through February), and spring (for students assessed in March through July). Age and grade equivalents are available to describe the norms of the test and the average performance of students across ages and grades. The GSV scale is an equal-interval scale of academic skills that can be used to measure academic progress throughout the school years. Whereas standard scores allow for comparison of an examinee's performance relative to his or her peers, GSV scores offer a measurement of the examinee's rate of progress compared to the typical growth rate in the normative sample. The test authors urge examiners to use caution when interpreting GSV scores to describe an examinee's achievement or skill level, as they can often be misleading.

INTERPRETATION

One of the primary goals of the KTEA-3 is to identify students' strong and weak areas of academic functioning from both *ipsative* (person-based) and *normative* (age-based or grade-based) perspectives (Breaux & Lichtenberger, 2016). Because the KTEA-3 allows examiners to customize the battery for each unique assessment situation, the approaches to interpretation must also allow for flexibility. The KTEA-3 manual (Kaufman & Kaufman, 2014b) offers a systematic method for interpretation of both the comprehensive and selective test batteries. However, examiners should be careful not to overestimate the significance or clinical utility of any score in isolation. KTEA-3 results can be quite valuable for generating hypotheses about why a student is struggling to learn, but these hypotheses should always be investigated or substantiated with multiple pieces of supportive data.

Most approaches to standardized test interpretation are based on the concept of *drilling down*, which begins with interpreting a student's global level of functioning and then subsequently interpreting the more specific, underlying skills and abilities that contribute to overall functioning (Flanagan et al., 2017). The KTEA-3 interpretive approach for the comprehensive battery models this hierarchical process, beginning with interpretation of the global ASB composite, followed by evaluation of composite and subtest scores, and concluding with a step-by step procedure for identifying a student's PSW. Additional guidance is provided below, but any person intending to administer the KTEA-3 or interpret the resulting data should refer to the test manual.

Standard Profile Interpretation

- *Step 1.* The first step is reporting the ASB standard score, along with its confidence interval and percentile rank. The ASB battery is composed of three subtests for students in PK, five subtests for kindergarteners, and six subtests for examinees in grades 1–12+. The ASB was designed to provide a reliable normative overview of the examinee's academic achievement in the core domains of Reading, Written Language, and Math. The ASB represents a midpoint for determining an examinee's relatively strong and weak areas of academic achievement.

- *Step 2.* The second interpretive step involves calculating the standard scores and confidence intervals of all composites and subtests administered. Depending on the normative sample chosen, these scores can be evaluated to identify the examinee's strengths and weaknesses, compared to those of same-age or same-grade peers.
- *Step 3.* The third interpretive step takes an ipsative approach by analyzing the examinee's performance on individual composites relative to his or her overall academic achievement. This is done by comparing any composite scores that were derived to the overall ASB score. Any significant difference in which the composite score is greater than the ASB score represents a personal strength, and any significant difference in which the composite score is less than the ASB score represents a personal weakness.
- *Step 4.* If any significant personal strengths or weaknesses are identified, the test authors also recommend reporting how unusual the difference is within the normative sample. Generally, if the difference occurs in 10% or less of the population, it is considered infrequent and of particular clinical interest. Step 4 then involves applying the same ipsative approach at the subtest level.
- *Step 5.* The last step in the formal interpretive process is making pairwise comparisons between specific academic or reading-related skills, which may provide useful information for diagnostic and instructional planning purposes. The authors recommend two specific subtest comparisons that should be analyzed as part of any standard battery: the Oral Expression subtest with the Written Expression subtest, and the Reading Comprehension subtest with the Listening Comprehension subtest.

Error Analysis

"The key to effective interpretation of test performance after administration is careful observation of test performance during administration. Integration of what was observed during administration with what is scored after administration enables the clinician to characterize more accurately the specific cognitive strengths and weaknesses of the child" (McCloskey, Hartz, & Slonim, 2016). Systematically examining the errors made by students with disabilities on tests of cognitive and academic performance can enhance diagnostic procedures, improve clinical judgment, and identify more specific and curriculum-relevant skills to target with educational interventions (Avitia, DeBiase, et al., 2016; Avitia, Pagirsky, et al., 2016). Following publication of the original KTEA, error analysis procedures were developed as a method for identifying patterns of errors that could be indicative of specific skills deficit. The original system accurately identified the number of errors in each category; however, it did not provide a rationale for understanding the inaccurate thought processing that led to the error (Breaux, 2017; McCloskey, 2017).

Traditionally, criterion-related tests have determined a student's skill level with specific cut-off scores, largely based on the judgments of curriculum experts. However, this type of subjective numerical value provides little information about the statistical significance of the student's level of mastery. Instead of using such arbitrary cut-off scores, the KTEA-3 compares a student's total errors within predetermined categories, with the average number of errors made by the reference group (normative comparison) to indicate whether the student's performance is above average, average, or below average.

The KTEA-3 uses two types of error classification methods. *Item-level error analysis* is available on five subtests and enables automatic classification of errors based on the item score (Phonological Processing, Written Expression, Math Concepts and Applications, Listening Comprehension, and Reading Comprehension). In this approach, each item is classified according to the process, concept, or skill assessed and these classifications constitute the error categories. Four additional subtests offer *within-item error analysis*, which requires the examiner to manually classify errors based on a qualitative analysis of the student's response (Letter and Word Recognition, Nonsense Word Decoding, Spelling, and Oral Expression). One subtest (Math Computation) includes both item-level and within-item error analyses. In a significant improvement from previous versions, the KTEA-3 error analysis incorporates aspects and skills that can be directly mapped to the Common Core State Standards (CCSS; National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010).

Language-Related Analysis

Language is not a unitary construct. Students with and without learning disabilities (regardless of subtype) exhibit different profiles of strengths and weaknesses across all language areas. There is strong evidence to suggest that four distinct language systems exist: language by eye (reading), language by hand (written), language by ear (listening), and language by mouth (speaking). Oral language skills typically begin to develop sooner than written language; however, the four language systems (listening, speaking, reading, and writing) then develop concurrently as integrated strands that influence one another (Berninger & Abbott, 2010; Carretti, Motta, & Re, 2016). Over the past 40 years, a sizable amount of research publications have focused on contrasting reading and writing disabilities and investigating ways to differentially diagnose SLD subtypes based on the levels of language (subword, word, syntax) and language systems (by ear, mouth, eye, hand) that are impaired, the developmental trajectory, and their relationships to instructional needs (Nielsen et al., 2017). Researchers have long promoted the value of error analysis procedures for gaining insight into how individuals learn to read, how literacy skills develop, and the strategies upon which students rely (Liu et al., 2017).

Letter & Word Recognition, Nonsense Word Decoding, and Spelling

The Letter & Word Recognition (LWR), Nonsense Word Decoding (NWD), and Spelling subtests assess an examinee's ability to connect speech sounds to letter patterns. LWR includes many words with both predictable and unpredictable letter patterns. NWD is designed to measure a student's ability to apply decoding and structural analysis skills to typically occurring letter patterns. The Spelling error analysis gives information about the student's ability to relate speech sounds to letter patterns.

The error analysis system for these subtests is made up of categories corresponding to letters and letter combinations that have a predictable relationship to their sound. The error categories are constructed to align with patterns and rules that are generally taught in school. The error analysis depends on dividing the words or nonsense words into parts based on orthographically predictable patterns. For example, the word *point* would be broken down into its parts: *p* (single consonant), *oi* (vowel team/diphthong), and *nt* (consonant blend). One-syllable words and words without affixes are divided into consonant and vowel parts, while multisyllabic words with roots and affixes are divided into morphemic word parts. Error Categories are similar across the three subtests and include:

Consonants: Single/Double Consonant, Initial Blend, Medial/Final Blend, and Consonant/Digraph

Vowels: Wrong Vowel, Short Vowel, Long Vowel, Vowel Team/Diphthong, and *R*-controlled Vowel

Other: Silent Letter, Prefix/Word Beginning, Suffix/Inflection, Hard/Soft *C, G, S*, Unpredictable Pattern, Initial/Final Sound, Syllable Insertion/Omission, Misordered Sounds, Nonphonetic, and Whole Word Errors

Phonological Awareness

Phonological processing is the ability to manipulate phonemes, the smallest units of sound heard in spoken language. Deficits in phonological processing skills—which include rhyming, matching, blending, segmenting, and manipulating sounds—are among the most prominent cognitive weaknesses exhibited by students with a specific learning disability in reading (SLD-R; Fletcher, Lyon, Fuchs, & Barnes, 2007). Phonological processing has long been acknowledged as a strong predictor of emerging literacy skills and an effective way for practitioners to identify poor readers. Children with poor phonological awareness may struggle with the following: identifying isolated sounds in words; manipulating sounds; perceiving a word as a fluid sequence of sounds; or isolating the beginning, middle, or ending sounds in a word.

On the KTEA-3 Phonological Processing subtest, error categories include blending, rhyming, sound matching, deleting sounds, and segmenting. Choi and colleagues (2017) compared errors made on the KTEA-3 Phonological Processing subtest across two error factors. Basic Phonological Awareness (BPA) reflects basic sound awareness, or the ability to identify and distinguish sounds in words, and includes the error categories of rhyming, blending, and phoneme matching skills; Advanced Phonological Processing (APP) reflects phonological skills that allow an individual to hold phonological information within working memory and decompose or manipulate it, which include deleting and segmenting. Choi and colleagues' research revealed some interesting results. First, both BPA and APP skills were significantly related to all subreading skills (including processing speed–related tasks); Spelling and

Written Expression (but not Writing Fluency); and Listening Comprehension, Oral Expression, and Associational Fluency (except Object Naming Facility and Letter Naming Facility). Furthermore, APP predicts students' reading, writing, and oral language skills better than BPA across ages. Second, segmenting errors are the most difficult and distinct on the KTEA-3. Third, statistically meaningful correlations were found between phonological processing and comprehension. Error analysis of phonological processing performance is especially important for poor readers because they may achieve a high score on easier BPA tasks (e.g., blending) but a poor score on the more advanced APP tasks (e.g., deleting), or vice versa. Students with oral language and literacy acquisition difficulties need more differentiated phonological processing tests because the overall cut-off scores do not distinguish the levels of difficulty or target specific skills for intervention. Although phonological processing is well established as a predictor of reading at younger ages, Choi and colleagues found that it is also predictive of reading performance in older children (Mather & Wendling, 2016). This emphasizes the importance of including comprehensive measures of phonological processing for all students referred for reading concerns, regardless of age.

Reading Comprehension and Listening Comprehension

Listening and reading comprehension are two essential receptive communication skills that serve as significant predictors of factors related to language development. Linguistically speaking, the most crucial factors involved in listening comprehension are phonological processing and knowledge of syntax/semantics. For reading comprehension, the most important linguistic factors include decoding, word recognition, syntax, semantics, and discourse (Hatcher et al., 2017). The error categories derived from these two KTEA-3 comprehension subtests are categorized as literal, inferential, narrative, and expository. Literal comprehension requires recognition or recall of information that is explicitly stated in a text. The KTEA-3 literal items require the student to find an answer that is stated verbatim or similarly paraphrased directly within the passage. Inferential comprehension requires the generation of novel ideas beyond those explicitly stated in the text. The KTEA-3 inferential items require the student either to deduce the central thought of the passage, make inferences about the content or the author's purpose, and recognize tone or mood.

The narrative category identifies errors that are made on both literal and inferential items about narrative passages, which include fictional information presented in a literary structure. The expository category identifies errors that are made on both literal and inferential items about expository passages, which include information presented in a nonliterary format. The distinction between these receptive skills is particularly important in grade school curricula, as the CCSS are specific to the literal and inferential comprehension of narrative and expository texts. Understanding the relationship between a student's errors in language comprehension of passages across oral and written modalities may assist in differentiating a specific reading weakness from a more general comprehension problem.

Written Expression and Oral Expression

Written and oral expression are primarily concerned with the production of language output and jointly measure a student's ability to communicate with words. Oral language establishes the basis for written language; therefore, weaknesses in oral expression are likely to emerge comparably in written expression. Despite these similarities, they also involve distinctive skills that develop independent of one other. Written expression exclusively involves letter formation, word formation, and text formation whereas oral expression encompasses vocabulary, syntactic and semantic knowledge, memory, comprehension, and storytelling (Hatcher et al., 2017).

Error analyses for Written Expression and Oral Expression subtests are somewhat parallel, developed to break down the speaking and writing processes to determine where a student exhibits weakness. Error categories identify the pragmatic aspects of the task (producing comprehensible and functionally effective writing or speech that adheres to the task demands), the structural aspects (ability to construct well-structured sentences), and the word-level morphological and grammatical aspects (using the correct forms of words). Written Expression includes a fourth category, which addresses the mechanical aspects of writing (capitalization and punctuation). Comparing a student's errors across skillsets can help the examiner to differentiate a specific writing weakness from a global language problem and identify specific skills on which to focus intervention.

Math-Related Analysis

Math Concepts and Applications

Math concepts are the ideas and relationships on which the system of mathematics is founded, and from which all applications are derived. For the Math Concepts and Applications subtest, items are classified into error categories based on the concept or application required to successfully solve the problem. In earlier grades, error categories include classifying objects into sets and identifying quantitative concepts (*more than, less than,* etc.). Primary grades include skills such as place value and regrouping, while errors for secondary students include linear functions, quadratic equations, and hypothetical problems such as reading graphs.

Math Computation

For the Math Computation subtest, the error analysis system addresses both item-level and within-item errors. Item-level errors are automatically categorized according to the math domains in which the student is weak, average, or strong (e.g., addition, subtraction, multiplication, division, fractions, decimals, and exponents or root). Examiners can also manually categorize within-item errors based on the specific processes that have not been mastered (wrong operation, fact or computation error, regrouping for both addition and subtraction, converting the common denominator, etc.).

Qualitative Observations

Qualitative observations are intended to provide information based on the student's testing behavior that can aid the examiner in developing, confirming, or refuting hypotheses about factors affecting test performance. According to Kranzler and Floyd (2013), Qualitative indicators allow the examiner to monitor and record potential construct-irrelevant influences on item-level performance by completing a brief checklist of notable behaviors after each subtest. Behaviors that can disrupt performance may include the failure to self-monitor or sustain attention, impulsive responding, perseverating despite feedback, task refusal, reluctant to commit to a response when uncertain, and worrying about time limits. Behaviors that may enhance performance might include closing one's eyes to concentrate, requesting repetitions, perseverance, trial-and-error, hyperfocus, verbalizing related knowledge or strategies for recall, and working quickly but carefully (Kranzler & Floyd, 2013).

On the KTEA-3, qualitative observations are available for 15 subtests and provide indicators of potential cognitive processing weaknesses organized by IDEIA domain. Cross-validating information suggested by the qualitative observations with other sources of assessment data (e.g., standard scores, error analyses, and measures of cognitive processing) can significantly enhance clinical judgment in the test interpretation process.

Recent Research with the KTEA-3

By systematically reviewing the performance of clinical groups on tests of intelligence and achievement, practitioners can observe specific cognitive profiles and error patterns that may emerge consistently for students with specific diagnoses or skill deficits. Breaux and Lichtenberger (2016) presented substantial research that focused on identifying cognitive and achievement profiles across different clinical groups. More recently, Alan Kaufman and colleagues published a group of studies using data from the KTEA-3 standardization sample to analyze the specific kinds of errors that students make in reading, writing, math, and oral language (Breaux, Bray, Root, & Kaufman, 2017). Results from this research are discussed below that may inform test selection, enhance clinical judgment, and improve tailored intervention design (Breaux et al., 2017).

Cognitive Processing and Academic Achievement

Difficulties in reading, writing, and math may be directly related to common cognitive processes and the shared neurological mechanisms that are needed for the development of these skills (Berninger & Richards, 2010). Numerous studies focus on identifying relationships between cognitive and academic achievement profiles. In one study, researchers analyzed score patterns of children with reading disabilities on the KTEA-3 and KABC-II (which were conormed). When a sample of 141 students ages 6–18 with SLD-R were compared to a matched, nonclinical reference group, both subtest and composite scores were significantly lower for children with SLD-R than for the reference group on both the KTEA-3 and KABC-II (Kaufman & Kaufman, 2004a, 2004b). The largest difference between the nonclinical group and the SLD-R group was found on the KABC-II Learning/Glr scale (with 1 *SD* difference between mean scores). Kaufman, Lichtenberger, Fletcher-Janzen, and Kaufman (2005) posit that the Learning/Glr scale is most demanding because it requires that all cognitive processes work together. Hence, it makes sense for students with SLD-R to achieve lower scores than a matched group on this subtest.

A similar pattern was observed in children with writing disabilities (SLD-W). In a study using the KABC-II, a sample of 122 students ages 6–18 with SLD-W were found to have significantly worse scores on all KABC-II scales than the nonclinical reference group (which was a sample matched on gender, race, and parent education). The lowest index score for the SLD-W group was also found on the Learning/Glr scale. Like the previous study, the Learning scale may have yielded the lowest for this group due to the large cognitive demand of both written expression and Glr tasks (Kaufman et al., 2005).

Breaux and Lichtenberger (2016) compared a sample of 96 students ages 6–8 with math disabilities (SLD-M) to a matched control group on both the KABC-II and the KTEA-3. As in the sample of students with SLD-R, scores on all scales were significantly lower for the group with SLD-M than for the matched control group. The largest standard score difference between the group with SLD-M and the control group (about 16 points) was on the Planning/Gf scale. Some studies have found that children with disabilities in math can be helped by implementing a plan of remediation related to planning and fluid reasoning (Rourke, 1989; Teeter & Semrud-Clikeman, 1998).

Specific Learning Disability

Reading disorders are often comorbid with disorders of written expression. Another study examined performance on the KTEA-3 by a sample of 67 students in grades 1–12 with SLD-R and/or SLD-W (Kaufman & Kaufman, 2014b). Results indicated that about 40% of the students were identified as having a specific learning disability in reading only, 5% (three students) had a disorder in written expression only, and a little more than half of the subjects had a disorder in both reading and writing. The KTEA-3 scores of the SLD R/W group were compared to those of a matched control group. The SLD R/W group scored significantly lower than the comparison group on all KTEA-3 subtests and composite scores. Results further support the comorbidity of reading and writing disorders.

Avitia, Pagirsky, and colleagues (2016) sought to compare error types made by children diagnosed with SLD R/W, children diagnosed with language impairment (LI), and two demographically matched control groups. Results suggest that children with SLD R/W and LI exhibit distinct patterns of academic errors, providing evidence that the two groups have distinct academic profiles. The children with SLD R/W made significantly more errors in word reading and decoding than the matched control group, particularly on error factors concerning contextual vowel pronunciation and letter-sound knowledge. The children with LI differed from their control group on intermediate sound knowledge. Both groups performed significantly worse than matched controls on tasks of phonological processing, reading comprehension, and written expression. Both groups also performed significantly lower than matched controls on tasks of listening comprehension and oral expression, although the authors reported that this was unexpected. The children with SLD R/W demonstrated significantly more errors compared with their control group on the error factors of math calculation and miscellaneous math concepts, whereas no differences were found between the children with LI and their matched control group on any of the math error factors. Results suggest that a student with SLD R/W may require more individualized interventions to address vowel pronunciations that require context and basic letter-sound knowledge, whereas students with LI may require stronger support in learning consonant digraphs and blends.

Koriakin and Kaufman (2017) sought to identify error patterns associated with specific reading disability profiles by comparing four groups of students with differentially diagnosed SLD-R-basic reading difficulties (BRD), reading fluency difficulties (RFD), reading comprehension difficulties (RCD), and typical readers with no formal diagnosis. No significant differences were found on any error factors between the RFD and RCD groups. However, compared to typical readers, the RCD group demonstrated significant difficulties on both error factors while the RFD group did not. This suggests that the RCD group was more affected by language-related difficulties than any other group, providing evidence for a significant relationship between language and reading comprehension skills. This also reinforces the importance of measuring language comprehension as part of any evaluation for dyslexia or SLD-R. On the Oral Expression error factors (which include task-oriented mechanics of speaking and general oral expression), the RFD group made significantly more errors than typical readers, while the RCD group did not. This indicates that children with reading fluency difficulties may experience difficulties with oral expression, but not reading comprehension. The RFD group also demonstrated a specific pattern of weakness in spelling problems compared to typical readers, which may be a function of phonetic deficits, which often co-occur with poor fluency (Koriakin & Kaufman, 2017).

Students identified with specific learning disabilities in math (SLD-M) also present with unique profiles. In one study using the KTEA-3 (Kaufman & Kaufman, 2014a), 51 students in grades 1–12 with SLD-M were administered the KTEA-3 Comprehensive Form. Compared to a matched control group, students with SLD-M scored significantly lower on all KTEA-3 subtests and composites. Approximately 15% of the SLD-M group had a comorbid reading disability, which Breaux and Lichtenberger (2016) suggest may have contributed to the deficits this group displayed on reading and writing tasks. The SLD-M group demonstrated their lowest score on the overall Math composite.

In another study examining SLD-M, the WIAT-III was administered to a sample of 90 students in grades 2–12, ages 7–19 (Breaux & Lichtenberg, 2016). About 9% of the group with SLD-M also had a diagnosis of SLD-R, which contributed to significant weaknesses in reading and writing subtests consistent with other research. When the group with SLD-M was compared to a matched control group, students with SLD-M earned the lowest mean scores on the math subtests.

A recent study was designed to evaluate the types of errors made by students with disabilities in reading and/or writing (SLD-R/W) compared to errors made by students with a SLD in math (SLD-M). In all academic areas assessed (reading, writing, language, and math), Avita, DeBiase, and colleagues (2016) found more similarities than differences between the two groups. The SLD-M group performed lower within some error categories that were not related to their area of disability when compared with the SLD-R/W group. These results support the clinical utility of error analysis procedures for these two clinical populations, as those with learning disabilities in reading and writing may require some assistance in math, and vice versa.

Attention-Deficit/Hyperactivity Disorder

ADHD is estimated to affect about 5% of children in the United States (American Psychiatric Association, 2013). Approximately one out of three children diagnosed with ADHD also meet criteria for SLD, and these rates may be higher among children who exhibit written language difficulties (Barkley, 2015). However, the relationship between ADHD and SLD remains complicated and the directionality is not quite clear. Symptoms of ADHD affect a child's ability to work productively in the classroom and perform well on academic material due to their inattention, restlessness, or impulsive behavior (Barkley, 2015). Barkley (2015) has also noted that children with ADHD are more likely to require academic tutoring, repeat a grade, or be placed in special education classes.

For school psychologists, it is important to understand the specific skill deficits exhibited by children with ADHD so that appropriate interventions can be put in place. On standardized tests of academic achievement, the ADHD population tends to earn standard scores that are 10–30 points lower than their peers in the areas of reading, spelling, math, and reading comprehension (Breaux & Lichtenberger, 2016). One study using the WIAT-III found that the lowest scores earned by the ADHD clinical group were on the Written Expression, Spelling, and Written Language subtests. This group's highest scores were on Listening Comprehension, Oral Expression, and the Oral Language Composite. Of interest, there were large gaps between typical students and those dually diagnosed with both ADHD and SLD. The lowest scores for the group with both ADHD and SLD were on Written Language, which requires sustained effort, planning, self-monitoring, and organizing ability (Breaux & Lichtenberger, 2016).

Another study measured performance on the WIAT-II by children with ADHD, combined type (ADHD-C) and ADHD, inattentive type (ADHD-I), and compared their achievement scores with those of students who were either nonreferred children or children who had been referred for testing for other reasons than ADHD (McConaughey, Ivanova, Antshel, & Eiraldi, 2009). When the two groups with ADHD were compared to the nonreferred comparison group, children in these two groups scored significantly lower on all three WIAT-II composites (Reading, Mathematics, and Written Language). The group with ADHD-C group did not significantly differ from the group with ADHD-I. The authors concluded that the

WIAT-II effectively separated those clients with ADHD (either type) from those who did not have the disorder, but that the tool may not be useful in distinguishing between the subtypes of ADHD. However, it should be noted that behavioral observations during assessment were found to be an effective way to distinguish these two groups.

In another study, the KTEA-3 was administered to a sample of 91 students in grades K–12 with ADHD only (no LI or SLD concerns) and their scores were compared to a matched sample of students with no diagnosed disability. Although many of the KTEA-3 composite scores were not significantly lower for the group with ADHD, the Written Language, ASB, Oral Language, and Oral Fluency composites were significantly lower for this group than for the control group (Breaux & Lichtenberger, 2016). However, these composite scores for the group with ADHD were still within the average range when compared to scores earned by other SLD sample groups, whose composite scores tended to be more than 1 *SD* lower than those of the matched controls.

The Comprehensive Assessment of SLD in the Schools

The purview of school psychological practice is ultimately dictated by professional codes of ethics, federal and state regulations, and school district policies. Approaches to special education assessments must be aligned with legal and ethical standards set forth by the following regulations:

General Education Law

- No Child Left Behind (NCLB; 2012)
- Every Student Succeeds Act (ESSA; 2015)
- Americans with Disabilities Act (ADA; 2008)
- Family Educational Rights and Privacy Act (FERPA; 1974)

Special Education Law

- IDEIA (2004)
- State special education regulations
- District policies

Professional Codes of Ethics

- American Psychological Association's Ethical Principles of Psychologists and Code of Conduct (2016)
- National Association of School Psychologists' Principles for Professional Ethics (2010)

Testing Standards

According to the NASP (2011) position statement on SLD, the primary purposes of a comprehensive evaluation are to determine whether a child has an SLD and to make recommendations regarding educational placement and instructional interventions. NASP supports the following best practices: Evaluations must include a variety of assessments and other evaluation methods, must not be discriminatory on a racial or cultural basis, and must be administered in the language and form most likely to yield accurate information; measures must be used only for purposes for which they demonstrate reliability and validity; they must be administered by trained and knowledgeable personnel and in accordance with instructions provided by the test producer; and they must encompass all areas of suspected disability. After analyzing the codes of ethics, professional standards, and federal laws that address psychological assessment, five broad ethical-legal concerns resulted. School psychologists must strive to ensure that psychoeducational evaluations are multifaceted, comprehensive, fair, valid, and useful (Jacob, Decker, & Lugg, 2016).

The Role of Intelligence in SLD Assessment

Cognitive abilities and academic achievement exist as highly related, but distinct constructs. A growing body of research supports an empirical relationship among specific academic skills, cognitive abilities, and neuropsychological processes (Decker, Hale, & Flanagan, 2013; Dehn, 2013a; Miller, 2013). This is especially salient among the school-age population (Breaux et al., 2017). However, experts consistently disagree over whether it is necessary to include measures of intelligence as part of a learning disability evaluation. This debate can be misleading and problematic for school psychologists, as federal regulations require that any student who is referred for a special education evaluation must be assessed in all areas of suspected disability, including health, vision, hearing, social and emotional status, general intelligence, academic performance, communicative status, and motor abilities (34 CFR § 300.304[c][4]). Additionally, federal definitions of SLD emphasize that a student must demonstrate average intellectual ability overall (*g*), but present specific weaknesses in certain cognitive processes that directly support academic learning (Toffalini et al., 2017). To practice in accordance with these guidelines, school psychologists are strongly encouraged to include measures of intelligence as a standard component of SLD assessments.

General Intelligence and the Intelligence Quotient (IQ)

Misunderstanding and potential misuse of intelligence tests frequently occur. This happens when cognitive ability scores are treated as measures of innate capacity when intelligence does not truly exist as a measurable trait. General intelligence is not housed somewhere in the brain, much like a person's "athletic ability" is not actually located within the body or how a car's maximum speed does not exist somewhere *in* the car (Kievit et al., 2012). Intelligence essentially reflects differences between people, so it can't really be "in" a person; rather, it represents a hypothesized statistical concept that scientists have inferred based on individual differences in how large groups of individuals perform on cognitive and achievement tasks (S. B. Kaufman et al., 2012).

Furthermore, the concepts of general Intelligence (*g*) and IQ are not synonymous. Accurate interpretation of test scores requires that school psychologists understand the difference. A student's general intelligence, or *g*, is essentially a latent trait, whereas their overall cognitive ability (traditional IQ) and academic achievement are observable and measurable outcomes (Horton & Reynolds, 2015). Kievit and colleagues (2012) compare cognitive abilities to physical properties, such as "height," whereas *g* is more akin to a construct, such as "physical fitness," that is dependent on a range of physical properties working together (e.g., lung capacity, metabolism, etc.).

Theories of Intelligence

Scientific theories allow us to make predictions about phenomena that has yet to be observed. Ultimately, intelligence tests have been used to define the theory of intelligence that the test is intended to measure (Goldstein & Cunningham, 2009). School psychologists should use approaches to link assessment to intervention that are supported by contemporary clinical practice, theory, and research.

Cognitive Abilities versus Psychological Processes

Within intelligence theories, the terms *process* and *ability* are often used interchangeably which is inconsistent with widely held definitions of cognition (Dehn, 2006). Cognitive abilities (Gf, Gc, Gwm, etc.) are essentially behaviors that can be observed as people complete similar tasks that are grouped together because they require common neurobiological proficiency for successful performance. Cognitive abilities are measurable factors that have been hypothesized to make predictions about the underlying brain functions that facilitate thinking. Psychological processes refer to the actual neurobiological mechanisms that are responsible for cognitive(conscious) and emotional (unconscious) thinking.

Psychometric Theories of Cognitive Ability: CHC

Cattell–Horn–Carroll (CHC) theory is considered the most empirically valid psychometric model for understanding human intelligence and the most widely used framework for developing and interpreting cognitive assessments (Cormier, McGrew, Bulut, & Funamoto, 2017; Keith & Reynolds, 2010; Schneider & McGrew, 2012). (For a comprehensive description of the current CHC taxonomy, see Schneider & McGrew, Chapter 3, this volume.) The KTEA-3 provides coverage of 20 narrow CHC abilities and eight broad abilities: fluid reasoning (Gf), comprehension–knowledge (Gc), long-term storage and retrieval (Glr), processing speed (Gs), auditory processing (Ga), reading and writing (Grw), quantitative knowledge (Gq), and psychomotor speed (Gps) (Kaufman & Kaufman, 2014b, p. 6).

The broad and narrow abilities defined by in CHC theory are essentially labels that refer to the many unseen steps that are required for completing a task. Cognitive abilities reflect the sum, or outcome, of underlying psychological processes. However, the CHC psychometric taxonomy of abilities cannot possibly account for all the factors that affect performance during an assessment. Ultimately, it is not important to determine how high or low an ability is; rather, it is what a student does with the ability that counts. The way in which an examinee completes a task *matters*. As such, CHC theory best serves school psychologists as a starting point when trying to figure out what a student's test score actually means.

Neuropsychological Theories of Cognitive Processing

When an individual is given any task to complete—educational, adaptive, or otherwise—an array of cognitive or neuropsychological processes are required to meet the demands successfully. Consider the mental tasks that might be required for a student who is asked to solve a simple oral arithmetic problem:

- Focus attention on the problem as it is presented (attention).
- Plan a strategy for problem solving; choose a strategy to use; initiate application of the strategy (executive functions).
- Transcribe the text into a mathematical equation (fluid reasoning).
- Remember arithmetic facts required to solve the problem (long-term retrieval).
- Check the solution for accuracy (executive functions).
- Express the response in the required modality (oral language).
- Hold information in mind long enough to solve the problem (working memory).

A task that seemingly lasts only a few seconds involves countless numbers of brain-based processes to solve. A deficit in any one of these processes might make the problem difficult or even impossible for the student to complete. Furthermore, students can arrive at answers and solutions to problems—either correct or incorrect—by employing a variety of different strategies. Variations in input, processing, and/or output demands can greatly affect performance on tasks involving identical or similar content. The only way to truly gauge what a subtest is measuring is to consider how the child performs.

Approximately 50 years ago, cognitive psychologists proposed a theory of mental processing and learning, known as *information processing theory*, that "described the flow of information through sensation, perception, cognition, memory, and expression" (Dehn, 2013a, p. 120; Dehn, 2013b). Since then, research in neuropsychology has greatly enhanced our understanding of how the brain functions during learning and memory. Based on the principles of neurodevelopment, neuropsychological theories examine the specific neurological processes that can be localized in the brain within the context of its typical developmental trajectory.

A plethora of research supports the fact that neuropsychological processes play a critical role in a person's ability to learn academic skills (Dehn, 2013a). Practitioners who employ these methods are primarily concerned with stimulus inputs that must be processed for a person to complete a task, as well as the ways in which information is apprehended, encoded, stored, organized, retrieved, and mentally manipulated (Jensen, 2006). Neuropsychological approaches to interpretation deemphasize the importance of understanding a student's performance relative to peers in favor of interpreting the student's intrapersonal pattern of processing strengths and weaknesses. Many neuropsychological approaches to interpretation have been developed that focus on cognitive processing, information processing, and task/demands analysis, including:

Lurian- and PASS-based approaches
Edith Kaplan's process approach
Milton Dehn's (2013b) processing assessment method
Hale and Fiorello's cognitive hypothesis testing (CHT)
Dan Miller's (2013) school neuropsychological approach

These approaches are discussed at length within other chapters of this text. School psychologists should use theoretical models of intelligence and related assessment approaches as a framework for designing a comprehensive SLD assessment. In general, school psychologists should never be wedded to a single instrument and the unique array of subtests they include in the comprehensive assessment of a student should be systematic. The following validated methodologies have been developed to aid in selecting the best assessment tools based on the school psychologist's theoretical orientation(s) and the student's referral concerns:

Dawn Flanagan's XBA (based on CHC psychometric theory) (Flanagan, McGrew, & Ortiz, 2000)
Jack Naglieri's (2015) PASS model (based on Luria's neuropsychological processing theory)
Sally Shaywitz's (2003) approach to diagnosing dyslexia
George McCloskey's interpretative system via process analysis (McCloskey, Whitaker, Murphy, & Rogers, 2012)

Flanagan and colleagues (2017; see also Chapter 22, this volume) have proposed an operational definition of SLD that is particularly useful for school psychologists because is reflects the most current federal regulations, theory, and research most salient to our field, including (1) the nature of SLD, (2) the methods of evaluating various elements and concepts inherent in SLD definitions, and (3) criteria for establishing SLD as a specific condition that cannot be explained by undifferentiated low achievement or below-average overall cognitive functioning. Primarily grounded in the CHC theory of intelligence, this model is referred to as the dual discrepancy/consistency (DD/C) operational definition of SLD. The DD/C encourages a continuum of data-gathering methods, beginning with curriculum-based measurements and progress monitoring and culminating in a comprehensive evaluation for students who do not respond adequately to high-quality instruction and intervention within general education. The DD/C model provides a framework for organizing data from multiple sources to evaluate whether an individual's PSW is consistent with the SLD construct.

Synthesizing Data from the KTEA-3, WISC-V, and WISC-V Integrated

A chapter appendix provides an interpretive case study that integrates assessment of academic achievement, cognitive abilities, and neuropsychological processes in a comprehensive assessment for intervention for a child referred for difficulties in mathematics. The KTEA-3 was specifically designed to be paired with measures of cognitive functioning to identify a student's unique profile of strengths and weaknesses. These relationships are important for both diagnosis and intervention planning. The two other major batteries used in this case study are the WISC-V (Wechsler, 2014) and the WISC-V Integrated (Wechsler & Kaplan, 2015). (For comprehensive reviews of the WISC-V and the WISC-V Integrated, see Wahlstrom, Raiford, Breaux, Zhu, & Weiss, Chapter 9, and Raiford, Chapter 11, this volume, respectively.)

APPENDIX 29.1

Illustrative Case Report

IDENTIFYING AND DEMOGRAPHIC INFORMATION

Name: Joseph M.

Date of birth: 3/10/2006

Age: 12 years, 2 months

Race/ethnicity: European American

Parents: Mr. and Mrs. M.

School: C. Middle School

Grade: 7

Date of Testing: 5/16/2017

Date of Report: 5/21/2017

Examiner's name: Susan Engi Raiford, PhD

REFERRAL QUESTIONS AND ANSWERS

Mr. and Mrs. M. requested an assessment of their son, Joseph, because he has received low grades in math in the past and because C. Middle School's admissions testing indicated that his math skills were below expectations for his grade. Testing is being done to document the specific nature of these difficulties, so that accommodations can be made and an intervention plan developed before he enters middle school. Joseph's parents wish to learn the answers to the following questions:

- Does Joseph have a specific learning disability in mathematics? If yes, what skills are impaired?
- What are Joseph's cognitive strengths and needs?
- What accommodations are needed?
- What other recommendations can be used in developing a plan to meet Joseph's educational needs?

ANSWERS TO REFERRAL QUESTIONS

Does Joseph Have a Specific Learning Disability in Mathematics?

Yes. I have diagnosed Joseph with specific learning disorder with impairment in mathematics: number sense, memorization of arithmetic facts, and accurate calculation, moderate; and fluent calculation, severe.

What Are Joseph's Cognitive Strengths and Needs?

Joseph's abilities to access, apply, and express knowledge he has gained about words and their meanings, and to reason with verbal material, are personal strengths relative to his other cognitive abilities. Joseph's visual–spatial processing—that is, his ability to evaluate visual details and to understand relationships of visual parts in space, and to use that information to assemble a geometric design that matches a model (either pictured or real) —is a personal weakness relative to his other cognitive abilities. He also has a personal weakness in naming facility (efficiency), which involves recognizing and recalling overlearned information (e.g., letters and numbers or quantities) as quickly as possible.

What Accommodations Are Needed?

Joseph's diagnosis of specific learning disorder in mathematics qualifies as a disability as defined by the Individuals with Disabilities Education Improvement Act of 2004 (IDEA 2004), which governs free public school education. Accommodations for this condition, if available within the private school environment, are appropriate. Refer to the accommodations listed in the "Recommendations" section of this report. Some of the most common accommodations would involve giving additional time to complete work or assessments related to math, allowing use of a calculator, providing content mastery support, and decreasing reliance on visual materials when teaching math. The accommodation plan should be discussed and agreed upon in a follow-up meeting with parents, educators, and Joseph himself.

What Intervention Recommendations Can Be Used to Develop a Plan to Meet His Educational Needs?

Joseph may benefit from math fact drills, math problem attack strategies, and summer or after-school math programs.

EVALUATION METHODS AND PROCEDURES

- History and background review
- Parent interview (Note: Joseph is coming from a home-schooling situation)
- Child interview
- Behavioral observations
- Review of admissions testing results
- Psychological testing

Psychological tests administered were as follows (see "Complete Test Data" at the end of this report for full results):

- Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V)
- Wechsler Intelligence Scale for Children—Fifth Edition Integrated (WISC-V Integrated)
- Kaufman Test of Educational Achievement, Third Edition (KTEA-3)

HISTORY OF PRESENTING PROBLEM

Joseph has good academic success in subjects other than mathematics. Since he began memorizing basic math facts as a first grader, however, he has struggled to learn math. He needs a great deal of support to keep up. He tends to learn math skills and move on, but at a review later he cannot reproduce the use of the skills he has learned. He can learn a skill in the moment and at this point has little trouble memorizing math facts.

Later in elementary school, math reasoning and word problems were difficult for Joseph; drawing pictures of problems to solve them was helpful. If he didn't draw pictures, such problems were very difficult or impossible for him. Mental arithmetic is very challenging for Joseph, as are changes to the problem or requirements of a task.

FAMILY HISTORY

Mr. and Mrs. M., Joseph's biological parents, have been married for 15 years. Joseph has one brother who is 3 years older and does not have academic difficulties. Joseph's mother struggled with math throughout school. She is beginning work as a preschool teacher after several years as a stay-at-home mother. Joseph's father presently works as an information technology professional in the private sector.

MEDICAL/DEVELOPMENTAL HISTORY

Mrs. M.'s pregnancy with Joseph was normal. Joseph was born after a full-term pregnancy with normal delivery. He had no health problems after his birth. He walked at 16 months (at the higher end of normal limits). He met his language developmental milestones on time and was toilet-trained on time.

ACADEMIC HISTORY AND STATUS

At age 3, Joseph began to recognize numbers, letters, colors, and shapes. He began reading well at age 5. Mrs. M. stated that his lowest grade last year was in math (78), and that he reads and writes at above grade level.

A review of Joseph's achievement test scores and his home-schooling records confirmed that his reading and writing both were at the seventh-grade level. He has a good vocabulary, and his spelling and grammar skills are average. Joseph states that he wants to be a police officer when he grows up.

PATIENT'S STRENGTHS, COPING MECHANISMS, AND AVAILABLE SUPPORT SYSTEMS

Joseph enjoys soccer and baseball and is on teams for both throughout the year. He is involved in his church's youth group. He also enjoys building model planes with his father.

MENTAL STATUS AND BEHAVIORAL OBSERVATIONS

Joseph presented dressed casually, with good grooming and hygiene. He appeared slightly older than his stated age. His rate of speech was normal. He was appropriately behaved and well mannered. He answered quickly when he seemed confident about an answer, and became quieter when he appeared less sure. His eye contact was good. His affect was congruent with stated mood, which was "OK."

Joseph was aware that the evaluation was to be used to help him in middle school and to understand better how he learns. He seemed clear about the purpose of testing and was self-disclosing with me, opening up about his problems with math. Rapport was easily established and maintained. Joseph put forth good effort on all tasks and persevered on challenging tasks. I believe that the test findings provide good estimates of his true abilities. Two breaks were offered and given, to ensure that Joseph could give his best effort and not become fatigued.

TEST RESULTS AND INTERPRETATION

Cognitive Functioning

Intellectual Ability

Joseph's performance on cognitive ability measures suggests that his overall intellectual ability is in the average range compared with that of other young people his age. In large studies, out of all the scores on cognitive tests, overall intellectual ability is the best score at predicting children's school success. However, it doesn't always tell us everything we need to know about a child's individual strengths and needs. An individual's cognitive picture is usually better and more deeply understood when narrower areas of ability are also considered.

Language

Speech

Joseph responded readily to items that required expressive responses. He elaborated sufficiently.

Verbal Comprehension

Joseph's ability to access, apply, and express knowledge he has gained about words and their meanings, and to reason with verbal material, is in the high average range and is a personal strength (relative to his other cognitive abilities). Because his verbal skills and vocabulary are relatively strong compared with his other cognitive abilities, teachers may expect him to perform math-related tasks more easily than he does in reality.

Visual–Spatial Processing

As noted above, visual–spatial processing is the ability to evaluate visual details and to understand relationships of visual parts in space, and to use such information to assemble a geometric design that matches a model (either pictured or real). Sometimes the expression of this ability is tested through manipulation of real objects.

Joseph's visual–spatial processing ability is in the low average range compared with that of other children his age, and is a personal weakness (relative to his other abilities). Such a weakness is common in children who have problems learning math, because learning math requires the ability to see objects and lines in one's head and use one's imagination to understand them and how they are constructed or related.

Joseph's difficulty in this area is similar on a task that involves trial-and-error problem solving and physical (motor) manipulation of components of a construction, and on a task that involves mental imagery. He performed slightly better on a task that required him to recognize correct solutions among multiple choices than to construct them himself.

Interestingly, assembling model planes is one of Joseph's favorite hobbies. This activity should be encouraged, to help him enjoy and feel confident about activities in the visual-spatial realm.

Reasoning and Problem Solving

Reasoning is the ability to detect and apply the underlying rules or relationships that define how objects or ideas are understood as a group. Joseph's visual reasoning ability is average compared with that of other children his age. He had greater difficulty on problems that required multiple operational steps or division than on those that merely required simple addition, subtraction, and multiplication. However, he was slow to complete the problems; even on very easy items, he often hesitated more than is typical and worked up to the time limit before responding. He also requested that items be repeated more frequently than is typical of other children. He was still working at the time limit for several problems he did not receive credit for.

Giving more time and allowing Joseph to use pencil and paper on the math problems did not assist him in better expressing quantitative reasoning, relative to his own prior performance or to that of his same-age peers. He continued to request a greater number of repetitions than typical of other children until he reached the phase in the task for which he received the pencil and paper. On a task for which the problem-solving load is reduced to requiring only simple responses to written math problems, he responded correctly to *fewer* items. He meticulously worked the math problems. Some of the items he missed were simple calculation errors at the last step, whereas his work was off track from the first step on others.

Learning and Memory

Learning and memory were assessed to examine their role in, and implications for, Joseph's future academic success. The two are closely related to each other and are very important to school achievement. Joseph's performance on a broad measure of his long-term storage and retrieval, which involves tasks that require accurate and fluent retrieval of overlearned associations as well as accurate retrieval of new associations, is in the low average range.

Working Memory

Working memory is the ability to take in, keep, and manipulate information in one's awareness to get some type of output that can be expressed. Joseph's working memory ability is in the average range relative to that of other children his age. Because he showed low visual–spatial processing skills, his visual working memory skills (i.e., visual stimuli and spatial locations) were also assessed, and they are also in the average range. However, his performance on a task that involved remembering and tracing spatial locations was significantly lower than one that involved remembering meaningful visual material in sequence. Joseph's working memory performance was consistent across items rather than variable, which suggests that his attention was consistent during the tasks.

Associative Memory

Joseph's visual–verbal associative memory, or the ability to form new associations between symbols and meanings, is in the average range relative to that of other young people his age. His performance suggests uniform ability when he is recalling associations he learned within the past few seconds or minutes, or when he is trying to recall them half an hour later. He performs better when he is permitted to select the association from among options read aloud, rather than recall them from memory without a cue half an hour later.

Rapid Automatic Naming

Rapid automatic naming involves recognizing and recalling overlearned information, like letters and numbers or quantities, as efficiently as possible. Overall, Joseph's rapid automatic naming is in the very low range. His ability to recognize, recall, and recite letters and numbers quickly is in the low average range relative to that of other children his age. His ability to rapidly recognize and name quantities is less efficient, and is in the very low range compared with that of others his age.

Cognitive Speed

Processing Speed

Processing speed is the ability to make speedy and accurate judgments about visual information and act on those judgments. Slow processing speed can lower academic performance, because information that cannot be processed quickly tends to be lost. Joseph's processing speed is in the low average range relative to that of other children his age, and is a personal weakness relative to his other cognitive abilities. He scored lower on a task that required him to scan symbols within a group to see if they match two other symbols or to indicate the symbol is not present, than he did on a subtest that required him to quickly associate and write codes that were paired in a key with numbers. He also scored somewhat lower on a task that required him to scan a page of objects for objects from a single meaningful category (i.e., animals).

Rapid Automatic Naming

Rapid automatic naming is also sometimes thought of as an aspect of cognitive speed; it has been discussed above under "Learning and Memory."

Achievement Skills

Math Skills

Math Computation

Math computation includes skills with the most basic building blocks of math (like addition and subtraction), all the way through more complicated skills like using fractions, decimals, algebra, roots and exponents, signed numbers, and so on. Joseph's skills in this area are in the low average range relative to those of other young people his age. He had more difficulty than is typical on problems involving multiplication, multistep problems, and word problems.

Math Fluency

Math fluency involves quickly answering simple math problems using basic operations like addition, subtraction, multiplication, and division that should be mastered by the end of elementary school. Joseph's math fluency is in the very low range relative to that of others his age.

Math Problem Solving

Math reasoning involves the application of reasoning and mathematical concepts to solve meaningful problems. Joseph's math reasoning skills are in the average range relative to those of other young people his age. He had more difficulty than is typical on items involving simple calculations and basic math operations.

SUMMARY AND DIAGNOSTIC IMPRESSIONS

Summary

Joseph qualifies for a diagnosis of specific learning disorder in math (see "Diagnostic Impressions" below for details). He is able to achieve at his present level with great support and effort, as often seen with specific learning disorders. He will need to receive assistance from a math specialist as he makes the transition to more difficult coursework in middle school.

There are various approaches to diagnosing specific learning disabilities. A traditional methodology, known as *ability–achievement discrepancy*, involves examining the difference between an indicator of cognitive ability (e.g., WISC-V Full Scale IQ) and a measure of achievement (e.g., KTEA-3 Math composite).

A newer method involves examining the child's cognitive ability and achievement results to determine whether there is a processing strength (e.g., WISC-V Verbal Comprehension Index) that is discrepant with from both an area of achievement (e.g., KTEA-3 Math composite) and from a processing weakness (e.g., WISC-V Naming Speed Index) that is empirically or theoretically associated with a specific learning disability in that skill. The Verbal Comprehension Index has served as the processing strength in Joseph's case, and it is not theoretically associated with math disabilities. It is discrepant from the KTEA-3 Math composite and also from the Naming Speed Index, which is commonly impaired in children with math disability. In particular, poor performance on the subitizing task (Naming Speed Quantity) is commonly found in children with mathematics problems in the published literature.

Regardless of the model used, the test results support the hypothesis that Joseph has a specific learning disability in mathematics.

Diagnostic Impressions

F81.2: Specific learning disorder with impairment in mathematics: number sense, memorization of arithmetic facts, and accurate calculation, moderate; and fluent calculation, severe

RECOMMENDATIONS

Several possible accommodations may be effective:

- Allow Joseph additional time (50% more) to complete math in-class work, quizzes, and tests, as well as standardized math achievement tests.
- Allow use of a calculator unless a test is explicitly designed to test math computation.
- Content mastery support is recommended for math.
- Support from a math specialist outside school hours and over the summer is recommended.
- Due to Joseph's low visual–spatial ability, use visual materials related to math sparingly, and supplement with verbal/auditory materials.
- Encourage Joseph to make his own flashcards to practice addition, subtraction, multiplication, and division facts and become more fluent. Various math quiz apps are also available; these will enable Joseph to practice math facts and complete problems more easily.
- While Joseph's math reasoning is presently at the low end of the average range, his math fluency and math computation skills are low. He could benefit from a streamlined and systematic approach to solving math problems: Teach him to analyze math problems, select a strategy, and then monitor his problem solving to ensure it is completed correctly. For each of the steps below, have Joseph say the purpose, ask what needs to be done, and check to ensure it has been done correctly. At home, ensure that he knows the calculations necessary to solve each problem and correct errors as needed. The steps for Joseph to use are as follows:
  1. Read the problem carefully, and clear up anything that is uncertain, such as words or math terms you don't understand.
  2. Restate the problem in your own words.
  3. Draw or create a visual to represent the problem.
  4. Decide how to best solve the problem, and create a plan to do it.
  5. Estimate the answer to the problem, using shortcuts such as rounding.
  6. Use the plan to calculate the answer.
  7. Check the calculation of each step, and compare the obtained answer to the estimated answer from step 6 to make sure the answer is reasonably accurate.

Thank you for the opportunity to work with Joseph. Please let me know if I can be of further assistance.

COMPLETE TEST DATA

Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V) and WISC-V Integrated

Subtest Score Summary

Index	Subtest name	Total raw score	Scaled score
Verbal Comprehension	**Similarities**	37	15
	Vocabulary	30	10
Visual Spatial	**Block Design**	22	7
	Block Design Multiple Choice[a]	17	9
	Visual Puzzles	13	7
Fluid Reasoning	**Matrix Reasoning**	18	8
	Figure Weights	23	10
	(Arithmetic)	19	8
	Arithmetic Process Approach Part A[a]	19	9
	Arithmetic Process Approach Part B[a]	19	9
	Written Arithmetic[a]	18	9
Working Memory	**Digit Span**	26	10
	Picture Span	33	11
	Spatial Span[a]	15	8

Index	Subtest name	Total raw score	Scaled score
Verbal Comprehension	**Coding**	37	15
	Symbol Search	23	6
	Cancellation	56	7
Complementary subtests			
Naming Speed	Naming Speed Literacy	52	83
	Naming Speed Quantity	32	77
Symbol Translation	Immediate Symbol Translation	65	91
	Delayed Symbol Translation	47	91
	Recognition Symbol Translation	29	99

Note. Subtests used to derive the Full Scale IQ are given in boldface. Secondary subtests are given in parentheses. Results on most subtests are reported as scaled scores. Average scaled score is 10. About 68% of scores fall between 7 and 13. About 95% fall between 4 and 16. Complementary subtest scores are reported as standard scores. Average standard score is 100. About 68% of scores fall between 85 and 114. About 95% fall between 70 and 129.

[a]WISC-V Integrated subtest.

Process Observations

	Raw score	Base rate
Arithmetic item repetitions	10	0.5
Arithmetic Part A item repetitions	3	1.3

Composite Score Summary

Composite	Sum of scaled/ standard scores	Composite score	Percentile rank	95% confidence interval	Qualitative description
Verbal Comprehension Index (VCI)	**25**	**113**	**81**	**104–120**	**High average**
Visual Spatial Index (VSI)	**14**	**84**	**14**	**78–93**	**Low Average**
Fluid Reasoning Index (FRI)	**18**	**94**	**34**	**87–102**	**Average**
Quantitative Reasoning Index (QRI)	18	94	34	88–101	Average
Working Memory Index (WMI)	**21**	**103**	**58**	**95–110**	**Average**
Visual Working Memory Index (VWMI)	19	97	42	89–106	Average
Symbol Translation Index (STI)	281	92	30	86–99	Average
Storage and Retrieval Index (SRI)	170	80	9	74–88	Low Average
Processing Speed Index (PSI)	**15**	**86**	**18**	**79–97**	**Low Average**
Naming Speed Index (NSI)	160	78	7	72–89	Very low
Full Scale IQ (FSIQ)	***69***	***99***	***47***	***93–105***	***Average***

Note. Boldface, primary index score. Italics, global composite score. Average composite score is 100. About 68% of scores fall between 85 and 114. About 95% fall between 70 and 129.

Kaufman Test of Educational Achievement, Third Edition (KTEA-3), Form A

Composite/Subtest Score Summary

Composite/subtest	Subtest raw score	Sum of subtest standard scores	Standard score	90% confidence interval	Percentile rank	Descriptive category
Math Composite	—	171	84	80–88	14	Below average
Math Concepts and Applications	58	—	90	85–95	25	Average
Math Computation	39	—	81	75–87	10	Below average
Math Fluency	17	—	78	71–85	7	Very low

Note. All KTEA-3 scores are reported as standard scores. Average standard score is 100. About 68% of scores fall between 85 and 114. About 95% fall between 70 and 129.

Error Analysis

	Math Concepts and Applications (last item administered: 70)				Math Computation (last item administered: 47)			
Error category	Items attempted	Average # of errors	Student's # of errors	Skill status	Items attempted	Average # of errors	Student's # of errors	Skill status
Number concepts	22	0–1	1	A				
Addition	3	0	0	A	14	0	1	W
Subtraction	3	0	0	A	12	0	4	W
Multiplication	3	0	2	W	7	0–1	1	A
Division	3	0–1	1	A	4	0–1	2	W
Tables and graphs	3	0	0	A

Data investigation	2	0–1	1	A				
Multistep problems	4	0–2	4	W				
Word problems	11	0–1	3	W				
Exponent or root					1	0–1	1	A
Algebra	7	0–1	1	A	—	—	—	—
Wrong operation					38	0–1	0	A
Fact or computation					38	0–2	0	A
Regrouping: Addition					2	0	0	A
Regrouping: Subtraction					4	0	0	A
Subtract smaller from larger					4	0	0	A
Add or subtract numerator and denominator					1	0	0	A

	Math Concepts and Applications (last item administered: 70)				Math Computation (last item administered: 47)			
Error category	Items attempted	Average # of errors	Student's # of errors	Skill status	Items attempted	Average # of errors	Student's # of errors	Skill status
Equivalent fraction/ common denominator					—	—	—	—
Multiply/divide fraction					—	—	—	—
Mixed number					—	—	—	—
Incorrect sign					—	—	—	—
Uncodable					38	0	0	A

Note. A, average; W, weakness.

Ability–Achievement Discrepancy

KTEA-3 subtests/composite	Predicted KTEA-3 score	Actual KTEA-3 score	Difference	Critical value (.05)	Significant difference?	Base rate
Math Concepts and Applications	109	90	19	8	Yes	≤5%
Math Computation	107	81	26	8	Yes	≤2%
Math Fluency	—	78	—	—	—	—
Math Composite	108	84	24	8	Yes	≤2%

Pattern of Strengths and Weaknesses Analysis

- Area of processing strength: WISC-V Verbal Comprehension Index (113)
- Area of processing weakness: WISC-V Naming Speed Index (78)
- Area of achievement weakness: KTEA-3 Math (84)

Comparison	Relative strength score	Relative weakness score	Difference	Critical value (.05)	Significant difference?	Supports SLD hypothesis?
Processing strength/ achievement weakness	113	84	29	10	Yes	Yes
Processing strength/ processing weakness	113	78	35	11	Yes	Yes

PART VI

Contemporary and Emerging Issues in Intellectual, Cognitive, and Neuropsychological Assessment

CHAPTER 30

Using the Joint Test Standards to Evaluate the Validity Evidence for Intelligence Tests

Alyssa Montgomery
Erica Torres
Jamie Eiseman

Anyone involved with assessment has at least two main legal and ethical responsibilities: (1) to administer and interpret tests correctly, and (2) to use tests that are adequate for their intended purpose. Since 1966, the *Standards for Educational and Psychological Testing* volume, or one of its revisions, has been considered the "gold standard" in guidance on testing (American Educational Research Association [AERA], American Psychological Association [APA], & National Council on Measurement in Education [NCME], 2014). Collaboratively prepared by AERA, APA, and the National Council on Measurement in Education (NCME), the most recent edition of the *Standards* (2014) is a product of the Joint Committee for the Revision of the Standards for Educational and Psychological Testing. The purpose of the *Standards* is to "promote sound testing practices and to provide a basis for evaluating the quality of these practices" (AERA et al., 2014, p. xx).

For the 2014 *Standards,* the Joint Committee responsible for overseeing the revisions was tasked with examining five specific areas: "consider the accountability issues for use of tests in educational policy; broaden the concept of accessibility of tests for all examinees; represent more comprehensively the role of tests in the workplace; broaden the role of technology in testing, and provide for a better organizational structure for communicating the standards" (AERA et al., 2014, p. 3). To meet the goals of considering accountability, broadening accessibility, comprehensively representing tests in the workplace, broadening technology in testing, and restructuring to better communicate the standards, several changes were made in the 2014 edition. One important change involved the issue of fairness. In 1999, fairness was woven into multiple chapters of the *Standards.* In 2014, by contrast, one chapter was dedicated specifically to fairness. The authors of the 2014 *Standards* believed that writing a separate chapter about fairness would allow for a broader application of it, rather than applications only for subgroups of test takers (e.g., individuals with disabilities, individuals from culturally and linguistically diverse backgrounds). Although subgroups are referenced frequently, the authors did not want readers to think that these are the only groups to which fairness considerations apply. Despite the wide range of considerations presented throughout the 2014 *Standards,* the present chapter, like the chapters by Braden and Niebling (2005, 2012) in previous editions of *Contemporary Intellectual Assessment,* focuses on issues related to validity—of which fairness is one.

According to the *Standards,* "Validation evidence allows for a summary judgment of the intended interpretation that is well supported and defensible" (AERA et al., 2014, p. 22). The guiding principle regarding the standards for validity is that tests provide "clear articulation of each intended test interpretation . . . and appropriate validity evidence in support of each intended interpretation" (p. 23). As such, we have integrated and analyzed the evidence available to support the validity of several tests, based on the *Standards*' guiding principles and individual themes. We have used the original conceptual framework of validity set forth by Braden and Niebling (2005, 2012) and applied that framework when determining evidence of validity based on the *Standards*.

Evaluating an intelligence test's validity involves a summary judgment of the collective evidence. Validity "cannot be determined by using a checklist" (AERA et al., 2014, p. 6). Therefore, this chapter outlines examples of evidence that can be considered in assessing validity, and provides clear and explicit examples of a test's validity found in the technical manuals of current measures of intelligence and cognitive abilities. This chapter is not intended to serve as an exhaustive and comprehensive list of evidence for each test, but rather as a guide to help clinicians evaluate a test's validity. Other issues to be considered by the reader, as outlined by the *Standards,* include: (1) When a test publisher claims to have made efforts to adhere to the *Standards,* the publisher should offer supporting evidence; (2) the reader should understand that the *Standards* do not set forth particular methods of statistical reporting, so a "generally accepted equivalent" (p. 6) can be implied and used as support; and (3) while the *Standards* make notes regarding relevant legal requirements, legal consultation should always be sought when appropriate.

Ensuring the validity or accuracy of any assessment is "the most fundamental consideration in developing tests and evaluating tests" (AERA et al., 2014, p. 11). Messick (1989) defines validity as "an integrated evaluative judgment of the degree to which empirical evidence and theoretical rationales support the adequacy and appropriateness of inferences and actions based on test scores or other modes of assessment" (p. 5). Validity can be thought of in terms of the extent to which a test measures what it intends to measure. Ensuring and evaluating test validity are the responsibilities of test developers and test users, respectively. For test developers, creating tests that accurately reflect the constructs intended to be measured is critical to a test's success. However, this chapter is meant primarily for test users, and is intended to serve as a reference for how to interpret the validity of the intelligence tests and the scores obtained from them. Users of these instruments maintain a responsibility to be able to say, with confidence, that the results of a particular test can be considered accurate and that the interpretations based on those results are relevant.

To provide examples of how to interpret the validity of intelligence tests, we have selected the following tests, all of which are described at length in separate chapters in this book: the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014a: see Wahlstrom, Raiford, Breaux, Zhu, & Weiss, Chapter 9, this volume); the Cognitive Assessment System—Second Edition (CAS2; Naglieri, Das, & Goldstein, 2014a; see Naglieri & Otero, Chapter 15, this volume); the Woodcock–Johnson IV Tests of Cognitive Abilities (WJ IV COG; Schrank, McGrew, & Mather, 2014; see Schrank & Wendling, Chapter 14, this volume); and the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007a; see Elliott, Salerno, Dumont, & Willis, Chapter 13, this volume). To identify evidence regarding each test's validity, information was gathered from their respective technical manuals and, in some cases, their administrative and scoring manuals. The following areas were assessed for each test.

TEST CONTENT

One source of evidence that practitioners should consider when evaluating the validity of a psychological test is its content validity. Critical validity evidence can be taken from "an analysis of the relationship between the content of a test and the construct it is intended to measure" (AERA et al., 2014, p. 14). *Test content* is defined as "the themes, wording, and format of the items, tasks, or questions on a test, as well as the guidelines for procedures regarding administration and scoring" (AERA et al., 2014, p. 14). Content includes the development of the instrument, including the specific steps that were designed and used in the process of creating it (Sullivan, 2011). With regard to the validity of test content, the items should cover the constructs that the test authors claim it measures (Huck, 2012). According to Goodwin and Leech (2003), test content validity is based on "logical analyses and experts' evaluations of the content of the measure, including items, tasks, formats, wording, and processes required of examinees" (p. 183). In other words, this type of validity is used to assess whether the content of a test represents a specific content domain accurately.

When evaluating an intelligence test's content validity, users should consider the test's "sufficiency, clarity, relevancy, and the match between the items and tasks" (Goodwin & Leech, 2003, p. 183). The test should provide the user with a clear definition of the broad and narrow constructs that the test intends to measure, as highlighted in Standard 1.1 (AERA et al., 2014). For example, the DAS-II clearly defines its overall composite score, General Conceptual Ability (GCA), as "the general ability of an individual to perform complex mental processing that involves conceptualization and the transformation of information" (Elliott, 2007b, p. 17). To further support its content validity, the DAS-II cluster scores and subtests are also clearly defined for the reader throughout Chapter 2 of the test's introductory and technical handbook (Elliott, 2007b).

In addition to clear definitions of constructs, it is important to consider the theoretical basis of the test structure and the relationship of the individual items to the specific domains (Sireci & Faulkner-Bond, 2014). This information helps the user better understand the foundation upon which the interpretations are made. These elements are also discussed in Standard 1.2, which states, "The rationale should indicate what propositions are necessary to investigate the intended interpretation. The summary should combine logical analysis with empirical evidence to provide support for the test rationale" (AERA et al., 2014, p. 23). Again, we use the DAS-II as an example: Elliott (2007b) explains that the test was designed to follow Cattell–Horn–Carroll (CHC) theory (Schneider & McGrew, 2012; see Schneider & McGrew, Chapter 3, this volume, for a complete explanation of current CHC theory). Seven broad factors (i.e., comprehension–knowledge [Gc], fluid reasoning [Gf], visual processing [Gv], short-term memory [Gsm] or short-term working memory [Gwm], long-term storage and retrieval [Glr], cognitive processing speed [Gs], and auditory processing [Ga]) that "appear to be the most robust and replicable" (Elliott, 2007b, p. 13) are incorporated into the test, and their relationships to the individual subtests are explained.

Finally, the appropriateness of the test development process should be evaluated, as explained in Standard 1.11: Information related to the "procedures followed in specifying and generating test content should be described and justified" (AERA et al., 2014, p. 26). As an example, the WISC-V technical manual (Wechsler, 2014b, pp. 37–41) outlines the development stages of this fifth edition of the test, including the use of an advisory panel, expert research, and feedback from professionals to guide its development.

RESPONSE PROCESS

Response process, according to the *Standards,* refers to the process utilized by a test taker before providing his or her response. The consideration of response process as a component of validity was first introduced into the *Standards* in the 1985 revision (Padilla & Benítez, 2014). Standard 1.12 of the 2014 revision of the *Standards* states:

> If the rationale for score interpretation for a given use depends on premises about the psychological processes or cognitive operations of test takers, then theoretical or empirical evidence in support of those premises should be provided. When statements about the processes employed by observers or scorers are part of the argument for validity, similar information should be provided. (AERA et al., 2014, p. 26)

Analyzing an individual's response process allows the examiner to ascertain "the fit between the construct and the detailed nature of performance or response actually engaged in by test takers" (AERA et al., 2014, p. 15). Did the examinee approach the items in a way that makes sense, given the nature of what the item is purported to measure? In the 2014 *Standards,* the example is given that if an examinee is working on a segment about mathematical reasoning, analyzing the response process will highlight "whether test takers are, in fact, reasoning about the material given instead of following a standard algorithm" (p. 15).

Questioning the examinee is one form of demonstrating evidence of response processes. Other methods of demonstrating evidence of this type of validity may include drafts throughout the writing process, response time, and eye movement (AERA et al., 2014). Methods such as analyzing multiple drafts of the same writing assignment, documenting how long it takes for an individual to respond, or tracking eye movements can be broken into two categories, according to Padilla and Benítez (2014): "those that directly access the psychological processes or cognitive operations (think aloud, focus group, and interviews), compared to those which provide indirect indicators which in turn require additional inference (eye tracking and response times)" (p. 139).

One example of how a test might employ this response process comes from the CAS2 Planning subtests (Naglieri et al., 2014a). On these subtests, guidelines for observing and quantifying strategies used by the test taker are provided. A Strategy Assessment Checklist is printed in the examiner's record form, offering brief descriptions of various approaches often employed. Additionally, there is a section on the checklist to document observed/reported strategies not included on the checklist. On the CAS2, questioning of the examinee takes place after a Planning subtest is completed, and examples of such queries are "Tell me how you did these," or "How did you find what you were looking for?" (Naglieri, Das, & Goldstein, 2014b, p. 7). These queries are designed to explore how the examinee arrived at his or her answers and to shed light on the meaning of obtained scores.

In addition to learning about how a test taker approaches various tasks, analyzing response processes helps identify what abilities, apart from those assumed to be needed based on what the items are intended to measure, may contribute to an examinee's performance. Response process studies from different subgroups can help itemize such abilities, and provide valuable information regarding variability in score interpretation (AERA et al., 2014).

INTERNAL STRUCTURE

Another type of validity evidence to be considered is *internal structure*. Rios and Wells (2014) outline three types of internal structure that can be assessed: *dimensionality, measurement invariance,* and *reliability*. This type of evidence is necessary to determine "the degree to which the relationships among test items and test components conform to the construct on which the proposed test score interpretations are based" (AERA et al., 2014, p.16). Analyzing the internal structure of a test gives test developers and test users a better understanding of whether the various test components (test items, composites, etc.) measure what was intended. Therefore, gathering evidence of the internal structure of a test assists in making well-grounded inferences based on test results.

Dimensionality is a component of a test's internal structure that relates to whether the relationships among subtest items support suggested inferences. Factor analysis is commonly used to illustrate the relationship among subtest components. Standard 1.13 states that when a test reportedly is unidimensional, it is "supported by a multivariate statistical analysis, such as a factor analysis, showing that the score variability attributable to one major dimension was much greater than the score variability attributable to any other identified dimension, or showing that a single factor adequately accounts for the covariation among test items" (AERA et al., 2014, p. 27). Conversely, when tests are multidimensional and more complex, the relationships between the scores "should be shown to be consistent with the construct(s) being assessed" (p. 27). Multidimensional tests that yield composite scores should provide the user with additional information related to the rationale for and interpretation of these subscores. As stated in Standard 1.14, evidence should be provided that supports the subscores' relationship to the construct and demonstrates that they can be validly and reliably interpreted.

Measurement invariance, or equivalence, is another type of internal structure that should be evaluated carefully. Standard 3.6 states: "Where credible evidence indicates that test scores may differ in meaning for relevant subgroups in the intended examinee population, test developers and/or users are responsible for examining the evidence for validity of score interpretations for intended uses for individuals from those subgroups" (AERA et al., 2014, p. 65). Because current intellectual assessments are administered to individuals from many different racial, cultural, geographic, or educational backgrounds, it is important that the tests are fair for all. Analyzing potential bias within a test allows clinicians to determine whether results are a fair representation of a client's skills, or whether his/her group membership influenced the score. One way to assess the fairness of a test across different groups is to evaluate the differential item functioning (DIF) (AERA et al., 2014, p. 51). Although DIF provides information regarding whether the scores of particular groups are significantly different, it does not, by itself, determine whether a test is biased (see Ortiz, Piazza, Ochoa, & Dynda, Chapter 25, this volume, for a discussion).

The final type of internal structure to be assessed is a test's reliability. The *Standards* volume includes a separate chapter on reliability because it is recognized as an independent characteristic of scores that must be considered. Before a practitioner can make statements about a test's validity, its reliability must be evaluated because it has implications for validity (AERA et al., 2014, p. 34). Simply put, if a test is not reliable, it cannot be valid for any purpose.

RELATIONS TO OTHER VARIABLES

When test users are examining the evidence of validity, it is important to consider whether the test predicts an expected outcome, as well as whether the test results relate to the results of other tests thought to measure a similar construct (AERA et al., 2014). In other words, would similar results be found, regardless of which intelligence test was administered? Test results can be compared to some "gold standard" of measurement, to determine whether the scores from one test correlate as expected with scores from another. When the relationships between tests are explored, three specific types of evidence are considered: (1) convergent and discriminant evidence, (2) test–criterion relationships, and (3) validity generalization.

Convergent evidence demonstrates relationships between measures that are expected to assess similar constructs (e.g., intelligence tests compared to intelligence tests), while *discriminant* evidence presents the lack of relationships between measures that assess dissimilar constructs (e.g., intelligence tests compared to behavior rating scales). An example of convergent evidence on the CAS2 is found by examining two subtests in the Attention composite scale, Expressive Attention and Number Detection. Both are intended to measure the construct of attention, but responses for the Expressive Attention subtest are oral, while the responses for the Number Detection subtest are written. In theory, the subtests should correlate highly, since they are both measuring attention. Discriminant evidence, for example, might be found by comparing the Planned Codes and Word Series subtests of the CAS2. The Planned Codes subtest is part of the Planning scale, which measures a test taker's ability to create a plan, follow it, reflect on whether the plan worked, and alter the plan accordingly, while the Word Series subtest is part of the Successive scale, which assesses an examinee's capacity to make sense of or understand information presented in a strict order. Although these two subtests should correlate (they are both assumed to be measuring some aspect of intelligence), they should have lower correlations to each other (they are assumed to be measuring different aspects of intelligence) than to subtests assessing the same construct of intelligence. Reviewing a correlation matrix and finding that the correlations between the two subtests are dissimilar would be evidence of discriminant validity.

For example, Naglieri and colleagues (2014b) compared the CAS2 and the CAS2: Brief. They found that the two assessments were "highly correlated (Full Scale r = .78 for Core and .80 for Extended Batteries)" (p. 88), and asserted that each scale of the PASS correlated highest with the same scale on the other assessment (e.g., the Planning composite on the CAS2 had the highest correlation with the Planning subtest on the CAS2: Brief).

In the 2014 *Standards,* Standard 1.16 states that when other variables are being considered with test results, "the rationale for selecting the additional variables should be provided" (AERA et al., 2014, p. 19). On the CAS2, for example, Naglieri, Das, and Goldstein (2014c) itemized disorders (e.g., attention-deficit/hyperactivity disorder [ADHD], anxiety disorder, autism spectrum disorder [ASD]) as other variables considered. Although these authors did not provide a clear rationale for why the specific variables were included, one can assume that this was done because these are among the disorders most commonly encountered by school practitioners. When examining the group with ASD, Naglieri and colleagues stated that those with an ASD diagnosis have been shown to have deficits in shifting their attention. An attention deficit was supported by the CAS and CAS2 results, as well as by results from independent researchers. Specifically, the group with ASD performed most poorly on the CAS2 Attention scale, which supports the validity of the Attention scale.

Figures 30.1 through 30.4 provide examples of validity evidence that were collected from the four intelligence tests referenced in this chapter: the WISC-V, WJ IV COG, DAS-II, and CAS2, respectively. Although these figures do not exhaust all evidence for each test, they provide examples of the types of information necessary to examine when evaluating a test's validity. In addition, Table 30.1 provides a few examples of how these four intelligence tests compare across various types of validity evidence.

IMPLICATIONS

Using the principles set forth by the 2014 *Standards,* we have reviewed the most recent editions of four contemporary intelligence tests in this chapter, and have discussed the evidence that the authors of these tests provided for them. Test developers have a responsibility to provide the information necessary for a practitioner to assess a test's validity; however, it is imperative that test users understand how to interpret and evaluate

Cross-cutting standards (Standards 1.1, 1.2, 1.3, 1.4, 1.8, 1.10, 1.23)

- Score interpretation and intended use are defined. (pp. 14–21)
- Research on the theories and models are addressed. (pp. 22–28)
- Factor analysis is discussed. (pp. 77–84)
- The Full Scale and the primary, ancillary, and complementary indexes are described. (pp. 20–21)
- Clear subtest descriptions are provided. (pp. 7–14)
- Neurodevelopment research, specific cognitive abilities, and working memory models support the rationale for test interpretation. (pp. 23–28)
- Guidelines for interpretation are provided. (pp. 149–186)
- Users are cautioned to use the results as part of a decision-making process, not as a sole factor. (pp. 147, 157, 186)
- Test developers explicitly indicate the norms upon which the test was used. (pp. 38, 39)
- Norming sample is clearly defined and relates to the target population. (pp. 42, 43)
- The standardization and development of the normative sample are clearly explained. (p. 31)

Test content (Standards 1.9, 1.11)

- Subtests and indexes are described in detail. (pp. 7–15)
- The updated structure and subtest modifications are explained, and the purpose of the changes is supported. (p. 6)
- An advisory panel was assembled in order to provide feedback regarding the clinical utility and appropriateness of the items. (p. 38)

Response processes (Standards 1.7, 1.12, 1.25)

- Test developers provide evidence to support the intelligence models and research that contributed to the foundation of the test. (pp. 22, 70)
- Response results were examined to ensure that the test was measuring its intended purposes. (p. 70)
- Specifically, responses were assessed to investigate the possibility of unintentionally providing a correct response, and then changes were made. (p. 70)

Internal structure (Standards 1.13, 1.14, 1.15)

- Intercorrelations for subtest, process, and composite scores are provided for all ages. (pp. 72–77)
- Evidence is provided for interpretation of composite scores, as well as subscores and score differences. (pp. 71–73)
- Confirmatory factor analyses provide evidence for the five-factor model chosen by test developers. (pp. 77–78)
- Evidence is provided to support the interpretation of four levels: the Full Scale, primary index, ancillary index, and complementary index levels. (pp. 20, 77, 78, 157–159, 165, 166)

Relations to other variables (Standards 1.16, 1.17, 1.18, 1.19, 1.20, 1.21, 1.22)

- The WISC-V developers examined two types of external variables: scores on other instruments designed to measure the same or similar constructs, and results for special groups.
- Evidence about correlations is provided with regard to other intelligence tests, achievement tests, adaptive scales, and rating scales.
- Special groups that were examined included children identified as intellectually gifted, children with mild or moderate intellectual disability, children with borderline intellectual functioning, children with specific learning disorders, children with ADHD, children with disruptive behavior, children with traumatic brain injury, children who were English-language learners, and children with autism spectrum disorder. Limitations of these studies are explained.
- Data suggest that the current edition correlates highly with the prior edition. (pp. 85–147)

(continued)

FIGURE 30.1. Examples of WISC-V validity evidence. All page numbers refer to the WISC-V technical and interpretive manual (Wechsler, 2014b).

Fairness, bias, and consequences of testing (Standards 1.5, 1.6, 1.7, 1.10, 1.17, 1.18, 1.19, 1.22, 1.24, 1.25)

- WISC-V scales have been evaluated using score differences between groups; race, ethnicity, sex, and socioeconomic status were specifically examined. (p. 147)
- Subtests and items were assessed for potential bias by expert examiners. Items that were deemed to be problematic were identified. (p. 32)

FIGURE 30.1. *(continued)*

Cross-cutting standards (Standards 1.1, 1.2, 1.3, 1.4, 1.8, 1.10, 1.23)

- Descriptions of tests and clusters are clearly and comprehensively explained and supported by their relation to the CHC theory. (Mather & Wendling, 2014, pp. 13–25)
- CHC abilities are defined. Implications for demonstrated strengths/weaknesses of skills are provided. (Mather & Wendling, 2014, pp. 7, 21–24, 84–96, 101)
- Evaluating individual strengths and weaknesses is encouraged, and procedures for doing so are provided. (Mather & Wendling, 2014, pp. 7, 92)
- Several types of scores can be interpreted, depending on the purpose of the assessment. (Mather & Wendling, 2014, pp. 77–84)
- Four levels of interpretation are encouraged: qualitative, level of development, proficiency, and relative standing in a group. (Mather & Wendling, 2014, pp. 75–77)
- When modifications are necessary to accommodate the test taker, the administrator is provided with recommendations, cautions, and implications for interpretation. (Mather & Wendling, 2014, pp. 41–53)
- The normative sample includes over 7,416 people ages 2–90. A detailed description of the sample (including age, sex, race, ethnicity, geographic location, and level of parent education) assists users in determining the test's appropriateness. (McGrew, LaForte, & Schrank, 2014, p. 1)

Test content (Standards 1.9, 1.11)

- Multidimensional scaling (MDS) was used to assess expert judgments in measuring content validity. (McGrew et al., 2014, pp. 129–134)
- All broad and narrow CHC factors are clearly described and explained. (McGrew et al., 2014, pp. 120–125)
- **Response processes (Standards 1.7, 1.12, 1.25)**
- Theoretical support and evidence are provided for the use of CHC theory. (McGrew et al., 2014, pp. 1–9)
- Broad and narrow abilities within the CHC model are identified and explained for use in interpretation. (Mather & Wendling, 2014, pp. 21–25, 84–90)

Internal structure (Standards 1.13, 1.14, 1.15)

- Cluster analysis is provided. (McGrew et al., 2014, pp. 143–149)
- Test and cluster correlations are provided for all age groups. (McGrew et al., 2014, pp. 143–149)
- To ensure that all items in each test measured the same narrow ability or trait, stringent fit criteria based on the Rasch model were employed during the process of item pool development and test construction. (McGrew et al., 2014, pp. 44–46)
- Broad- and narrow-ability constructs are justified by the CHC theory. (McGrew et al., 2014, pp. 120–125)
- Guidelines for interpreting performance are provided, which include four levels of test information to consider. Again, these levels are known as qualitative, level of development, proficiency, and relative standing in a group. (Mather & Wendling, 2014, pp. 75–77)
- Scores can be interpreted by grade equivalents, age equivalents, relative proficiency indexes, cognitive–academic language proficiency levels, percentile ranks, and standard scores. (Mather & Wendling, 2014, pp. 77–84)

(continued)

FIGURE 30.2. Examples of WJ IV COG validity evidence.

Relations to other variables (Standards 1.16, 1.17, 1.18, 1.19, 1.20, 1.21, 1.22)

- In the technical manual, results of 15 studies are charted to illustrate the relationships among other cognitive measures, oral language measures, and achievement measures. (McGrew et al., 2014, pp. 220–223)
- A three-stage model of structural validity is employed. (McGrew et al., 2014, pp. 149–167)
- Nine clinical groups are clearly identified, and group studies were completed to identify differences across groups. These groups included individuals with giftedness; intellectual disability/mental retardation; learning disabilities in reading, writing, or math; language delay; ADHD; head injury; and ASD. (McGrew et al., 2014, pp. 221–222)
- Data suggest that the current edition correlates highly with the prior edition. (McGrew et al., 2014, p. 2)

Fairness, bias, and consequences of testing (Standards 1.5, 1.6, 1.7, 1.10, 1.17, 1.18, 1.19, 1.22, 1.24, 1.25)

- Outside experts were consulted to ensure construct representation and limit confounding variables. (McGrew et al., 2014, pp. 43–44)
- Bias and sensitivity issues were evaluated for women, individuals with certain disabilities, and cultural or linguistic minorities. (McGrew et al., 2014, pp. 53–56)
- Differential item functioning was evaluated by using the Rasch iterative-logit method. Items were flagged if the difference was considered significant, and were removed from the test as appropriate. (McGrew et al., 2014, pp. 53–56)

FIGURE 30.2. *(continued)*

Cross-cutting standards (Standards 1.1, 1.2, 1.3, 1.4, 1.8, 1.10, 1.23)

- The normative sample includes 3,480 children between the ages of 2 and 17. Information on sex, race, ethnicity, level of parental education, and geographic location is included. The sample is broken down by group and compared to the U.S. population. Inclusion and exclusion criteria for the participants are included to further define the normative sample. (Chapter 6)
- The DAS-II follows a hierarchical structure and is influenced by various theories and perspectives, including CHC theory and neurodevelopmental research. (pp. 8–16)
- Subtests are related to associated broad and narrow CHC abilities to aid in interpretation. (pp. 9–11)
- A process of analysis is suggested, involving stages of comparison (e.g., core comparisons, diagnostic comparisons, ability–achievement comparisons). (Chapter 5)
- Examiners are encouraged to utilize multiple sources of information when interpreting the results of the evaluation. (p. 36)

Test content (Standards 1.9, 1.11)

- Clusters are described and related to CHC abilities, and interpretive considerations are provided. (Chapter 4)
- For each subtest, specific information is provided, including the subtest's purpose, contributing factors, interpretive considerations, and (for some subtests) alternate methods of administration. (Chapter 4)

Response processes (Standards 1.7, 1.12, 1.25)

- Specific clusters are supported by factor analysis. (pp. 153–158)
- An alternative stop point rule was incorporated, due to the probability of a child's providing an accurate response after a certain amount of incorrect responses. (p. 4)
- Rasch scaling was used to determine scoring. (pp. 115–118)

(continued)

FIGURE 30.3. Examples of DAS-II validity evidence. All chapter and page numbers refer to the DAS-II introductory and technical handbook (Elliott, 2007b).

Internal structure (Standards 1.13, 1.14, 1.15)

- Intercorrelations of subtests and composites are illustrated and comprehensively explained. (pp. 242–259)
- Subtest and composite correlation coefficients are provided for three age groups (2:6–3:5, 3:6–6:11, 7:0–17:11). (pp. 150–158)
- Confirmatory factor analysis is provided for core and diagnostic subtests. (pp. 158–162)
- CHC theory is used to support the rationale for test interpretation and implications. (pp. 8–14)
- Age equivalents are provided for norm-referenced subtests; limitations are outlined. (p. 86)

Relations to other variables (Standards 1.16, 1.17, 1.18, 1.19, 1.20, 1.21, 1.22)

- Correlations between other cognitive and academic achievement assessments are illustrated and discussed. (pp. 163–184)
- Special-group studies were conducted to identify differences between groups. The groups included individuals with intellectual giftedness, intellectual disability, reading disorders, reading and writing disorders, math disorders, ADHD, ADHD and learning disorders, expressive language disorder, mixed receptive–expressive language disorder, limited English proficiency, developmental risk, and deafness/hearing impairment. Groups are compared to matched controls. (pp. 184–218)
- Data suggest that the current edition correlates highly with the prior edition. (pp. 164–165)

Fairness, bias, and consequences of testing (Standards 1.5, 1.6, 1.7, 1.8, 1.10, 1.17, 1.18, 1.19, 1.22, 1.24, 1.25)

- A review panel was established and included members from a variety of cultural backgrounds. The panel evaluated the assessment to ensure fairness of test items. The technical handbook includes detailed description of the process involved in evaluating item bias and associated modifications of the findings. (p. 101)
- Fairness of prediction was assessed to determine whether the test can predict achievement similarly for different groups. (pp. 222–224)
- Examples of what factors should be considered before considering the scores valid and interpreting the results are presented. (pp. 21–24)

FIGURE 30.3. *(continued)*

Cross-cutting standards (Standards 1.1, 1.2, 1.3, 1.4, 1.8, 1.10, 1.23)

- Norming sample is clearly defined and relates to the target population of school-age children in the U.S. population in 2011. (Naglieri et al., 2014c, p. 42)
- Test authors explain the assessment's roots in planning, attention, simultaneous, successive (PASS) theory and in Luria's work on brain functioning. (Naglieri et al., 2014c, p. 1)
- Subtests and PASS scales are clearly defined. (Naglieri et al., 2014c, pp. 7, 10)
- The CAS2 is described as being able to determine factors such as individual strengths and weaknesses, processing compared to that of same-age peers, and PASS scores as they relate to achievement abilities. (Naglieri et al., 2014c, p. 12)
- Flexibility is discussed in regard to the administration of instructions to bilingual, deaf, and hard-of-hearing students. (Naglieri et al., 2014b, p. 6)

Test content (Standards 1.9, 1.11)

- Subtests and composites are described in detail. (Naglieri et al., 2014c, pp. 6–12)
- Test improvements and their purposes are explained and connected to PASS theory. (Naglieri et al., 2014c, pp. ix–x)
- PASS theory is explained and related to the measurement of PASS abilities. (Naglieri et al., 2014c, pp. 1–6)

(continued)

FIGURE 30.4. Examples of CAS2 validity evidence.

Response processes (Standards 1.7, 1.12, 1.25)

- The CAS2 is based on PASS theory and consists of four scales: Planning, Attention, Simultaneous, and Successive. (Naglieri et al., 2014b, p. 1)
- Test developers provide evidence to support this model. (Naglieri et al., 2014c, p. 4)
- Questioning about strategies utilized on various subtests gives insight into how test takers determine answers, and how the strategies relate to the standard score achieved. (Naglieri et al., 2014c, p. 99)

Internal structure (Standards 1.13, 1.14, 1.15)

- Confirmatory factor analysis (CFA) was used; "each subtest is permitted to load only on the factor that it represents." (Naglieri et al., 2014a)
- CFA models were utilized regarding the PASS theory in four age intervals. (Naglieri et al., 2014c, p. 111)
- Based on the criteria used by the authors, factor loadings range from moderate to very large. (Naglieri et al., 2014c, p. 112)
- All subtest correlations are significant. (Naglieri et al., 2014c, p. 116)
- When subtests were correlated with their designated PASS scale, subtests correlated highest with their specific PASS scale and lowest with the scales in which they are not utilized. (Naglieri et al., 2014c, p. 116)

Relations to other variables (Standards 1.16, 1.17, 1.18, 1.19, 1.20, 1.21, 1.22)

- Evidence is provided about the correlations between the CAS2 and other intelligence tests and achievement tests. (Naglieri et al., 2014c, p. 84)
- Special groups are explained (e.g., the bilingual and hard-of-hearing groups). (Naglieri et al., 2014b, p. 6)

Fairness, bias, and consequences of testing (Standards 1.5, 1.6, 1.7, 1.10, 1.17, 1.18, 1.19, 1.22, 1.24, 1.25)

- Scores were evaluated based on different groups: gender, region, ethnicity, Hispanic status, exceptionality status, household income and parental education (Naglieri et al., 2014c, p. 43)
- The test authors analyzed the potential for gender, ethnicity, and racial bias in test items. (Naglieri et al., 2014c, p. 82)

FIGURE 30.4. *(continued)*

validity claims. As such, this chapter is intended to be used as a reference for test users to guide them in evaluating whether any given test is valid for its intended use. The authors of the *Standards* state: "It is commonly observed that the validation process never ends, as there is always additional information that can be gathered to more fully understand a test and the inferences that can be drawn from it" (AERA et al., 2014, p. 12). The authors therefore encourage test users to reference multiple sources of validity evidence, and to develop opinions about validity that are "supported and defensible" (p. 13).

In addition to gathering evidence regarding test validity, we have presented strengths and limitations of the validity evidence presented in the test manuals of the four intelligence tests reviewed. Most manuals include a separate section on validity, which is often broken down into validity types. For example, Naglieri and colleagues (2014c) allocated 48 pages in the technical manual of the CAS2 to content description validity, criterion predication validity, and construct identification validity. Organizing validity evidence by specific types of validity assists users in accessing the information needed to make well-founded decisions about whether to use the test for a given purpose.

A strength of the intelligence tests reviewed is that their manuals contain comprehensive and explicit data for their respective standardization samples. This level of detail allows test users to determine whether the test is appropriate for the population of individuals they intend to evaluate. Including members of a particular group (e.g., individuals with specific learning disabilities) in a test's norming sample does not, of course, automatically make the test fair for that group, and omission of members of a group does not automatically invalidate the test for that group. However, the manuals for the tests referenced herein provide data to allow test users to judge the fairness of the test for specific groups. It should be noted that not

TABLE 30.1. A Comparison of Data Related to Validity Evidence across Tests

Norming sample and intended uses clearly explained	Evidence of internal structure	Correlations with clinical samples
	WISC-V	
N = 2,200 20 age groups from ages 6:0 to 16:11 are created and include 200 children in each group	Verbal Comprehension Index and Similarities = .92 Processing Speed Index and Similarities = .29	Mean General Ability Index for those with traumatic brain injury = 85.4 Mean GAI for matched control group = 103.9
	WJ IV COG	
N = 7,416 Groups are based on individual ages from 2 to 19, and grouped by tens starting at 20. Number of participants varies based on age. Examples (age/number of participants): 3 = 203 11 = 329 20–29 = 759	Oral Vocabulary and other Gc tests = .62–.70 Oral Vocabulary and Gs tests = .26–.32	Mean Spelling score for those with learning disability in reading = 74.2 Mean Spelling score for those with learning disability in math = 85.9
	CAS2	
N = 1, 342 Ages: 5.0–17.11 11 age groups are reported, and number of participants varies per group 686 males 656 females	Ages 5–7: Matrices and Verbal–Spatial Relations = .40 Figure Memory and Expressive Attention = .19 Ages 8–18: Planned Connections and Planned Number Matching = .46 Number Detection and Sentence Questions = .18	Mean Full Scale IQ for Core and Extended Batteries: Giftedness/talent: Core Battery = 111.8; Extended Battery = 112.9 Speech–language impairment: Core Battery = 90.9; Extended Battery = 91.2 Learning disability: Core Battery = 87.1; Extended Battery = 86.4 ADHD: Core Battery = 93.5; Extended Battery = 92.5 Emotional disturbance: Core Battery = 91.9; Extended Battery = 90.8 Anxiety disorder: Core Battery = 91.2; Extended Battery = 90.4 ASD: Core Battery = 83.8; Extended Battery = 82.1
	DAS-II	
N = 3,480 Children divided into 18 age groups from ages 2:6 to 17:11, with 200 children per group	Early Years: Naming Vocabulary and Verbal ability = .91 Naming Vocabulary and Nonverbal Reasoning ability = .56	Mean General Conceptual Ability (GCA) for children with ADHD = 100.2 Mean GCA for matched control group = 105.9

all data necessary for reviewing validity information for the WISC-V are contained in the manuals that come with the test. A special supplement (Wechsler, 2014c) must be downloaded from the test company's (Pearson's) website.

Test publishers and authors over the years have generally adhered to the *Standards*. In the 2012 edition of this book, Braden and Niebling noted, "We appreciate that test developers cannot be held accountable for all possible consequences of test scores" (p. 755). While this remains true overall, it appears that current test manuals provide sufficient information to allow test users to make sound decisions about test use and interpretation.

ACKNOWLEDGMENTS

It is with sincere gratitude that we acknowledge the guidance, dedication, and instructional support provided by Ronald Dumont and John O. Willis. Additionally, we extend our respectful appreciation to Jeffrey P. Braden and Bradley C. Niebling for their validity standards framework, and for their chapters in the previous editions of this book. We would also like to acknowledge and thank Dawn P. Flanagan for offering this publication opportunity.

CHAPTER 31

Using Confirmatory Factor Analysis to Aid in Understanding the Constructs Measured by Intelligence Tests

Timothy Z. Keith
Matthew R. Reynolds

Factor analysis is inexorably linked with the development of intelligence theory and intelligence tests. Early intelligence theories and factor-analytic methods were developed in tandem, and the connection continues to this day. Carroll's (1993) three-stratum theory of intelligence was developed in part through the use of *exploratory factor analysis* (EFA).

For much of its history, the term *factor analysis* meant what is now called EFA. In its simplest form, EFA involves making a series of decisions about the method of factor extraction to use, the number of factors to retain, the method of rotation to use, and the criterion for meaningfulness of factor loadings. For researchers who do not wish to make these decisions, most computer programs will default to a common method if none is specified (not always a wise choice). The output from the analysis consists of factor loadings of each variable on each factor and, if an oblique rotation was used, correlations among the factors. The researcher then assigns names to the factors based on the loadings of the variables on the factors, along with relevant theory and previous research.

In the hands of an expert, EFA can be much more complex and sophisticated than the simple approach just described. A variety of extraction methods can be used, depending on the questions of interest; complex decision rules and expert judgment can be used to determine how many factors should be extracted; and a variety of graphical and mathematical methods can be used to rotate the extracted factors to simple structure. For example, Carroll (1993, Ch. 3) outlined an EFA approach that was an elegant combination of consistency and judgment; see also McDonald (1999, p. 187). Whether simple or complex, EFA involves judgment on the part of the researcher: judgment concerning the decisions required, and judgment concerning the meaning of the extracted factors. It is this aspect of EFA that can be disconcerting to those wanting yes–no answers to questions, but it is also this requirement for theory, thought, and judgement that makes the approach so alluring and so powerful. Although researchers sometimes choose EFA to allow the data to "speak for themselves," it is always ultimately the researcher who does the "speaking," given the judgment needed.

In contrast, and in its simplest form, *confirmatory factor analysis (CFA)* requires the researcher to decide, in advance, the nature of the factor structure underlying the data. He or she must specify the number of factors and the variables that load on each factor. So, for example, the researcher may specify that variable 1 loads on factor 1, but not on factor 2. The researcher may specify that factors are correlated, or may specify that they are uncorrelated. The results of the analysis provide *fit statistics,* which provide feedback as to the adequacy of the specified factor structure, or the degree to which the *model* (factor structure) *fits* the data (reproduces the covariances among the data). In CFA, in other words, the researcher tests the adequacy of a particular factor structure by restricting the factor solution (thus the method is sometimes called *restricted factor analysis*) and seeing whether that restricted solution is consistent with the data. In contrast, in EFA, the researcher examines and imparts meaning to the best factor structure (given the decision rules used).

CFA is often described as a more theory-driven approach than EFA. This assertion probably involves some overstatement. It is possible, for example, to use EFA in a theory-driven, hypothesis-testing manner (cf. Thorndike, 1990; Thurstone, 1947), just as it is possible to use CFA in an exploratory, theory-absent manner. Indeed, Jöreskog and Sörbom (1993, p. 115) argued that a combination exploratory–confirmatory "model-generating" approach is likely the most common approach to structural equation modeling (SEM) and CFA. Nevertheless, because CFA requires the specification of a model—and thus knowledge about the probable structure of the characteristic being measured—some sort of theory (formal or informal, strong or weak) is required. EFA can easily be conducted in the absence of theory, although theoretically driven analyses are almost invariably more complete and informative than atheoretical ones. EFA can be a valuable tool for *developing* theory, whereas CFA may be better suited for *testing* existing theory.

This chapter demonstrates the use of CFA to understand the constructs measured by modern intelligence tests. It begins with a "simple" CFA model, and gradually moves to CFA methods that provide a more complete evaluation of the theories underlying tests (e.g., hierarchical analysis, the comparison of alternative models, testing hypotheses about tests and constructs, and multisample analyses). Our emphasis is on the use of CFA to *test hypotheses* about *tests* and *theories.*

There are several computer programs available that conduct CFA. At this writing, it is possible to obtain manuals for all of these programs as .pdf files online. These programs are designed to conduct latent-variable SEM; SEM includes and subsumes CFA (the *measurement model,* in the jargon of SEM), and thus SEM programs also conduct CFA. The oldest program is LISREL (LInear Structural RELations; Jöreskog & Sörbom, 1996); extensive information about the program is available at *www.ssicentral.com.* Other common programs include EQS (Bentler, 1995; *www.mvsoft.com*) and Mplus (Muthén & Muthén, 1998–2010; *www.statmodel.com*), perhaps the most powerful and flexible SEM program. The analyses presented in this chapter were conducted using Amos (Analysis of MOment Structures; Arbuckle, 2014; *www.amosdevelopment.com* or *www-03.ibm.com/software/products/en/spss-amos*), likely the easiest-to-use such program. Amos uses a drawing program to provide pictorial input and output of models. The figures in this chapter were drawn with Amos, and the graphical output shown was produced by the Amos program. Finally, the free statistical software R has several SEM packages: Lavaan, OpenMx, and SEM (*www.r-project.org*).

AN INTRODUCTORY EXAMPLE

The Kaufman Adult and Adolescent Intelligence Test (KAIT) is an older measure of cognitive abilities for adolescents and adults ages 11 through adulthood (Kaufman & Kaufman, 1993). According to the manual, the KAIT was designed to measure intelligence according to the Cattell–Horn theory of intelligence, although only two of the Cattell–Horn factors are included in the KAIT model (*fluid intelligence,* also known as *novel reasoning,* and *crystallized intelligence,* also known as *comprehension–knowledge*). In addition, the KAIT was designed to measure *delayed recall,* or a person's memory for material learned earlier in the test. Thus the KAIT includes 10 subtests designed to measure three abilities: fluid intelligence (Gf), crystallized intelligence (Gc), and delayed recall.

Figure 31.1 shows this theory underlying the KAIT in figural form. The 10 subtests are shown in rectangles, and the abilities they are designed to measure are enclosed in ovals. Directed arrows or paths point from the abilities to the subtests, in recognition of the implicit assumption that the abilities residing within a person are what cause him or her to score a certain way on a subtest. So, for example, examinees' levels of fluid intelligence are the primary determinant of their scores on the Mystery Codes subtest.

Figure 31.1 is also the beginning of a CFA model; a more complete CFA model is shown in Figure 31.2.[1] In the jargon of CFA, the variables enclosed in rectangles (the subtests) are the *measured,* or *manifest,* or *observed* variables, whereas

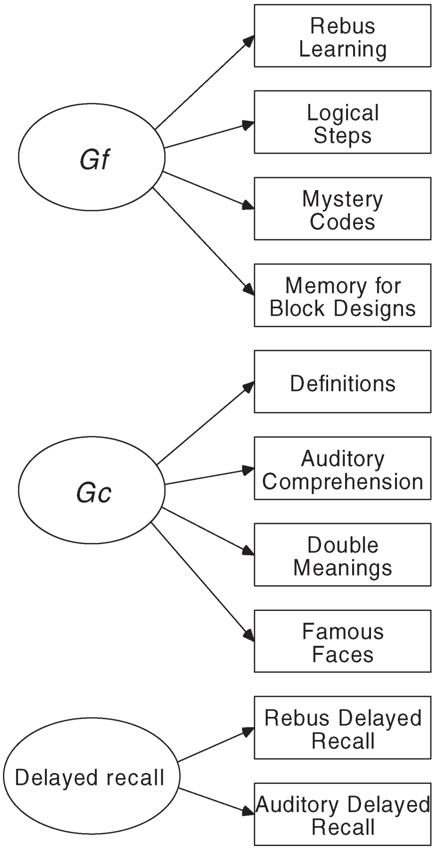

FIGURE 31.1. Theoretical structure of the KAIT.

the variables enclosed in ovals (i.e., the KAIT abilities) are *unmeasured* or *unobserved* variables, also known as *latent* variables, or *factors*. The paths from latent to measured variables represent the factor loadings. Notice that not all possible paths are drawn. Theoretically, the lack of a path from, say, Gf to Double Meanings means that the test authors believe Double Meanings does not measure fluid intelligence, or that variation in fluid intelligence does not produce variation in scores on the Double Meanings subtest. Rather, scores on Double Meanings are a reflection of crystallized intelligence, as indicated by the path drawn from Gc to Double Meanings. At a practical level, the path from Gc to Double Meanings means that the factor loading will be estimated in the analysis, and the lack of the path from Gf to Double Meanings means that the factor loading of Double Meanings on G*f* will be fixed to 0.

Figure 31.2 includes information beyond that included in Figure 31.1. The curved, two-headed arrows between factors represent covariances (or, in the standardized output, correlations). Although the KAIT manual does not say so explicitly, it is reasonable to expect that the abilities measured by the KAIT are not independent of (uncorrelated with) one another. Modern intelligence theories recognize this relation among factors (e.g., Carroll, 1993, Chs. 2–3), and CFAs of intelligence tests should specify correlated factors (unless the theory underlying the tests maintains that the factors are independent). The figure also includes small ovals, labeled u1 through u10, with paths drawn to each of the subtests. The factors are not the only cause of a person's scores on the subtest; each subtest is also partially the result of other influences that are unique to each subtest, generally called *unique* or *specific* variances. In addition, each subtest is also affected by errors of measurement (*error* variance). These unique and error variances, combined, are represented by u1 through u10; they are enclosed in ovals because they are unmeasured. These unique and error variances are hereafter termed *unique variances*, although they are referred to by a variety of names here and in the literature, including *errors* and *residuals*.

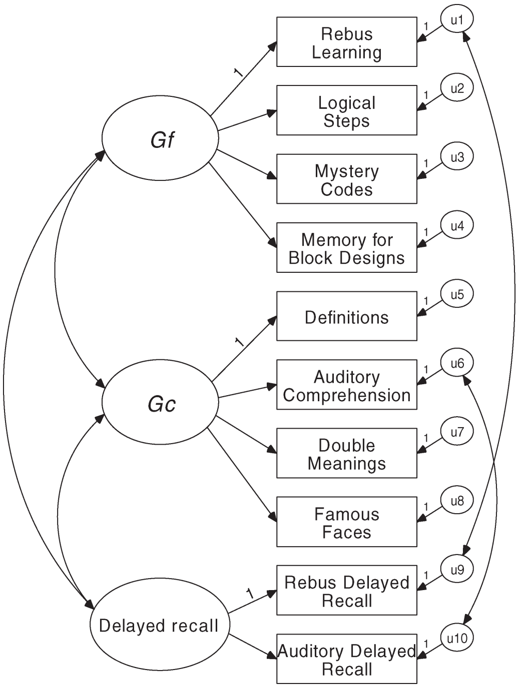

FIGURE 31.2. A CFA model of the structure of the KAIT.

Several of the paths in Figure 31.2 have the value 1 beside them. The measured variables in the model have a defined scale, and that scale is whatever scale was used for each subtest (e.g., a scaled score from 1 to 19). But none of the latent variables (neither the factors nor the unique variances) has a predetermined scale. The 1's beside the paths serve the purpose of setting the scales of the latent variables by setting the path to 1.0. The path of 1.0 from Gf to Rebus Learning, for example, sets the scale of the Gf factor to be the same as the scale for Rebus Learning. Thus each factor includes one path, or loading, of 1.0, and the path from each of the unique variances to the measured variables is set to 1.0 (to set the scale of the unique variances to be the same as the corresponding measured variable). The use of 1.0 is arbitrary—any value could be used—and once all of the parameters of the model that were not fixed to a value are estimated (called the *unstandardized* solution), all values are restandardized (the *standardized* solution).

Finally, the model in Figure 31.2 includes a less common characteristic: correlations among the unique variances, as represented by the curved lines connecting two pairs of the unique variances (e.g., u1 and u9). The Rebus Delayed Recall test on the KAIT requires examinees to remember rebuses learned earlier in the Rebus Learning subtest. Since Rebus Delayed Recall builds on Rebus Learning, it seems likely that the unique variances affecting Rebus Delayed Recall will be related to those affecting Rebus Learning. Similarly, the *error* variances affecting Rebus Delayed Recall may well be related to those affecting Rebus Learning. These possibilities may be built into the CFA model by specifying that the unique variances of the Rebus Delayed Recall and Rebus Learning subtests are allowed to correlate. There are other ways of doing so as well, including the specification of minor factors.

The KAIT standardization data were used to estimate the model. The KAIT manual includes correlation matrices of subtests for the KAIT at each age level, along with an average correlation matrix for the entire sample (Kaufman & Kaufman, 1993, p. 136). The correlation matrix and standard deviations for the entire standardization sample were used as input for the Amos computer program (Arbuckle, 2014) that converts them to covariances for the analysis. The average sample size ($N = 143$) for the different age groups was used as the sample size.

The results of the analysis are shown in Figure 31.3. The fit indices for the model are shown in the lower left of the figure. The model is *overidentified,* meaning that we could have estimated many more parameters in the model than we actually did. For example, the path from Gf to Definitions was fixed to 0, as were many other possible paths (note that the lack of a path is equivalent to fixing the path to 0). In an overidentified model, the number of parameters estimated is less than the number of variances and covariances among the measured variables. As a result, the model has positive degrees of freedom. *Degrees of freedom (df)* are an index of the degree of overidentification of a model; they are not, as in most other statistical analyses, related to the sample size. For the current model, *df* = 30 means that we could have estimated 30 additional parameters (e.g., paths, correlations).

It is also possible to conduct the analysis in reverse: to estimate the correlation or covariance matrix from the solved model. That is, we could have used the factor solution shown in Figure 31.3 to estimate what the covariances among the subtests should be, given the model. But because the model is overidentified, the estimates of the predicted covariances will not be identical to the covariance matrix used to estimate the model in

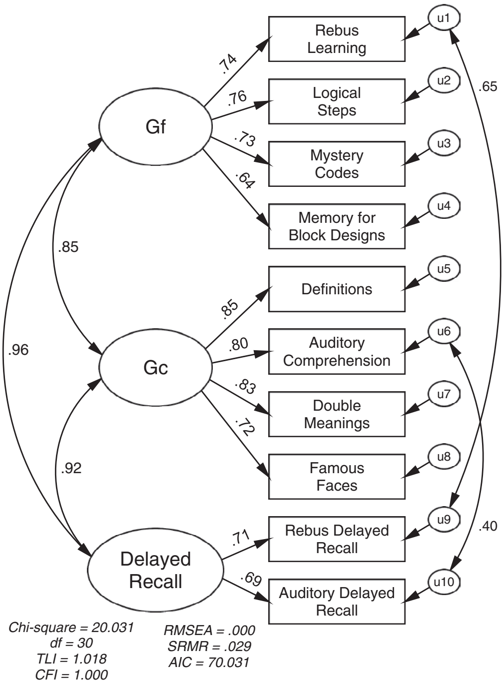

FIGURE 31.3. Results of a CFA of the structure of the KAIT. The results are for the standardized solution.

the first place (see Keith, 2015, Ch. 13, or Kline, 2016, Ch. 7, for a discussion of overidentification). The fit indices shown in the figure are all measures of the degree to which the matrix *implied* by the model differs from the matrix *actually* used to estimate the model.

Five fit indices are shown in the figure, although there are dozens to choose from. Chi-squared (χ^2) is the most commonly reported fit statistic. It has the advantage of allowing a statistical test of the fit of the model; it can be used with the *df* to determine the probability that the model is, in some sense, "correct." Thus a large χ^2 in comparison to the *df* (and a small probability—e.g., $p < .05$) suggests that the actual and implied covariance matrices are statistically significantly different, that the model provides a poor fit to the data, or that the model could not have produced the data. The model, therefore, is not a good representation of the "true" factor structure. In contrast, a small χ^2 in comparison to the *df* is desirable; if it is statistically nonsignificant ($p > .05$), it suggests that the model *could* have produced the data, and that the model does provide a reasonable explanation of the data.

Although χ^2 fits well within the tradition of significance testing in psychology (somewhat confusingly, however, the researcher wants it to be nonsignificant), it also has well-known problems (as does the tradition of either–or significance testing itself; cf. Cohen, 1994; Little, 2013). In particular, it is directly related to sample size, so that with large samples, virtually all χ^2's will be significant, even when the model is only trivially incorrect (see Tanaka, 1993, among others, for further discussion). With small samples, even inadequate models may have a good fit, as judged by χ^2. For this and other reasons, fit indices have been developed; the ones listed for this analysis were chosen because they highlight different dimensions of fit, and have shown promise in simulation studies (Fan, Thompson, & Wang, 1999; Hu & Bentler, 1998, 1999). Methodologists generally recommend using a combination of criteria.

One criticism of χ^2 is that it is a measure of the exact fit of the model to the data, whereas, at best, models are designed to *approximate* reality. The *root mean square error of approximation (RMSEA)* is, in contrast, a measure of approximate fit. Smaller values suggest a better fit, with values of .06 or smaller suggesting a good fit (Hu & Bentler, 1999), and those of approximately .08 suggesting an adequate fit (Browne & Cudeck, 1993). The RMSEA is sometimes reported along with its 90% confidence interval. The *standardized root mean square residual (SRMR)* may be one of the more intuitively appealing measures of fit. Recall that fit indices are derived from the similarity or dissimilarity between the actual covariance matrix used to estimate the model and the matrix implied by the model. The *root mean square residual (RMR)* represents the average of these differences, and the SRMR is the standardized average of these differences. Because a standardized covariance is a correlation, the SRMR, therefore, represents the average difference in the actual *correlations* among the measured variables and those implied by the model. Values of .08 or less suggest little difference in the two matrices (Hu & Bentler, 1999).

The *Tucker–Lewis index (TLI)* and the *comparative fit index (CFI)* both compare the fit of the model with that of a *null* model, one in which the measured variables are assumed to be unrelated (the null model is also referred to as the *independence* model; there can be other types of null models). The TLI appears to be relatively unaffected by sample size; the CFI is designed to estimate the fit in the population. For both, values of .95 or greater suggest a good fit of the model to the data (Hu & Bentler, 1999), with values above .90 suggesting an adequate fit. We sometimes report one of these indices (because they often are fairly similar in magnitude), sometimes both.

Briefly, all of the fit indices suggest that the KAIT model provides an excellent fit to the standardization data. χ^2 is small and statistically nonsignificant ($p = .668$); the TLI and CFI are large; and both the RMSEA and the SRMR are quite small. Thus the "theory" underlying the KAIT appears to fit the KAIT standardization data; the test appears to measure what the authors designed it to measure; and the structure of the KAIT appears valid. The next step, then, is to interpret the substantive results.[2]

The paths from latent to measured variables show the factor loadings. They are all large, and examination of their standard errors and *z* values (shown in the detailed printout, but not included here or in the figure) shows that they are all statistically significant. Likewise, the factor correlations are large and statistically significant, ranging from .96 for the correlation between the latent delayed-recall and Gf factors to .85 between Gf and Gc. Finally, the correlations among unique variances suggest that there is a substantial correlation between the variance of the Rebus Learning test that is not accounted for by the Gf factor and the variance of the Rebus Delayed Recall subtest that is not accounted for by the delayed-recall factor (*r*

= .65). Similarly, the unique variances of Auditory Comprehension and Auditory Delayed Recall are substantially correlated.

These findings generally support the validity of the KAIT. One curious finding, however, is the magnitude of the correlation between the delayed-recall and the Gf and Gc factors (.96 and .92, respectively), which are higher than the correlation between the two presumably more intellectual factors, Gf and Gc (.85). Such a finding could be investigated by comparing this model with plausible alternative models, as shown below.

An Alternative Method of Specifying Factor Models

Before we illustrate the comparison of competing alternative models, it is worth illustrating an alternative method of scaling the factors. The previous model set the scale of the latent factors by fixing a single factor loading from each factor to 1.0 (what Kline, 2016, refers to as *unit loading identification [ULI]*). An alternative is to fix the *factor variances* to 1.0 (*unit variance identification [UVI]*) and then estimate all factor loadings; a KAIT model using this method is shown in Figure 31.4. This procedure has advantages over the method of fixing a factor loading. When the factor variances are set to 1, the factor covariances in the unstandardized solution are in fact correlations. Because constraints to models are made in the unstandardized metric, this method makes it possible to set factor correlations to 1, or 0, or some other value to see what this constraint does to the fit of the model. This ability to constrain and test the magnitude of correlations is used later in this chapter. The UVI method also has its limitations. With hierarchical models (to be discussed below), only the highest factor level can use this alternative method, and so a ULI approach is common. The ULI method is also more common in SEM.

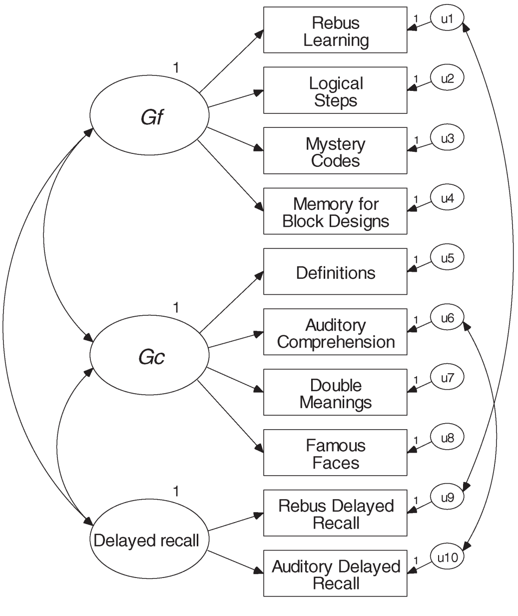

FIGURE 31.4. An alternative method of specifying factor models. Factor variances rather than factor loadings are set to 1 to set the scale of the factors.

The results of the analysis of the model shown in Figure 31.4 are identical to those shown in Figure 31.3 and are not repeated here. It is worth noting, however, that this method can occasionally produce slightly different results than the ULI method does (Millsap, 2001).

COMPARING ALTERNATIVE MODELS

The previous section has presented the basics of CFA, but has also presented a fairly sterile approach: the simple rejection of or support for a single model. Such an approach is problematic. The simple fact that a model does or does not fit the data provides only partial support for the validity of a test or theory. A model may fit the data well, but there may be other, competing models that fit the data as well or better. Or a given model may provide an inadequate fit to the data, but may be the best model among the alternatives. Formal or informal theory may suggest several possible models to explain the test scores we observe; if all fit the data well, how is one to decide which is the *best* model? What is needed is the ability to compare competing models, or to compare a target model with one or several alternative models. "At best, a given model represents a tentative explanation of the data. The confidence with which one accepts such an explanation depends, in part, on whether other, rival explanations have been tested and found wanting" (Loehlin & Beaujean, 2017, p. 63).

Figure 31.5 shows an alternative model of the constructs measured by the KAIT. The reasoning behind this model is that if the two nondelayed versions of these tasks (Rebus Learning and Auditory Comprehension) measure Gf and Gc abilities, then shouldn't the delayed versions also measure these underlying abilities? Since, for example, Rebus Delayed Recall asks examinees to recall material first learned in the Rebus Learning test,

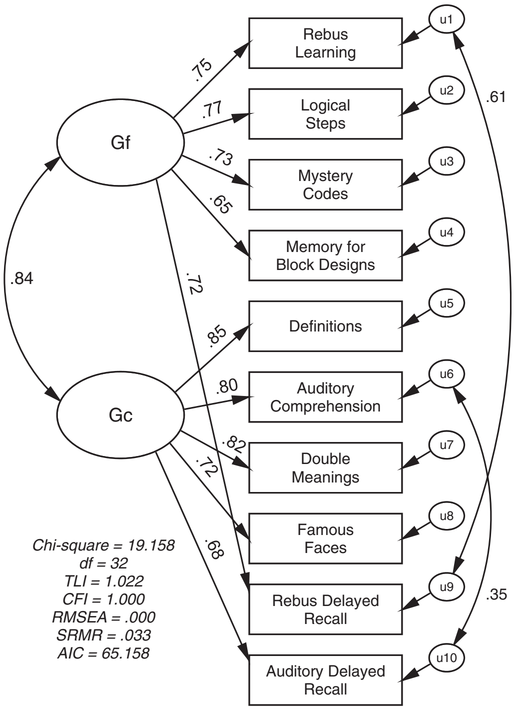

FIGURE 31.5. An alternative model of the structure of the KAIT. Rebus Delayed Recall and Auditory Delayed Recall are assumed to measure Gf and Gc, respectively, instead of delayed-recall ability.

isn't Rebus Delayed Recall really a measure of Gf? Similarly, is Auditory Delayed Recall a measure of Gc instead of delayed recall? This supposition may also help explain why the correlations between the delayed-recall and the Gf and Gc factors are so high: They measure overlapping constructs.

The fit indices shown in Figure 31.5 suggest that it also shows a good fit to the data. The SRMR, for example, suggests an average difference between the actual correlations and those implied by the model of .033, versus .029 for the initial model. The TLI barely changes with the model in Figure 31.5. Can we conclude that one model is better than the other—and thus come to a conclusions about the likely constructs measured by the KAIT?

Fortunately, fit statistics can be used to *compare* competing models as well. If two models are *nested*—that is, if one model can be derived from another by placing additional constraints on the model—then the χ^2 for the two models can be compared. The χ^2 for the less constrained model (the model with smaller *df* and smaller χ^2) can be subtracted from the χ^2 for the more constrained model. The χ^2 difference ($\Delta\chi^2$) can then be compared to the change in *df* (Δdf) to determine whether the constraints added to the model result in a statistically significant increase in χ^2. If the $\Delta\chi^2$ is not statistically significant—if one model is not significantly better than another—then, as scientists, we generally prefer the more parsimonious (more constrained, higher-*df*) model. If the $\Delta\chi^2$ is statistically significant, then the less parsimonious model is preferred. Parsimony is reflected in CFA models by *df*; the larger the *df,* the more constraints in the model, and therefore the more parsimonious the model. Again, nested models are those in which it is possible to get from one model to the other by constraining one or more parameters to some value (or, alternatively, by freeing existing parameter constraints). This is a powerful use of CFA, and allows the testing of specific hypotheses about the constructs being measured by a test. In our opinion, this is one of the biggest advantages of CFA over EFA: the ability to test hypotheses derived from such questions. It is often possible to do so statistically (via $\Delta\chi^2$) using carefully planned, nested models.

The *Akaike information criterion* (*AIC*; Akaike, 1987) is another useful measure for comparing competing models, and does not require that the models be nested. The AIC is not interpreted in isolation; rather, the AICs for two or more competing models are compared, with the smaller AIC suggesting the better model. Other, related fit indices include the *Bayes information criterion* (BIC; Schwarz, 1978), and the sample-size-adjusted BIC (aBIC; Sclove, 1987). The AIC and aBIC have performed well in intelligence test CFA simulation research (Keith, Caemmerer, & Reynolds, 2016). Finally, a highly constrained "baseline" model may be used instead of a null model in the calculation of fit indices such as TLI and CFI. For example, a one-factor *g* model may provide a useful baseline model in CFAs of intelligence tests. Of course, with these alternative baseline models, the resulting values will generally not approach the .95 cutoff recommended for these fit statistics when null models are used.

Testing Hypotheses by Comparing Alternative Models for the KAIT

Figure 31.3 displays the results of an initial CFA of the KAIT, and Figure 31.5 shows an alternative. Unfortunately, these models are not nested: To get from Figure 31.3 to Figure 31.5, we have freed two parameters (the paths from Gf to Rebus Delayed

Recall and Gc to Auditory Delayed Recall), but we have also fixed the paths from these two Delayed Recall tests to 0 (and deleted the now-empty delayed-recall factor), and the two correlations of the delayed-recall factor with Gf and Gc have also been constrained to 0. Nested models require the addition or the relaxing of constraints, but not both. It is possible to compare these two models via the AIC, however, with the model with the smaller AIC being the preferred one. As shown in the figures, and in Table 31.1 (see the model labeled "4. Gf-Gc (Figure 31.5)"), the initial model has an AIC of 70.03, versus 65.16 for the Figure 31.5 model. Our research thus suggests that the delayed-recall tests should be considered as further measures of Gf and Gc, rather than as a measure of a separate delayed-recall factor.

The use of nested-model comparisons is a powerful methodology, however, so it is useful to see how we *could* get from Figure 31.3 to Figure 31.5 through a series of nested models. The model shown in Figure 31.6 evaluates the hypothesis that the two delayed-recall subtests also measure Gf and Gc abilities *in addition to* delayed recall by freeing two constraints. In addition to allowing Rebus Delayed Recall to load on the delayed-recall factor, it is allowed to load on the Gf factor; Auditory Delayed Recall loads on both the delayed-recall and the Gc factors. One more change in this model (compared to the one shown in Figure 31.3) is required for the model to be properly identified: Some sort of additional constraint is required for the two Delayed Recall subtests. To allow estimation, the factor loadings for Rebus Delayed Recall and Auditory Delayed Recall on delayed recall need to be constrained to be equal.[3] Because going from Figure 31.3 to Figure 31.6 involves first adding a constraint (two paths equal) and then freeing other constraints (freeing two paths), it is conducted in two steps. The model fit results are shown in Table 31.1.

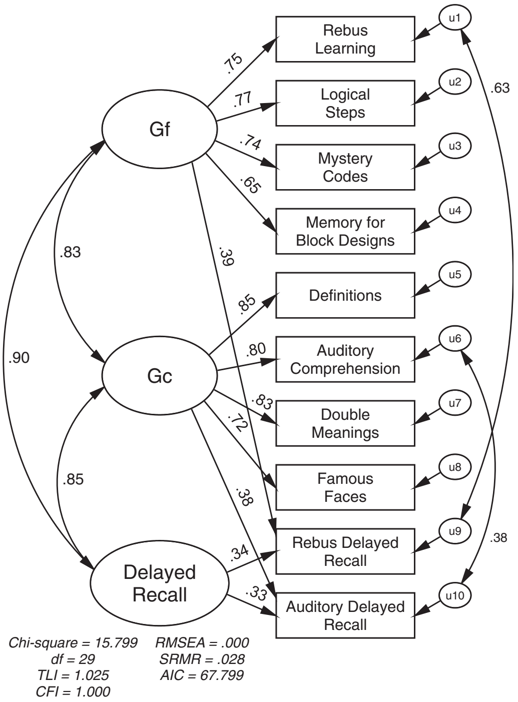

FIGURE 31.6. Another alternative model of the structure of the KAIT. The two Delayed Recall subtests (Rebus and Auditory) are assumed to measure Gf and Gc and a separate delayed-recall ability.

As shown in Table 31.1, constraining the two delayed-recall paths from the model in Figure 31.3 to be equal (this type of constraint is easy to do in all SEM programs) results in 1 extra *df* and an increase in χ^2 of only 0.01 ("2. Equal delayed-recall loadings"). This model is a more constrained version of the model in Figure 31.3, and is therefore nested with that model. As shown in the table, this change in $\Delta\chi^2$ is not statistically significant. If $\Delta\chi^2$ is not significant, this finding is generally

TABLE 31.1. Comparison of Various CFA Models of the KAIT

Model (Figure no.)	χ^2	*df*	$\Delta\chi^2$	Δdf	*p*	TLI	CFI	SRMR	AIC
1. Actual structure (Figure 31.3)	20.031	30				1.018	1.00	.029	70.031
2. Equal delayed-recall loadings	20.032	31	0.001	1	.97	1.019	1.00	.029	68.032
3. Delayed recall and Gf-Gc (Figure 31.6)	15.799	29	4.233	2	.12	1.025	1.00	.028	67.799
4. Gf-Gc (Figure 31.5)	19.158	32	3.359	3	.34	1.022	1.00	.033	65.158
5. Subtests affect delayed recall (Figure 31.7)	19.158	32				1.022	1.00	.033	65.158

Note. All comparisons are with the preceding model.

taken as support for the more parsimonious model, which is the model with more *df* (the table does not include RMSEA values, which do not vary from model to model). Model 2 has nearly equivalent χ^2 and a larger *df* than model 1, and thus is preferred. In other words, specifying these two paths (factor loadings) as equal is reasonable, and it is reasonable to use this model to compare to other nested models.

Figure 31.6 (model 3 in Table 31.1) shows the results for the next step: A model in the previous constraint is retained (the delayed-recall paths are constrained to be equal), *and* paths are allowed from Gf to Rebus Delayed Recall and from Gc to Auditory Delayed Recall. This model and the previous one are nested. The results of this analysis are also shown in Figure 31.6 and Table 31.1. Like the previous models, this variation provides an excellent fit to the averaged standardization data. But does the model provide any better fit than the structure as intended by the test authors? The χ^2 for the model is 15.779 for Figure 31.6 (model 3) versus 20.032 for the previous model (i.e., model 2, with equal loadings for the delayed tests on the delayed-recall factor). As shown in Table 31.1, the change in χ^2 is 4.233, which, given the change in *df* ($\Delta df = 2$), is not statistically significant ($p > .05$). Thus specifying that Rebus Delayed Recall and Auditory Delayed Recall measure Gf and Gc in addition to delayed recall improves the fit of the model, but not to a statistically significant degree. It would be perfectly reasonable to stop model comparisons at this point and conclude that model 2 (with the addition of equal loadings on the delayed-recall factor) is a reasonable explanation of the KAIT structure.

It is worth comparing the model in Figure 31.5 (model 4 in Table 31.1) with the one in Figure 31.6 (model 3), however, and this is also done in the table. These models are nested because it is possible to get from Figure 31.6 to Figure 31.5 by deleting the two paths from delayed recall and by deleting the two correlations of Gf and Gc with delayed recall. This comparison results in an increase in *df* of 3, as opposed to 4, because the two delayed-recall paths are constrained to be equal, and thus they are equivalent to 1 *df* in the model. This model resulted in a $\Delta\chi^2$ of 3.359, which is not statistically significant. Once again, with the $\Delta\chi^2$ not statistically significant, we would prefer the more constrained (higher-*df*) model—the model that considers the delayed-recall tests as further reflections of Gf and Gc. So now we have a dilemma. On the one hand, the Figure 31.5 model is "better" (equivalent fit based on χ^2, more parsimonious) than the Figure 31.6 model. But on the other hand, the Figure 31.6 model is not better than the original Figure 31.3 model. And on yet a third hand, the Figure 31.5 model fits better than the Figure 31.3 model, according to the AIC. Although nested-model comparisons provide a powerful method for testing hypotheses about the constructs measured by intelligence tests, the results are not always clear-cut![4]

The substantive interpretation of the model in Figure 31.5 is straightforward. Rebus Delayed Recall and Auditory Delayed Recall provide measures of Gf and Gc abilities, respectively, that are almost as strong as the tests intended to measure those abilities. The factor loadings (paths) are all reasonable, as is the factor loading between Gf and Gc (.84).

One final model for the KAIT is shown in Figure 31.7 and is used to illustrate two points. In the models shown so far, the presumed overlap between the delayed-recall tests and the nondelayed versions of the tests (i.e., Rebus Learning and Auditory Comprehension) is modeled using correlated error terms. This is a common method of dealing with such overlap, and means that the two tests are thought to measure something in common beyond the factors that are shown as affecting them (e.g., Gf, Gc, delayed recall). This is not the only way of dealing with the overlap. It is not simply the case that performance on the delayed-recall tests *share* unique and error variance with the tests from which they were derived. Rather, performance on the delayed-recall tests should depend in part on how well the material was learned when first presented. Thus, in addition to being affected by delayed recall, Gf, and Gc, these two tests should also be *affected* by their original versions. Figure 31.7 shows a model that embodies this reasoning; it builds on the Figure 31.5 model, but has Rebus Learning affect Rebus Delayed Recall and has Auditory Comprehension affect Auditory Delayed Recall. As shown in Figure 31.7 and Table 31.1, this model fits the data quite well. Note the strong effect of Rebus Learning on Rebus Delayed Recall, and the moderate effect of Auditory Comprehension on Auditory Delayed Recall.

The first points we believe this example illustrates nicely are the power and the flexibility of CFA (and, more generally, SEM), and their ability to model conceptions of the way the world works. Researchers who can think through the way they believe that intelligence works on various outcomes (including the subtests used to measure it)

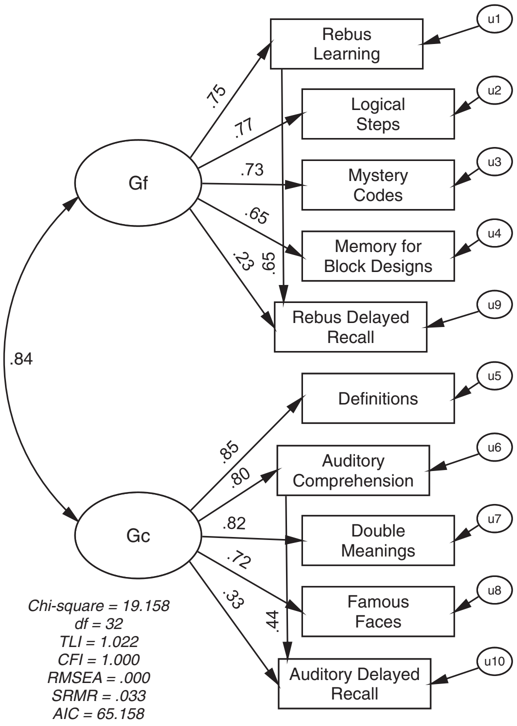

FIGURE 31.7. Yet another alternative model of the structure of the KAIT. The Rebus Learning and Auditory Comprehension tests are assumed to *affect* performance on the subsequent Rebus Delayed Recall and Auditory Delayed Recall tests.

can probably model that notion. This flexibility is further illustrated by the fact that we have used the KAIT to illustrate the basics of CFA in previous editions of this chapter, but have analyzed different models each time!

The second point this model illustrates is that sometimes it is not possible to differentiate plausible alternative models based on fit. As already noted, this model in Figure 31.7 fits the data well. But note that this model has an identical fit to the previous model in Figure 31.5 (see Table 31.1). These equivalent models have the same fit, and thus cannot be compared. It is always worth considering alternative models to one's preferred model; Keith (2015) and Kline (2016), among others, have demonstrated rules for generating equivalent, alternative models (see also Lee & Hershberger, 1990). Before turning to the next topic, we simply note that these models do not constitute an exhaustive examination of the structure of the KAIT; there are other plausible models from other perspectives (see, e.g., Cole & Randall, 2003; Flanagan & McGrew, 1998).

HIERARCHICAL CFA

Many modern theories of intelligence recognize a factor that is more general and broader than the specific abilities tested in first-order CFA. This *general factor* is often considered to subsume, affect, or partially cause the more narrow abilities, and is often symbolized as *g*. For example, Carroll's (1993) three-stratum theory of intelligence includes *g* as the most general, highest-order factor. Although conceptually similar to Spearman's *g*, most modern theories assume that *g* is a higher-order factor (cf. Burt, 1949; Vernon, 1950). Most modern intelligence tests also tacitly recognize such a general, overall factor by summing subtests or subscales into an overall score. Although this general score goes by a variety of names—Full Scale IQ, General Cognitive Ability, or General Intellectual Ability—it generally represents an overall, general, summative ability.

If *g* is recognized in formal theory (as a latent variable that partially explains the positive correlations among all tests of mental ability) and through the informal theory of the scoring of intelligence tests, it is also valuable to test such a construct through CFA. One approach has been to specify a single-factor model, such as the one shown in Figure 31.8 (a *g*-model version of the Wechsler Intelligence Scale for Children—Fifth Edition [WISC-V; Wechsler, 2014]). This model suggests that scores on the individual subtests are a product of a general factor and of unique and error variances. Such an approach mirrors, to some degree, the common practice of isolating a *g* factor in EFA by examining the unrotated first component in principal-components analysis. It is also an unsatisfying solution for several reasons. First, *g* is generally recognized as a *hierarchical* factor; a more realistic structure for the tests from Figure 31.8 is shown in Figure 31.9, in which the subtests are explained (in part) by first-order factors, and the first order factors are, in turn, explained (in part) by a second-order *g* factor (a higher-order hierarchical model). Second, if Figure 31.9 represents the *true* structure of the abilities measured by the 16 WISC-V subtests, then Figure 31.8 represents an inadequate test of the second-order *g* factor. The presence of first-order factors means that the verbal tests (Gc) measure something in common other than general intelligence; the working memory

(Gsm) tests measure something in common other than *g;* and so on. These first-order factors may be identified by characteristics shared among groups of subtests, whereas *g* is not. To reiterate, Figure 31.8 represents an inadequate test of a higher-order *g* factor. It may be, however, a useful comparison model for other models. If we were interested in whether a test *only* measures general intelligence, versus general intelligence plus other cognitive abilities, for example, the fit of the models shown in Figures 31.8 and 31.9 should likely be compared.

Figure 31.10 shows an alternative conception for a hierarchical general factor, often referred to as a *bifactor* model (or, alternatively, as the *nested-factors* model or *direct hierarchical* model). Like a higher-order model, a bifactor model includes both general intelligence and more narrow abilities, but all are first-order factors. Although not strictly hierarchical in organization, the bifactor model is commonly referred to as a hierarchical model, and has become more popular in recent years.

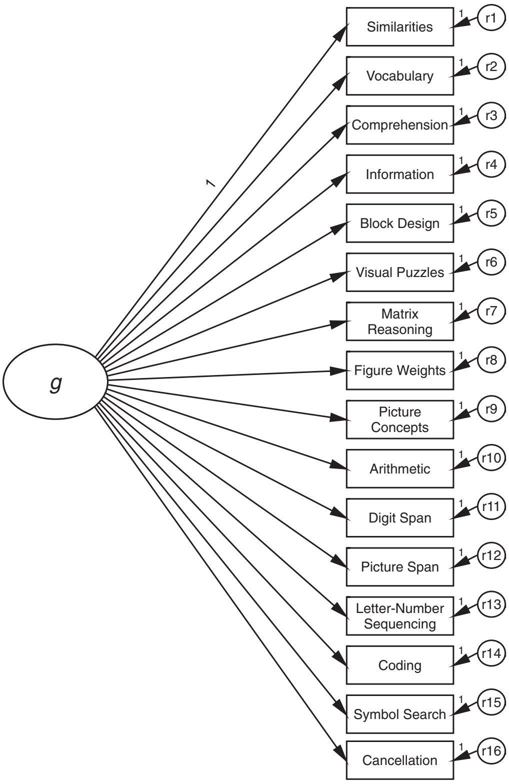

FIGURE 31.8. A general intelligence, or *g*, model of the structure of cognitive abilities. The model assumes that the Wechsler tests are reflections of general intelligence only, rather than more specific, shared abilities, such as verbal or spatial abilities.

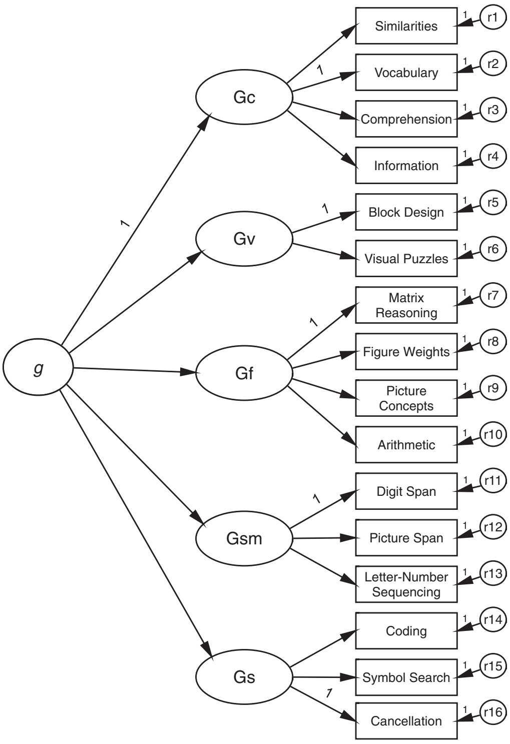

FIGURE 31.9. A higher-order model of the structure of the WISC-V. The model assumes that each test is a reflection of narrow, shared abilities (e.g., Gc or verbal ability), and that these narrow abilities are in turn partially a product of *g*. Note that the model is incomplete as a CFA model; the unique variances associated with the first-order factors are not shown.

Higher-Order Model

Figure 31.11 shows a CFA model to test the higher-order structure of the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007). In scoring the School-Age version of the DAS-II, two "core" subtests are each added together to form Verbal, Nonverbal Reasoning, and Spatial scores, respectively, and all six of those scores are added together to form a General Cognitive Ability score. Thus the core subtests are designed to measure both a *general* ability and more specific abilities (Gc, Gf, Gv). The informal theory underlying the test is clearly hierarchical in nature. There are three memory tests included as well, two of which are added together to form a Working Memory com-

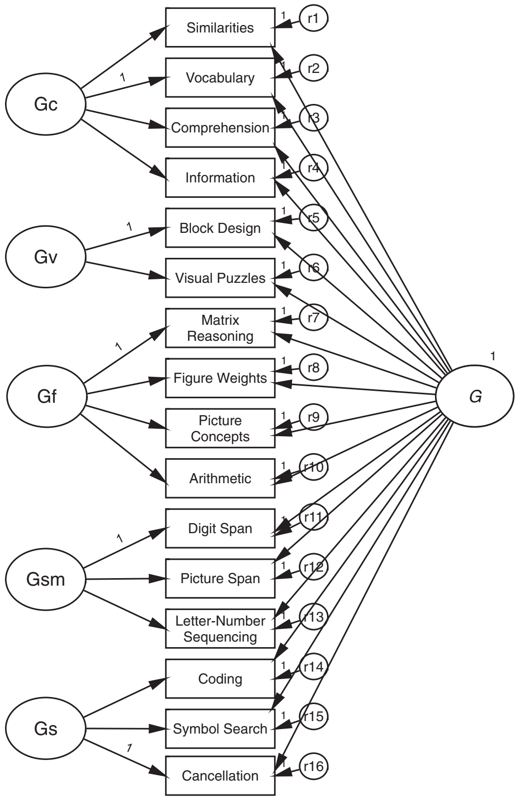

FIGURE 31.10. A bifactor model of the structure of the WISC-V. The model assumes that each test is affected by general intelligence and a broad ability. Both general intelligence and the broad abilities are first-order factors, however, and are unrelated to one another beyond this shared influence.

posite. Here we have used all three as measures of Gsm, which is also affected by a second-order *g* factor. To simplify presentation, these analyses do not include the subtests assessing long-term retrieval or processing speed.

One interesting feature of the DAS-II is that although the structure of the test changes in going from the Early Years to the School-Age version, all tests were given to children ages 5–8 in the standardization sample; these age levels, with multiple indicators of each construct, are the ones used here. The structure shown (including the correlated errors and cross-loading) is based on findings presented in Keith, Low, Reynolds, Patel, and Ridley (2010; see this article for more complete analyses of the structure of the DAS-II, including cross-age tests of measurement invariance).

The figure is quite similar to the higher-order model from Figure 31.9, except for the presence of small ovals (f1 through f4) pointing to the first-order factors. These represent the *unique* variances of each of the first-order factors. Just as the first-order factors are not the only causes of the scores on the subtests, *g* is not the only cause of a person's Verbal or Spatial scores; there is also something unique about Verbal ability as opposed to Spatial ability. This *unique factor* variance, with the test-specific and general factor variance removed, is recognized in the model through the presence of the latent variables f1 through f4.[5] As in earlier models, each latent variable (including *g* and the unique factor variances) has its scales set by fixing one loading to 1.0.

As noted above, the model has been estimated on the basis of the standardization data for ages 5–8. The results of the higher-order CFA of the DAS-II are shown in Figure 31.12. Although χ^2 is statistically significant, the other fit statistics suggest that the model fits the data well, and thus support the scoring structure of the DAS-II. The first-order factor loadings suggest that the core subtests generally measure their corresponding factors well, although the Verbal Comprehension subtest appears to require both Verbal (or Gc) and Nonverbal Reasoning (Gf) ability.

The second-order factor loadings are perhaps even more interesting. In scoring the DAS-II, subtests from the Verbal, Nonverbal Reasoning, and Spatial domains are combined to create an overall score. The figure shows that the three corresponding latent factors are indeed strongly affected by *g*, thus supporting the hierarchical structure of the scale. Also of interest, the Nonverbal Reasoning factor has a very high loading, .92, on the second-order *g* factor. Although the factor is statistically distinguishable from *g* (based on $\Delta\chi^2$), the loading is quite high in practical terms. This finding supports the claim that the Nonverbal Reasoning scale of the DAS-II should be considered a measure of Gf (Elliott, 2007; Keith et al., 2010), given evidence that Gf is generally quite similar to, and very often indistinguishable from, *g* (e.g., Carroll, 1993, Ch. 15; Gustafsson, 1984). Interestingly, if the correlation between the Gf and Gv disturbances were removed, the *g*-Gf loading would be .98. As a result, the unique variance of Gf (the variance of the disturbance f2) would be nonsignificantly different from 0. The finding of indistinguishable (or nearly indistinguishable) *g* and Gf factors is not the result of having relatively few measures of Gf from a single battery; cross-battery CFA of four different tests, including seven measures of Gf, showed a

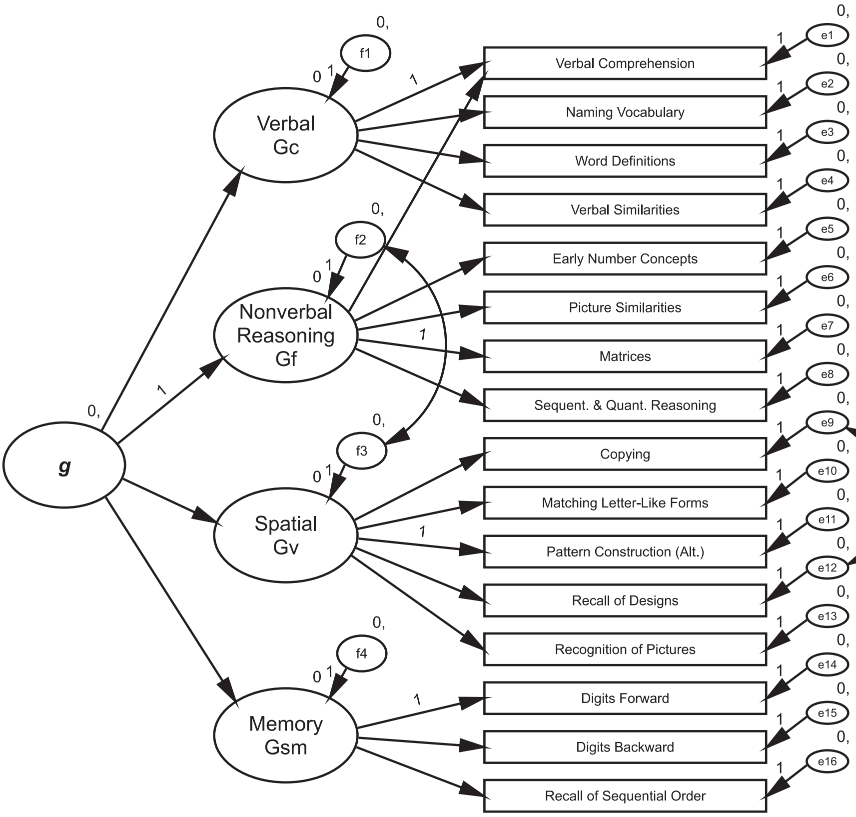

FIGURE 31.11. A hierarchical, higher-order model of the structure of the DAS-II. Digits Forward, Recall of Digits—Forward; Digits Backward, Recall of Digits—Backward.

loading of .98 for a Gf factor on a higher-order *g* factor (Reynolds, Keith, Flanagan, & Alfonso, 2013). G and Gf are hard—often impossible—to distinguish. The high loading by Gsm for the DAS-II is less common, and may suggest that this factor is more cognitively complex (e.g., working memory) than our label of Gsm would suggest.

Researchers and clinicians are often interested in the loading of the subtests on *g*, or the relative strength or weakness of tests as measures of *g*. It is not necessary to resort to *g*-only models (Figure 31.8) or bifactor models (discussed below) to get such estimates, however. In higher-order models, the loadings of the subtests on higher-order factors are calculated as the total indirect (and total) effects of the hierarchical factors on the subtests, through the intermediate factors. So, for example, in Figure 31.12, the loading of Sequential and Quantitative Reasoning on *g* is .736 (.92 × .80). SEM (and CFA) programs will easily calculate these indirect effects. The *g* loadings of the DAS-II are shown in Table 31.2 (arranged from largest to smallest, based on the higher-order loadings). Note that these *g* loadings are model-specific; the estimates shown in Table 31.2 apply to the model shown in Figure 31.12. If the model is correct, then the *g* loadings will be accurate.

Bifactor Model

As noted above, an alternative method of testing hierarchical models is through what is called a *bifactor* model. In a bifactor model, all subtests are loaded directly on both a G factor (see below regarding G versus *g*) and on narrow factors, with the factors generally orthogonal or uncorrelated (cf. Carroll, 1995; Gignac, 2008; Gustafsson & Balke, 1993; Keith, 2015; Reynolds & Keith, 2013).

A bifactor version of the DAS-II model is shown in Figure 31.13. (The ovals representing the unique variances of the subtests are not shown in the figure to help simplify it, but were included in the

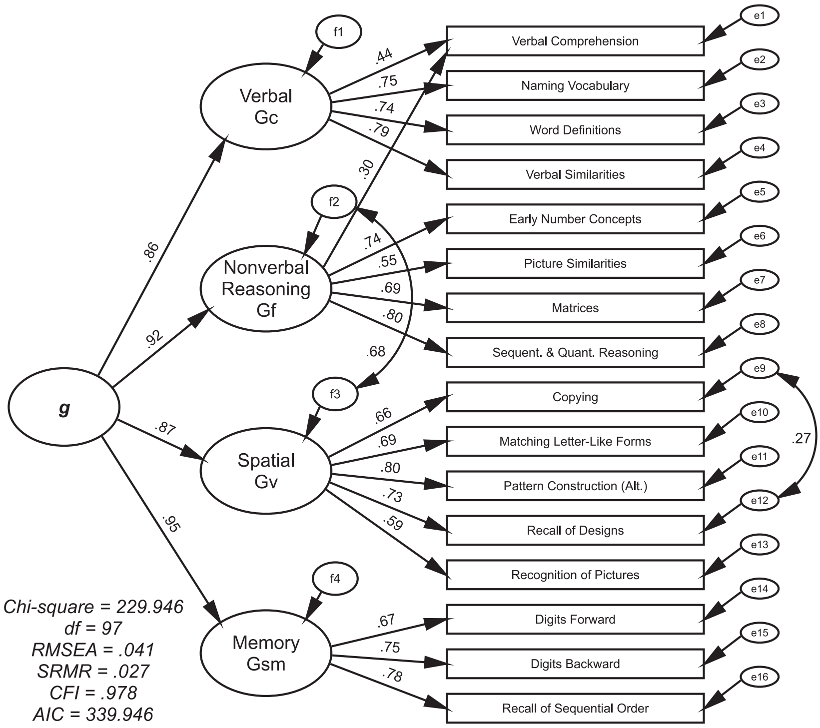

FIGURE 31.12. Standardized solution for a higher-order model of the structure of the DAS-II.

TABLE 31.2. Loadings of DAS Subtests on a Higher-Order *g* Factor and a Bifactor *G* Factor

analysis.) This initial version of the model did not estimate well, and required modification. (The residual variance of the Sequential and Quantitative Reasoning test was negative, among other issues.) We have constrained the loadings of the subtests on the Gf factor to be equal (except Verbal Comprehension). The results of this model are shown in Figure 31.14. This model also fits the data well, although slightly worse than the higher-order model (with the changes, the models are not nested, so this comparison is based on the AIC).[6]

We first focus on the findings of this model, and then discuss how this model relates to the previous higher-order model. First, as shown in Table 31.2, the loadings of the subtests on the (first-order) G factor are similar, but not identical, to those shown as indirect effects for the higher-order model (we refer to such first-order general factors as G, rather than g, to make the distinction between first- and second-order general factors explicit). In contrast, the loadings of the subtests on the Gc, Gv, and Gsm factors are much smaller than in the previous model (see Table 31.3). The practical and conceptual differences in the two models lead to these differences.

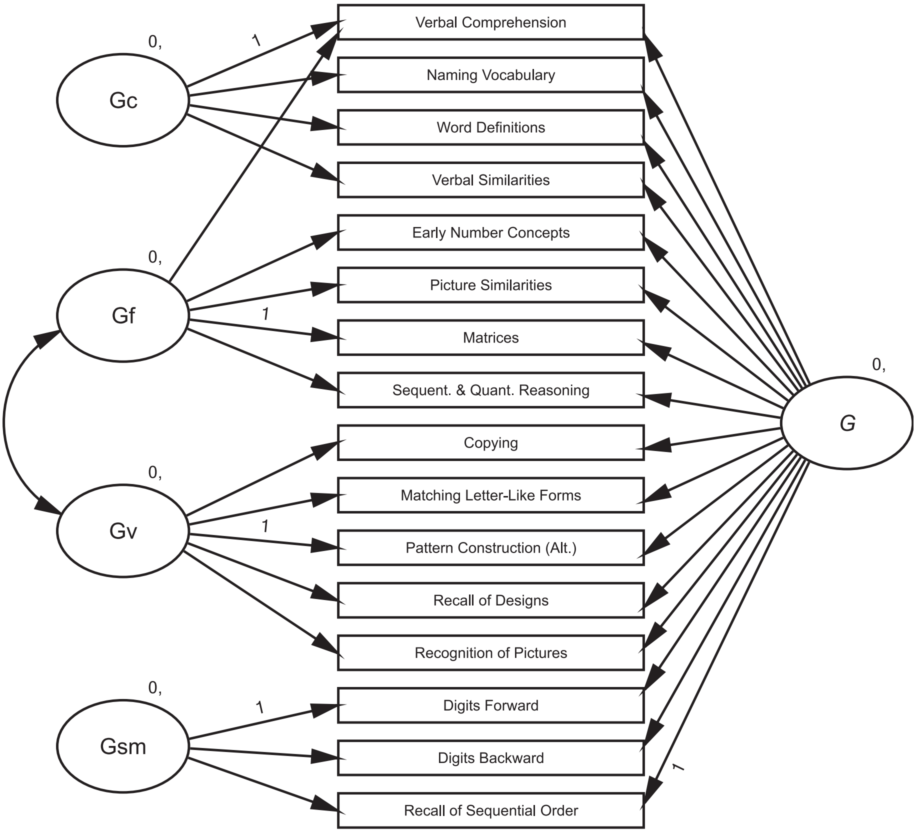

FIGURE 31.13. A bifactor model of the structure of the DAS-II.

Bifactor versus Higher-Order Models

How do the models differ, and in what ways are they similar? Some researchers treat bifactor models as equivalent to higher-order models, but clearly they are not. Although both models suggest that the subtests are affected both by general intelligence and by one or more abilities that are less broad, the nature of that influence differs. The higher-order model assumes that *g* influences individual tests through the broad abilities, or multiple intelligences, and that *g* indeed influences, or is related to, the broad abilities (or the broad abilities are to some extent also reflections of *g*). The bifactor model seemingly makes no assumptions about the relation between *g* and the broad (first-order) factors, instead only specifying that the subtests measure both G and broad abilities. Further examination shows this initial impression is not correct, however. This model in fact asserts that G is *unrelated* to the broad abilities, and (usually) the broad abilities are unrelated to each other. Relatedly, the bifactor model assumes only direct effects for G on the measured variables, whereas the higher-order model asserts indirect effects.

The higher-order model is more restricted than is the bifactor model. Because *g* only affects the subtests via the broad abilities in the higher-order model, the indirect effects of *g* on the subtests are restricted by the effect of *g* on the broad abilities. The bifactor model has no such restrictions. Because of these restrictions, the higher-order model is a more constrained model than is the bifactor model. In fact, it is possible to go from one model to another in several ways (Yung, Thissen, & McLeod, 1999). Most simply, both models may be considered subsets of a model in which *g* influences all first-order factors and subtests directly (a model that would be underidentified without additional constraints). With such a model, if the effects of *g* on the first-order factors are deleted, the bifactor model ensues; or, if the direct effects of *g* on the subtests are deleted, the higher-order model results.

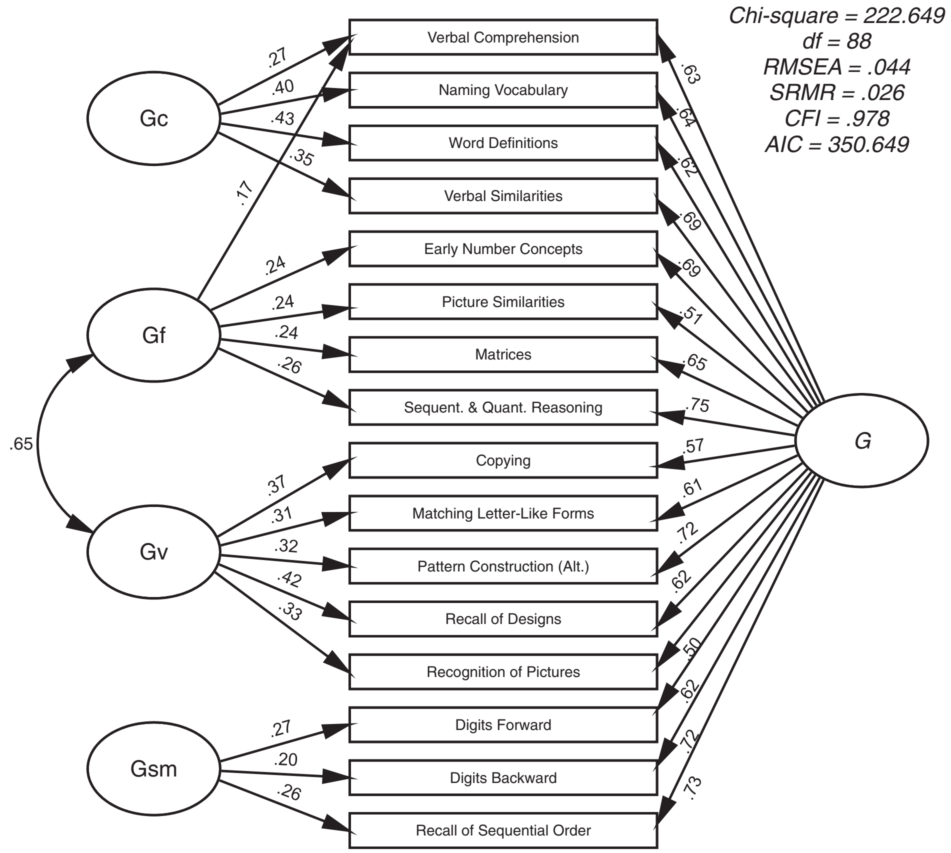

FIGURE 31.14. Standardized solution for a DAS-II bifactor model.

It is also possible to get equivalent-fitting bifactor and higher-order models by adding paths from *g* directly to the subtests in the higher-order model. The number of additional paths is equal to the difference in *df* for the two models. And the difference in *df* for a strict higher-order and a strict bifactor model equals the number of subtests minus the number of factors. To do so, one adds *g*-to-subtest paths for every subtest, minus 1, per factor. So, for example, if factor 1 has four measured variables, we would add three additional *g*-to-subtest paths in addition to the existing factor 1-to-subtest paths (and so on, for the other factors) (Mansolf & Reise, 2017).

One seeming advantage of the bifactor approach is that when all factors are included at the same level, the paths may be considered *partialed* effects. That is, the loadings of the Gc, Gf, and Gsm factors are the effects of these factors on the subtests, *with* G *statistically removed,* or partialed out. As a result, the findings from such models are often similar to a Schmid–Leiman transformation in a higher-order EFA, in which first-order and higher-order loadings are orthogonalized to aid in interpretation (Schmid & Leiman, 1957). This would seem to be an important (practical) advantage for the bifactor approach. But it is also very simple to obtain such orthogonalized results in a higher-order model as the indirect effect of the factor disturbances on the subtests (f1, f2, etc., in Figure 31.12). (To obtain the paths from disturbances to first-order factor, UVI can be used for scaling the disturbances. This has been done in Figure 31.12.) Because the factor disturbances are the factors with the effects of *g* removed, these indirect effects (i.e., the path from the disturbance to the first-order factors times the subtest loading on the factor) are then the loadings of the subtests on the factors, with *g* removed (see Reynolds & Keith, 2013 or 2017, for illustrations; the 2013 chapter also compares these models in more detail). The difference, as shown in Table 31.3, is

TABLE 31.3. Loadings of DAS Subtests on Broad-Ability Factors in a Higher-Order and a Bifactor Model

Note. The "Direct" column in the higher-order model shows the uncorrected loadings. The "Unique" column shows the direct values, with *g* removed from the broad abilities. The "Direct" bifactor values are the values with G removed from the subtests.

that the higher-order approach allows the estimation of the effects of both the actual broad abilities on the subtests (the simple effects) *and* the effects of the broad abilities with *g* partialed out (the partialed effects). A bifactor approach only produces the partialed effects; that is the only interpretation allowed.[7] The partialed effects for the two solutions are often quite similar (see, e.g., Reynolds & Keith, 2017).

Another potential advantage of the bifactor approach is that it appears agnostic as to the relation between the *g* factor and the other factors. Said differently, this approach may be somewhat more exploratory than a higher-order approach. But this advantage does not come without a cost. All CFA models (and, indeed, all EFA models) make assumptions about the nature of intelligence. The models shown in Figures 31.11 and 31.13 make very different assumptions about the nature of intelligence. The higher-order model says that *g* is a superordinate ability—an ability that is further removed from the subtests, indicating a higher-level of abstraction. In a strict higher-order model, there are no direct effects from *g* to the subtests, which seems consistent with the inability to define *g* based on surface characteristics of specific tests (see Jensen, 1998, Ch. 4). *g* is more abstract than the broad abilities,[8] and it is also more general because it influences every subtest, albeit indirectly. The second-order loadings in the higher-order model are also useful, in that they provide validity information about the broad abilities and their relation to *g*. Carroll (1993), for example, arranged the stratum II factors (broad abilities) by their loadings on *g*, with Gf being the most closely related. Many studies have shown this same relation with higher-order intelligence models.

The bifactor approach, in contrast, says that *g* is no more important than other abilities; that is, it does not affect those abilities, but affects test scores directly. The bifactor method is a more top-down approach, with G taken into account concurrently with the broad abilities, whereas the higher-order approach is more of a bottom-up approach (Gustafsson, 2002). In sum, models imply theories, and researchers should know what theory their model is implying! Given the intertwined nature of measurement and theory, it is important to base the choice of a model on theoretical grounds as well as well as practical ones.

A practical disadvantage of the bifactor approach is that the model is sometimes difficult to estimate. Factors must include more than two indicators, or empirical underidentification will result. To avoid this, additional indicators, or meaningful factor intercorrelations (cf. Keith, Reynolds, Patel, & Ridley, 2008), are required; or one must make additional constraints, which may result in a worse fit and which require justification. A common method for dealing this problem is to constrain the loadings of the two indicators of a factor to be equal to each other (here we have constrained four loadings to be equal). This method is useful in getting the models to converge, but should be explained in the research results. Even with three or more tests per factor, bifactor models can be touchy. In our experience, it sometimes helps to specify start values for many parameters.

The bifactor model often fits better than the higher-order model. As already noted, the higher-order model is a more constrained version of the bifactor model. Because the effects of *g* on a broad ability (e.g., Gc) are the same for each subtest within that broad ability in the higher-order model, the ratio of *g* loadings to unique loadings within each broad ability is proportional. The bifactor model does not have this underlying proportionality condition. This condition is often referred to as a *proportionality constraint,* and research shows that inducing such proportions in simulated data results in equivalent-fitting models for the two methods (Gignac, 2016). As noted by Mansolf and Reise (2017), this is not a CFA model constraint in the common sense of the term. It is in fact the result of a unique set of underlying tetrad constraints for the higher-order model.

The often better-fitting nature of the bifactor model may seem a reason to prefer it, but research has shown that the bifactor model often fits better even when it is incorrect (Murray & Johnson, 2013). Unmodeled complexity (e.g., small, unmodeled correlated errors or cross-loadings) may increase the tetrad violations and make a bifactor model fit better than a higher-order model even when a higher-order model is the true model (Mansolf & Reise, 2017). The bifactor model is prone to overfitting and may fit even in the presence of unlikely or invalid data (Reise, Kim, Mansolf, & Widaman, 2016). These findings make sense if we consider that in a bifactor model the correlations among measured variables are assumed to reflect a general factor, even if they do not result from an underlying latent variable that is the "cause" of those correlations. "A bifactor model may provide a superior fit, not because it more accurately reflects the substantive phenomenon, but because fit indices are biased in its favor when models are misspecified (i.e., pure models are applied to data that contain unmodeled complexities)" (Mansolf & Reise, 2017, p. 121). At any rate, it appears that the choice between a bifactor and a higher-order model should not be based on model fit.

Our position is that one's model choice should reflect one's guiding theory. Theoretically, the model analyzed should, at a minimum, reflect the theory underlying the test, or an alternative theoretical specification. The higher-order model would seem to have a clear advantage in this regard, given that most theories of intelligence that include a general factor suggest that it is a higher-order, hierarchical factor (Jensen, 1998). As already noted, it may also be considered useful for theory testing, since effects of *g* on the first-order factors should have predictable effects across studies. Tests are not always scored this way, of course (e.g., subtests, rather than scales, are often added together to form IQ composites), but most test manuals reference a higher-order type structure if theoretical justification for the test structure is presented. In contrast, the bifactor model is not consistent with most modern theoretical orientations with which we are familiar. See, however, Beaujean (2015) for a spirited defense of the bifactor model as reflecting Carroll's three-stratum theory. Indeed, even the Schmid–Leiman transformation was originally developed to transform, for interpretive purposes, results of *higher-order* EFAs. For these reasons, we generally prefer a higher-order model. But we also believe that all models are incorrect to some extent, and that all models to some extent have their own set of practical uses. Thus we routinely look at both types of models, and interpret them in combination rather than in competition. The bifactor model may be especially useful for isolating measured variables that do not belong on a broad ability (Keith et al., 2016). See Gustafsson and Åberg-Bengtsson (2010) and Reynolds and Keith (2013) for further discussion.

TESTING HYPOTHESES ABOUT THE SIMILARITY OF FACTORS

CFA is also a useful method for testing hypotheses about how factors or tests should be interpreted. Such research often involves testing the similarity of factors within a test or between two tests. CFA can be used to test whether two tests designed to measure the same factors (e.g., the G*f* factors from the Woodcock–Johnson IV [WJ IV] and the KAIT) do, in fact, measure statistically indistinguishable factors. By the same token, the method can be used to test whether two tests designed to measure *different* abilities do in fact measure distinguishable factors (e.g., Keith, Kranzler, & Flanagan, 2001). A brief within-test example follows.

Are Gf and Gv Separable for the WISC-V?

The WISC-V (Wechsler, 2014) is designed to measure five distinct yet correlated cognitive abilities consistent with the constructs Gc, Gf, Gv, Gsm, and Gs (crystallized ability, fluid reasoning, visual–spatial ability, working memory, and processing speed, respectively) from Cattell–Horn–Carroll (CHC) theory. One major difference between the WISC-V and the previous version, the WISC-IV, is the separation of the nonverbal tests into a Fluid Reasoning Index (Gf) and a Visual Spatial Index (Gv); the WISC-IV had such tests combined into a single Perceptual Reasoning Index. Recent research has questioned this separation in the WISC-V, however, suggesting instead that the Fluid Reasoning Index and Visual Spatial Index measure one set of underlying abilities, not two (e.g., Canivez, Watkins, & Dombrowski, 2017).

Figure 31.15 shows a first-order version of the WISC-V's structure, with the 16 subtests and the five factors (with CHC-type labels) they measure, according to the test publisher. Note that the Arithmetic test is thought to measure both fluid reasoning and working memory, and thus has a cross-loading on both Gf and Gsm. There are several additions to the figure that need explanation. First, note that UVI (factor variances set to 1) has been used to define the factors. This helps in the hypothesis testing described below. Note also the values of 0 above the factors and the residuals. Means and intercepts have been analyzed for these models; latent means are here (and commonly) fixed to 0. Finally, note the labels for some of the correlations (eq1, eq2, etc.). These are used to constrain these values sequentially.

Figure 31.16 shows the standardized solution for the model, with various fit indices. The model generally fits well, and all factor loadings are substantial. Because the UVI method has been used to set the scale of the latent factors, the unstandardized solution would show the same values for the factor covariances as shown here for the factor correlations (with the factors standardized, the

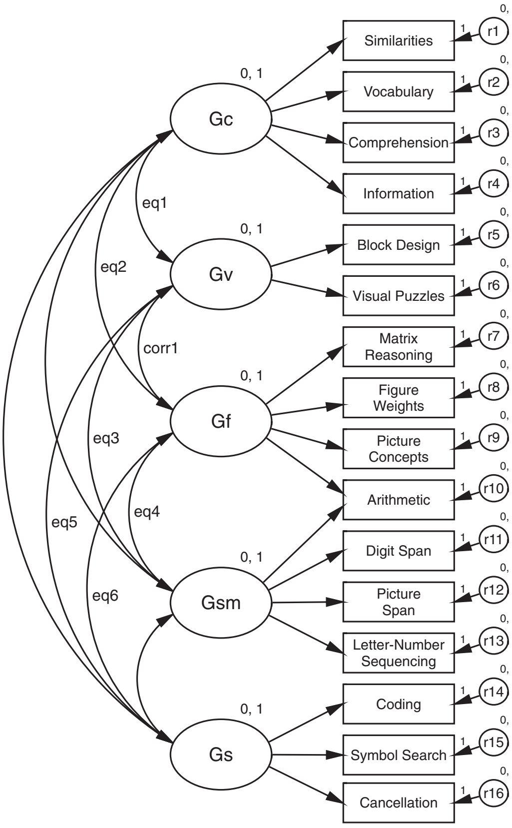

FIGURE 31.15. A first-order CFA model of the WISC-V. This model is designed to test the similarity or dissimilarity of the Gf and Gv factors.

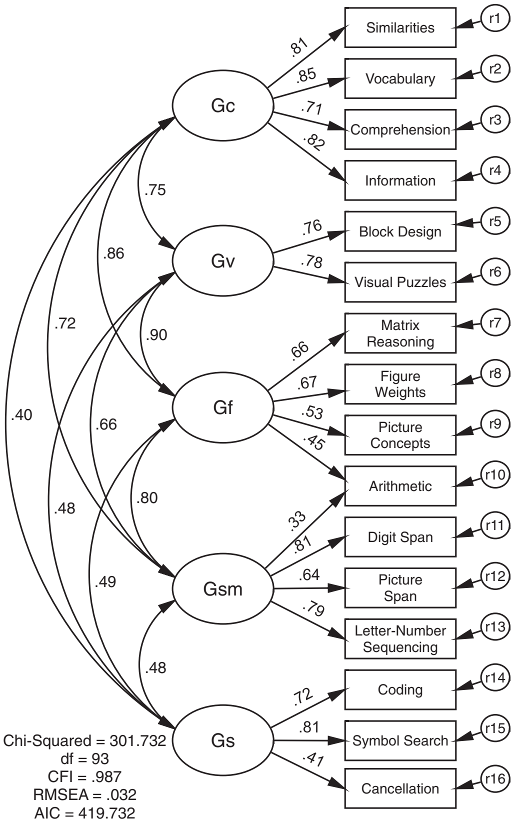

FIGURE 31.16. Standardized solution for the WISC-V CFA model. The correlation of the Gf and Gv factors is higher than the other factor correlations (.90).

covariances are standardized also; standardized covariances are correlations). Note the very high correlation between Gf and Gv (.90). This value certainly suggests considerable overlap between these two variables. But are they statistically distinguishable; are they separable?

For the next step in this analysis, we have constrained the correlation between Gf and Gv to 1 (corr1 = 1). As shown in Table 31.4, the fit of this model is considerably worse than that of the original five-factor model ($\Delta\chi^2 = 43.71$, $df = 1$, $p < .01$). This finding would seem to suggest that the two factors are indeed different. But if Gf and Gv were the *same* factor, then they would also have the same correlation with other variables, including other factors. Thus a more complete test of the identity of the two factors would also set correlation eq1 equal to eq2, correlation eq3 equal to eq4, and correlation eq5 equal to eq6. These additional constraints further degrade the fit of the model, as shown in Table 31.4 ("3. Correlations same" model).

A more direct way of testing the equivalence of these two factors would be to simply combine them into a single perceptual reasoning factor, similar to the Perceptual Reasoning Index from the WISC-IV. It may be unclear, however, whether this model is to be nested with the initial model. As shown in Figure 31.17, this method produces exactly the same fit and *df* as the "correlations same" model does, demonstrating that this model can indeed be considered the same as model 3, and thus nested with model 1 (see Table 31.4).

One final model is worth examining. We have so far rejected the notion that Gf and Gv on the WISC-V overlap to such an extent that they should be combined into a single factor. But is the Gf-Gv correlation of larger-than-normal magnitude for cognitive factors? For model 5, the correlation between Gf and Gv has been set to the level of the median correlation between other pairs of factors (.66). As shown in Table 31.4, this model also leads to a degradation in model fit. The correlation between these two factors is not 1.0, but it is also statistically significantly larger than the average (median) correlation among the other cognitive factors.

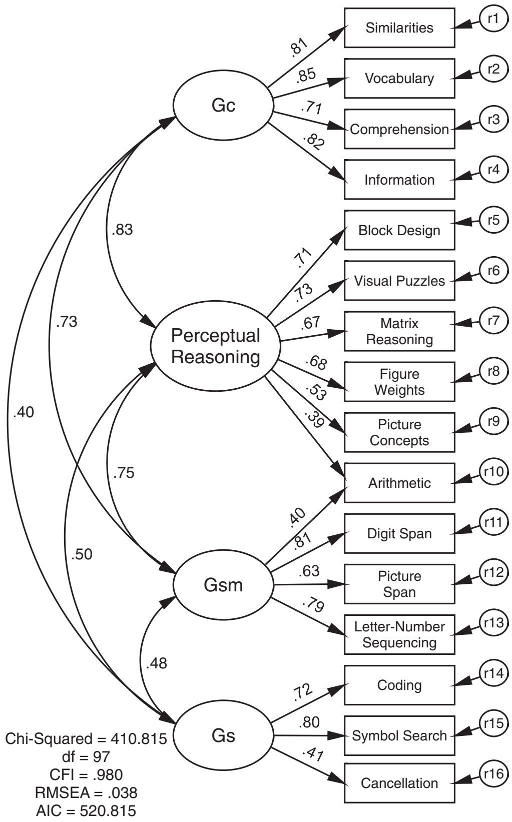

FIGURE 31.17. A model in which the Gf and Gv factors are combined. This model fits worse than the models with separate factors.

TABLE 31.4. Comparison of Competing Hypotheses about the WISC-V Structure (Gf and Gv Factors)

Model (Figure no.)	χ^2	*df*	$\Delta\chi^2$	Δdf	*p*	CFI	RMSEA	AIC
1. Five factors (Figure 31.16)	301.73	93				.99	.032	419.73
2. Gf = Gv	345.44	94	43.71	1	<.01	.98	.035	461.44
3. Correlations same	410.81	97	109.08	4	<.01	.98	.038	520.81
4. Four factors (Figure 31.17)	410.81	97	109.08	4	<.01	.98	.038	520.81
5. Median correlation	381.32	94	79.59	1	<.01	.98	.037	497.32

Note. Each model is compared to the first model.

It is worth noting that the combined Gf-Gv factor shown here differs from that proposed by Canivez and colleagues (2017), in that we show Arithmetic as loading on both the Gf and the Gsm factors, whereas Canivez and colleagues have included this subtest only on Gsm. The conclusions (that the factors are indeed separable) would be the same with that starting model, however. Our starting model is consistent with the first-order model supported in Reynolds and Keith (2017).

For a further illustration of the power of CFA to test competing theory- and research-driven hypotheses about the constructs measured by tests, see Keith and colleagues (2001). In that study, the authors tested whether the Cognitive Assessment System (CAS) measured CHC abilities, or whether it measured distinct processes as outlined in the Planning, Attention, Simultaneous, and Successive theory of mental processing. In addition to testing the similarity of factors, the authors tested a series of joint hierarchical and integrated models from both theoretical orientations, and whether the higher-order *g* factor assessed by the two instruments was the same underlying factor (cf. Floyd, Reynolds, Farmer, & Kranzler, 2013; Johnson, Bouchard, Krueger, McGue, & Gottesman, 2004).

TESTING THE SIMILARITY OF FACTOR STRUCTURE ACROSS GROUPS: INVARIANCE

An important subset of questions about the constructs measured by intelligence tests involves questions about whether the test measures the same constructs across groups. Does a multiple-age battery, for example, measure the same set of constructs for 8-year-olds as it does for 18-year-olds? Does a new intelligence test measure G*f* and G*c* abilities for European American students, but merely test-taking skills for students from other ethnic backgrounds? Does a verbal comprehension factor have the same meaning for boys as it does for girls? These questions ask, in essence, whether the factor structure and corresponding factor loadings of the tests vary across groups. These are questions of factorial invariance.

The method of *multigroup CFA (MG-CFA)* provides an excellent method for answering such questions. In MG-CFA, any of the parameters that are estimated or fixed in a model can be specified as being invariant across two or more groups. For example, suppose we wish to determine whether a set of tests measures the same constructs for boys and girls. We could specify that the factor loadings of that series of tests on their associated factors are the same for boys and girls. Additionally, we could also specify that the factor covariances, the factor variances, and the unique and error variances are identical across groups.

In one of the earliest examples of using CFA to test for invariance (Jöreskog, 1971), MG-CFA was used to test for invariance of covariance structures. Meredith (1993) extended and formalized the testing of factorial invariance under the more general scope of measurement invariance. Most of the models tested thus far in this chapter have focused on structuring covariances (solving for CFA models using variances and covariances), and have not involved structuring the means. Meredith demonstrated the use of MG-CFA with mean structures, often referred to as *multigroup mean and covariance structure analysis (MG-MACS),* to test various aspects of measurement invariance. This model-based framework compares various models specifying different degrees of invariance in a structured approach using MG-CFA. The following is an example of this approach.

This example uses test score data from 128 girls and 122 boys who were part of the Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004) norming sample to test for measurement invariance across the sexes. The example tests whether the KABC-II measures the CHC abilities in the same way for 4-year-old boys as it does for 4-year-old girls. For children who are 4 years of age, the KABC-II provides four index scores designed to reflect four CHC abilities: Gsm, Glr (long-term retrieval), Gv, and Gc. These composite scores are generated from scores obtained from two or three subtests. The factor model is shown in Figure 31.18. This factor model is consistent with the scoring structure of the KABC-II. Note that the KABC-II also includes a global composite score, but in this example we focus on testing for measurement invariance in the broad-ability composites only and not the global composite (for higher-order models for the KABC-II, see Potvin, Keith, Caemmerer, & Trundt, 2015; Reynolds, Keith, Fine, Fisher, & Low, 2007; Reynolds, Keith, Ridley, & Patel, 2008).

As with the WISC-V models, the model shown is slightly different from previous models. Note the values of 0 next to all the latent variables ("0," in Figure 31.18). Again, these are the means of the latent variables, which are initially fixed to 0.

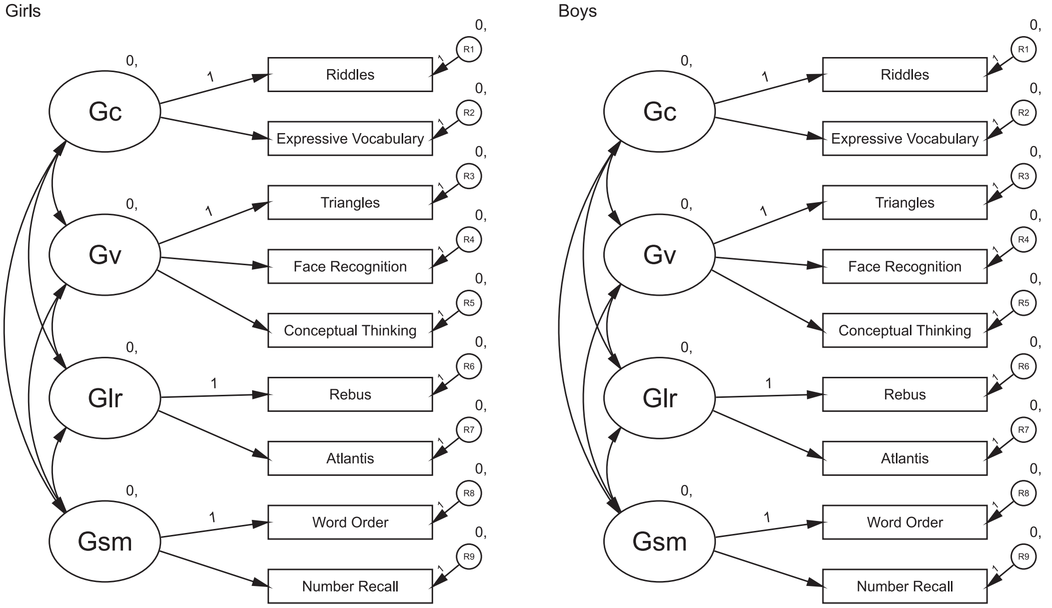

FIGURE 31.18. MG-CFA setup for testing configural invariance across sexes for the KABC-II for 4-year-olds. The same configuration of factors is specified for girls and boys.

This model also estimates the intercepts for the subtests, although these are not shown in the figure. The intercepts, when estimated, may be interpreted in a way similar to those in a regression model, with the factor being the independent variable and the subtest the dependent variable. Thus the intercept for the Riddles subtest, for example, is the expected Riddles score for someone with a value of 0 on the latent Gc factor. In previous models, we have not been concerned with means or intercepts; however, it is necessary to consider, and explicitly model, means and intercepts when testing for measurement invariance. All SEM programs can explicitly model means and intercepts (i.e., mean structures).

Steps in Invariance Testing

Testing for measurement invariance via MG-CFA typically involves the application of increasingly restrictive sets of equality constraints on parameters across groups. Different researchers use different terms to describe the different facets of invariance; we generally use the hierarchy discussed by Meredith (1993). In the first step, the same factor structure is imposed on each group. This initial step is often referred to as *configural invariance* (cf. Thurstone's [1947] *configurational invariance*). This type of invariance requires that the CFA model is configured similarly across groups. This step may be performed with multigroup analysis; alternatively, models can be estimated separately for each group. After that step, steps for testing for *weak factorial invariance* (also known as *metric* or *factor-loading invariance*), *strong factorial* (*scalar* or *intercept*) *invariance*, and *strict factorial* (*item/subtest residual*) *invariance* are followed. Greater detail about the meaning of invariance at each step is explained as the example is worked through. This particular order is not strictly required. For example, some might first test for invariance of the covariance structure (factor loadings and residuals) and then introduce the means (intercepts). There are some important considerations, however. For example, factor loadings should be invariant if the intercepts associated with those loadings are to be tested for equality.

Configural Invariance

Configural invariance simply entails establishing the same configuration of factors across the groups. In this example, the model shown in Figure 31.18 has been estimated for both boys and girls by using MG-CFA (the model for girls is on the left, the model for boys on the right). The factors and pattern of free and fixed loadings within groups are the same across the groups. One loading per factor has been fixed to 1 to scale the factors; this is an important consideration because the factor variances (and covariances) should vary freely across groups. There are alternative ways to scale the factors, such as the *fixed-factor method* and *effect coding.* These will result in the same model fit statistics, but may provide some interpretive advantages. These variations are beyond the scope of the current chapter (see Little, 2013).

The fit of this MG-CFA model is excellent (Table 31.5). The parameter estimates within each group are reasonable. The fit within each group is excellent as well. The factor model appears to be a good fit to the data for boys and girls. Note that if these models were analyzed separately, the sum of the χ^2 and *df* for boys (χ^2 = 17.5; *df* = 21) and girls (χ^2 = 23.3; *df* = 21) would be equal to the χ^2 and *df* from the MG-CFA. Configural invariance is typically thought of as a baseline model, one that future models may be tested against. If modifications are needed to the factor model, this step is the best place to make those modifications.

Weak Factorial Invariance

The configuration of the factor structure has been established in each group in the configural invariance model. The next step is to restrict corresponding factor loadings to be equal across groups, and is referred to as a test of weak factorial (or metric or factor loading) invariance. Each factor has one loading already fixed to 1, and those remain.[9] The factor loadings estimated freely within each group in the configural model are now constrained to be equal across groups. These constraints are made to the unstandardized loadings. So for example, the (unstandardized) loading of Expressive Vocabulary on Gc is constrained to be equal across the sexes. Such a constraint, if supported in this example, means that a one-unit increase in Gc should result in the same unit increase in Expressive Vocabulary performance for boys as for girls. In all, five constraints have been added: one loading on each Gc, Glr, and Gsm factor, and two loadings on the Gv factor. Figure 31.19 shows the models for boys and girls, with these constraints. In Amos, these are accomplished by labeling the corresponding parameters with the same names across the two groups (a for the factor loading of Expressive Vocabulary, etc). Other programs use other methods, but such cross-group constraints are possible in all SEM programs. These constraints resulted in a change of 5 *df.* Because this model is nested within the configural model, $\Delta\chi^2$ may be used to test for degradation in model fit. The inclusion of these five additional constraints does not result in degradation of model fit ($\Delta\chi^2$ = 3.18 [5], *p* = .67). Our experience suggests that the $\Delta\chi^2$ criterion may be overly sensitive for *measurement* invariance tests in larger samples (especially for tests beyond weak factorial invariance), but it is useful for specific aspects of *structural* invariance, which we discuss later. It works well here, in part because of the small (for CFA) sample sizes.

Simulation research has supported change in CFI (ΔCFI) as a useful fit index for comparison of models in invariance testing, with the decreases in CFI of less than .01 providing support for invariance (Cheung & Rensvold, 2002), and ΔCFI is often our preference for comparing models in invariance testing at the measurement level, especially if the goal of the research is not related to the studying the scale itself (χ^2 and *df* should, however, always be reported for all models). Here, however, almost all CFI values are 1.0, so we have used the $\Delta\chi^2$ criterion instead. Weak factorial invariance is tenable. This finding means that the relations between the factors and the subtests are the same across groups, or that the factors are the "same" (in some sense of the word) for both groups. Group comparisons of *factor* variances and covariances would now be considered acceptable. And

TABLE 31.5. Tests of Factorial Invariance for the KABC-II Data for 4-Year-Olds

Invariance model	$\chi2$	*df*	$\Delta\chi^2$	Δdf	*p*	CFI	ΔCFI
Configural	40.82	42				1.000	.000
Weak (metric)	44.36	47	3.54	5	.62	1.000	.000
Strong (intercept)	49.54	52	5.18	5	.39	1.000	.000
Strict (residual)	62.96	61	13.42	9	.14	.997	–.003

Note. Each model is compared to the previous model.

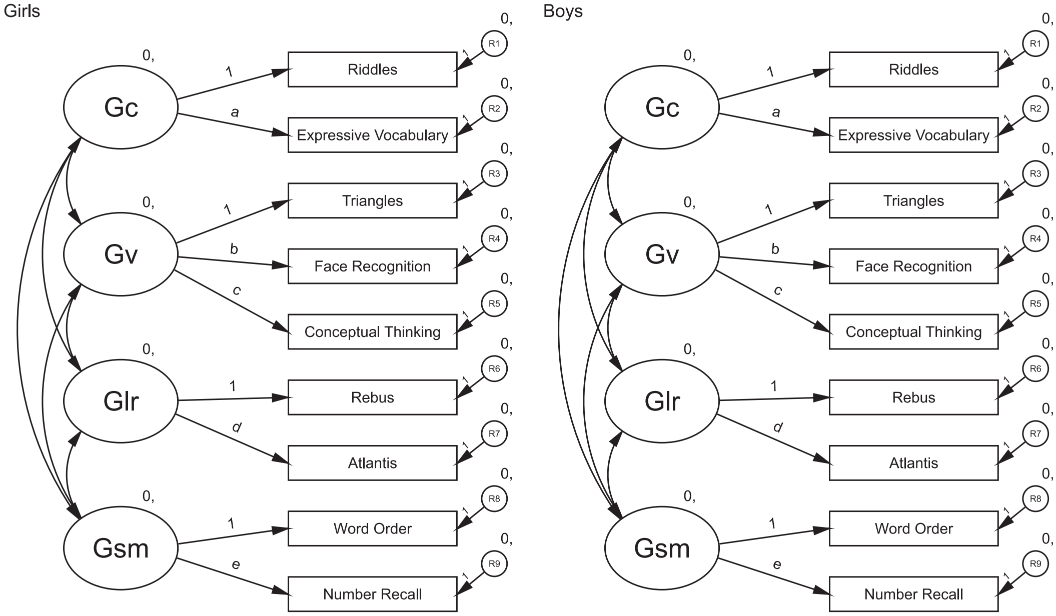

FIGURE 31.19. Testing for weak factorial (metric) invariance. Factor loadings are constrained to be equal for girls and boys.

in our experience, weak factorial invariance is in fact commonly supported, especially in research using intelligence subtests, which often do not involve many indicators per factor and have relatively strong loadings (i.e., reliable factor indicators). On the rare occasions when it is not supported, there are often very large numbers of groups. Even though weak factorial invariance is tenable, this is not yet enough evidence to say that boys and girls with the same latent levels of the CHC factors would indeed have the same observed scores.

Strong Factorial Invariance

Strong factorial (or intercept or scalar) invariance needs to be established before group comparisons may be made of the common factor means (or composite score means). Strong invariance requires that covariances *and* means are analyzed and modeled. In the weak invariance model, the corresponding unstandardized factor loadings have been constrained to be equal across groups. As in previous models, the means have not been modeled. Or more exactly, the factor means have been fixed to 0, and subtest intercepts have been allowed to vary across groups. A test of strong factorial invariance requires that the subtest intercepts (means) also be modeled. Specifically, factor mean differences are allowed across groups, while all corresponding subtest intercepts are constrained to be equal across groups. This specification imposes the restriction that all subtest mean differences *are the results of difference in means on the common factors*. Unstandardized results are shown in Figure 31.20. Nine equality constraints, one per subtest, have been added to the corresponding subtest intercepts (e.g., the Expressive Vocabulary intercepts have been constrained to be equal across boys and girls). In previous models, the latent factor means have been fixed to be 0 (this is the default). To allow differences in the common factor means across groups, the latent means of one group have been freed, while the other "reference" group means remain fixed to 0. Here we denote girls as the reference group and keep their latent means fixed to 0. Boys are the comparison group, and their latent factor means are freed and estimated (note that the 0's are replaced by other values for the boys' factors in Figure 31.20). Technically speaking, the latent means are not estimated; rather, the boys' latent mean estimates represent the difference from the means of the girls because the constraints on corresponding intercepts essentially force mean differences "up" through the factor means. Freeing these four factor means results in 4 fewer degrees of freedom. Therefore, the Δdf

for this model compared to the weak factorial invariance model should equal 5 (i.e., 9 subtest intercept constraints minus 4 latent means freed). It is important to check the *df* changes in the models; as reviewers for journals, we have often noticed *df* values that are not consistent with the intended invariance test. For example, a common mistake is that researchers keep latent factor means set to 0 for both groups after they constrain the intercepts. It is important both conceptually and statistically that the factor means be allowed to differ because strong factorial invariance is a test that the factor mean differences can fully account for differences in the observed means. It is not simply a test of the difference in observed means across groups.

Given that girls are the reference group and their latent means are fixed to 0, positive latent mean values for boys indicate that boys have higher latent means, and negative values indicate that girls have higher latent means. Before those latent means may be interpreted meaningfully, however, strong factorial invariance must be tenable. That is, those differences in latent means should account for the differences across the sexes in the observed test scores. If the strong factorial constraints have been added and the model fit has been degraded, then the researchers should investigate the reasons for such misfit, and the latent mean differences at this point would be misleading. Similarly, the composite scores from the test may be misleading across the sexes. It is important not to stop at this point, but rather to investigate the model to determine why invariance is not tenable. The answers may suggest that it is of very little practical importance, or they may provide new insights (e.g., one group differs on a subtest-specific mean rather than the common factor mean).

To return to our example: Because the weak factorial invariance model is tenable, all prior constraints are maintained; nine additional intercepts constraints are applied; and the boys' Gc, Gv, Gsm, and Glr factor means are freed. The addition of these constraints does not result in a statistically significant degradation in model fit ($\Delta\chi^2 = 5.18$ [5], $p = .36$). Strong factorial invariance is tenable. The unstandardized results are shown in

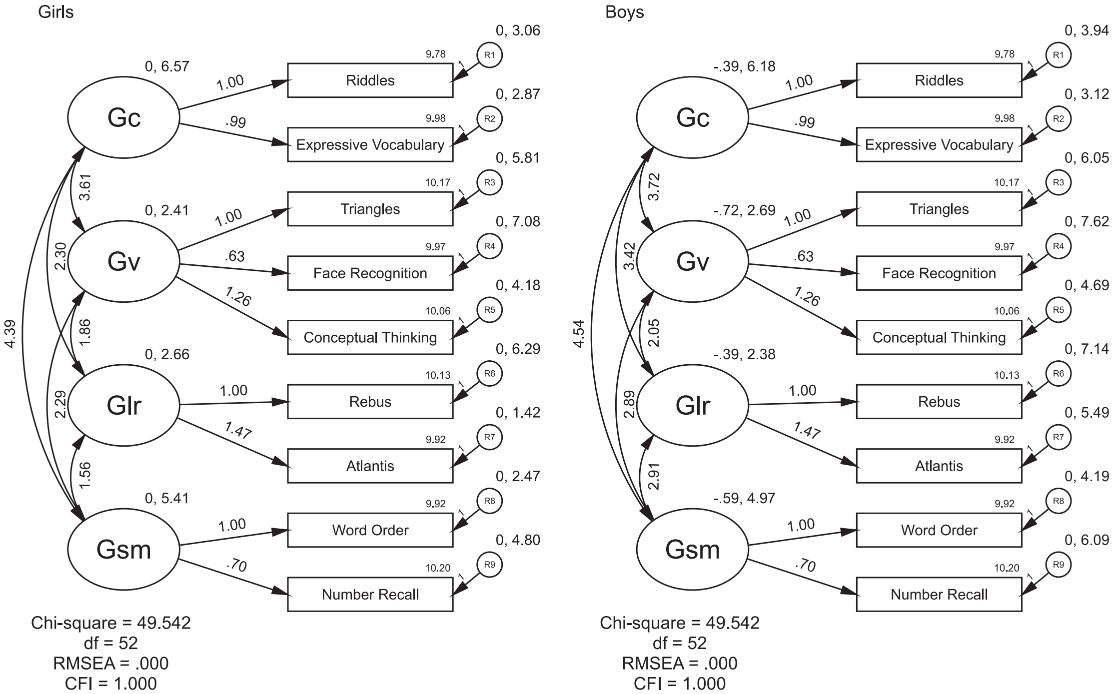

FIGURE 31.20. Unstandardized results for a test of strong factorial (intercept) invariance. Note the numbers above each measured variable. These are the intercepts, which are constrained to be equal across the sexes in this step. The numbers above the latent variables are the means and variances. The latent means for the broad abilities are allowed to vary for boys, and the numbers shown are the latent mean differences for boys as compared to girls.

Figure 31.20. Differences in subtest means across the sexes are explained by differences in the latent factor means between boys and girls. Stated differently, boys and girls with the same level of Gc (or Gv, etc.) would earn the same score on the subtests. It would thus be acceptable for researchers to compare the factor means or the observed composite means for boys with girls. It may also be said that KABC-II CHC scores are unbiased with respect to sex.

Strict Factorial Invariance

The last step in testing for measurement invariance is referred to as strict factorial or residual invariance. In tests of strict factorial invariance, equality constraints are imposed on the variances of the residuals (error + specific variance; R1 through R9 in the figures). Strict factorial invariance allows for cross-group comparisons of both observed means and variances. There is disagreement about the necessity of strict factorial invariance (cf. Little, 1997; Lubke & Dolan, 2003). Some of it boils down to the purpose of the research. Strictly speaking, however, strict factorial invariance is consistent with measurement invariance (Meredith & Teresi, 2006).

The application of these nine additional constraints on the residuals does not result in a statistically significant degradation of model fit (Table 31.5). All sex differences in observed (subtest) score means and variances are due to differences in the common factor means and variances/covariances. The CHC composites from the KABC-II are completely unbiased with respect to sex (for 4-year-olds). Observed scores on the KABC-II depend on the examinees' latent abilities, not on sex.

In this example, measurement invariance has been established with relative ease. In many situations, however, the findings may be more complicated, and partial measurement invariance may be investigated. Such a topic is beyond the scope of this chapter (see Byrne, Shavelson, & Muthén, 1989).

Substantive Questions

We have thus far focused on tests of measurement invariance, which may subsume many interesting research questions. Researchers are often interested in testing for construct bias for a test across two or more groups (e.g., Trundt, Keith, Caemmerer, & Smith, 2017). Such questions may be modeled by using tests of factorial invariance.

Other interesting research questions may also be answered. For example, we have mentioned that differences in latent means are estimated and can be compared because strong factorial invariance is tenable (and even better, strict factorial invariance is). Girls' latent means for each factor are 0, while the boys' are estimated. Negative latent mean values thus indicate that boys' levels of abilities are lower. Each latent mean is negative (Gc = –.39; Gv = –.72, Glr = –.39, Gsm = –.59), although only Gv is statistically significant at the $p < .05$ level (see Figure 31.20). To be clear, a mean difference on this latent factor does *not* indicate that the test is biased; rather, it indicates that there is a "true" mean difference between boys and girls in these latent constructs. That mean difference in the latent factor accounts for the differences in the observed scores, so at age 4, boys on average score slightly lower on Gv (it may also be of interest to include a *g*-factor and test for differences using higher-order models) (see Keith et al., 2008; Reynolds et al., 2008). Latent mean differences can also be tested with model-fitting procedures by constraining the factor mean to be equal for boys and girls (by fixing the boys' factor means back to 0) and checking for degradation in model fit.

Other questions may also be of interest. Are the factor variances equal across groups? Or are the latent factors equally differentiated across groups? To answer those questions, researchers may want to test for equality of the variances and covariances/correlations (see Little, 1997). It is once again important to note that these are substantive questions, and measurement invariance must be established before these comparisons are made. These questions may follow tests of measurement invariance, but *during* testing for measurement invariance, it is imperative to allow for group differences in factor variances and covariances, and (when the means are modeled) differences in the factor means. Furthermore, the use of the χ^2 difference test is more commonly used to test specific *substantive* research questions (Little, 2013).

Intercepts and Means

As already noted, means are often not modeled in factor analysis, so it is worth describing strong factorial (intercept) invariance in a bit more detail. For example, if there is a difference in intercepts, this means that for equal levels of the latent trait, a constant score is added to the mean of one group; however, this constant is specific and is not related to the common factor.

Say, for example, that researchers are interested in comparing boys and girls on a composite score from a test battery designed to measure visual–spatial ability (Gv). The composite score includes four subtests that are supposed to measure four aspects of visual–spatial ability (e.g., closure speed, visual memory, spatial scanning, and spatial visualization). Measurement invariance is investigated. Weak factorial invariance is supported. Strong factorial (intercept) invariance, however, is not. Specifically, the intercept associated with spatial visualization differs across groups, such that boys score higher on this test even when boys and girls have the same levels of Gv. When the constraint on the intercept for this subtest is removed, partial intercept invariance is tenable. This means that if a Gv composite score is calculated that includes spatial visualization, boys score higher even when boys and girls have equal levels of Gv. Without this test in the composite, however, boys and girls with equal levels of true Gv obtain the same score on the composite.

If the factor model is considered in terms of a linear equation, then the expected score for a person equals the intercept plus the product of the factor loading times the "true latent ability." Imagine a boy and girl with exactly the same latent Gv mean (e.g., 10). Weak factorial invariance is established, so that the factor loading (.5) is equivalent across groups. Strong factorial invariance is supported for all of the tests except for spatial visualization. The intercept values for spatial visualization are 15 for boys and 10 for girls. The expected score for boys is therefore $15 + (.5 \times 10) = 20$. The expected score for girls is $10 + (.5 \times 10) = 15$. The expected score for boys is higher, even though the latent Gv ability is identical. Note that in contrast, if the intercept are invariant, the expected scores are the same for boys and girls (see Gregorich, 2006, for more examples).

Finding intercept differences (or other differences) may be discouraging for a researcher. But from a substantive point of view, and from that of research and understanding what intelligence tests measure, the finding may be quite informative. In this hypothetical Gv example, *partial* strong factorial invariance is demonstrated, and it is found that there are no sex differences in the broad Gv factor, but only specific subtest mean differences. In our experience, such intercept differences are often the results of a subtest's measuring a specific narrow ability, and one on which there are differences. Such knowledge is interesting substantively, and may lead to a better understanding of sex differences and a better understanding of the measurement of Gv. What should be obvious, however, is that the application of a model-based framework allows for more specificity and sophistication in investigating such measurement and substantive questions.

TESTING FACTOR–COMPOSITE OVERLAP

Some of the methods discussed previously are useful for determining whether two tests measure the same underlying construct. A related question is this: How well does a test *composite* or cluster measure a construct? There are different ways to go about answering this question, and it is important to think about what construct the composite is intended to measure.

Cross-battery analysis, or joint factor analysis of more than one test battery administered to the same group of examinees, may be useful for this purpose. For example, Keith and colleagues (2001) found that a higher-order *g* factor from the WJ III correlated perfectly with a higher-order *g* factor from the CAS. In another analysis, they then correlated the higher-order *g* factor from the WJ III with the Full Scale score from the CAS and found that it was lower (.79). A similar analysis was conducted by Farmer, Floyd, Reynolds, and Kranzler (2014) with other intelligence batteries, including versions of the WISC, DAS, and WJ. Research had already demonstrated that the *g* factors from these various test batteries were either perfectly or nearly perfectly correlated (Floyd et al., 2013). Farmer and colleagues showed that range-corrected correlations of the *g* factor from one battery (e.g., the WJ) with a global composite from another battery (e.g., the DAS) ranged from .88 to .95. Thus there is considerable variability (.79 to .95) in the degree that overall or global composite scores (such as Full Scale IQs) correlate with latent *g* factors (cf. Reynolds, Hajovsky, Pace, & Niileksela, 2016). Taken together, the findings suggest that all these test batteries measure the same *g* factor, but that the composites from some batteries do a better job of measuring *g* than others do. The finding may be particularly important in deciding which test to use for a possible diagnosis of intellectual disability if intellectual disability is thought to be primarily the result of a deficit in *g*.

The correlations of global composites with *g* have been described as the *g-loading* of the composites (Jensen, 1998). Reports of factor analysis typically report subtest (or item) loadings on factors, but it is the composites that are interpreted as indexes of the factors or constructs. Knowledge of the loadings of the composites on the factors would thus be very useful. Conceptually, obtaining this estimate would be akin to also including, for example, the global composite in a factor analysis of subtests and interpreting the composite factor loading on *g*, but this solution is not practical for other reasons. Applying cross-battery CFA to estimate the correlations of a global composite with a *g*-factor from another battery has been one way to estimate the *g*-loading of that global composite. It may also be thought of as a way to estimate the validity of a global composite as an index of *g*.

Having data from multiple batteries administered to the same examinees is a luxury, however. How might such estimates be obtained if data from multiple batteries are not available? Spearman (1927) originally provided a formula for calculating the correlation of a composite with a factor (see Jensen, 1998). If that correlation is squared, the estimate reflects the variance in a composite explained by the factor. Other methods to calculate the variance explained in composites by factors are used today and are commonly calculated from estimates obtained via factor analysis. A popular coefficient, if the test is unidimensional, is referred to as *coefficient omega*, or the proportion of variance explained in the global composite by the general factor (McDonald, 1999). Of course, intelligence tests measure multiple factors, not a single factor, and that is why hierarchical models are employed. Fortunately, however, such calculations are easily applied to multidimensional hierarchical models to estimate the overlap of the multiple factors in composites. In this context, the estimates are sometimes referred to as *omega hierarchical* (Zinbarg, Yovel, Revelle, & McDonald, 2006). For example, using estimates from a factor model, an omega hierarchical coefficient for the *g* factor can be calculated as the square of the sum of subtest *g* loadings divided by the total variance in the subtest scores included in the composite (Gustafsson, 2002). This coefficient is an estimate of the *g* saturation in a global composite, and the square root of that estimate is essentially the *g*-loading of that global composite.

Omega hierarchical coefficients and related *g* loadings associated with global composites in the WISC-IV, DAS-II, and KABC-II were estimated in this way in a study using the standardization samples from those tests (Reynolds, Floyd, & Niileksela, 2013). The square roots of those estimates (i.e., the *g*-loadings) ranged from .88 to .93, and were very similar to those found in Farmer and colleagues' (2014) cross-battery approach. Although conceptually very similar (given that all tests appear to be measuring the same *g*), the cross-battery coefficients are more likely to be described as *validity indices*, whereas the within-test coefficients are likely to be called *composite reliability estimates*. Researchers almost always refer to all of these estimates as composite reliability coefficients. Others (e.g., Gustafsson & Åberg-Bengtsson, 2010; McDonald, 1999) however, have described the omega hierarchical estimates as validity estimates (cf. Bollen, 1989), representing indices of how well certain latent variables are measured in the composites. We believe that this validity-based interpretation makes a great deal of sense. We also tend to prefer the unsquared versions (e.g., construct–composite correlations) because these indices tend to be more easily translatable into the real world—unlike variances.

Omega-type estimates may be used for all kinds of composites, including the composites associated with the broad abilities. These estimates can be calculated both with and without *g* included in the factor (although the broad-ability *observed* scores do not have *g* removed from them).

Rather than demonstrating the calculation of omega hierarchical by using the formula described above, we demonstrate how to obtain these estimates by using model-implied estimates from a CFA that includes a phantom variable. We think that this method may provide some conceptual clarity. Earlier, we have mentioned that a conceptually clear but unrealistic way to obtain the *g*-loading of a global composite is to include that composite in a factor analysis of the subtests. Here we demonstrate how this method is approached via the use of phantom composite variables in CFA (see Fan, 2003; Gignac, 2007). The data are again from the DAS-II, and take the form of a covariance matrix, averaged across the age ranges 7 and older. We use a different mix of DAS-II tests than in previous examples, in order to provide greater comparability to Reynolds, Floyd, and Niileksela (2013).

As the first step, we have developed a model that explains the data (see Figure 31.21). Shown in the figure is a higher-order model, but we also report omega hierarchical estimates obtained from a bifactor model for comparison. The higher-order model provides an adequate description of the covariances among all of the DAS-II subtests.

Our initial interest is in the *g* loading of General Conceptual Ability (GCA in the figure) from

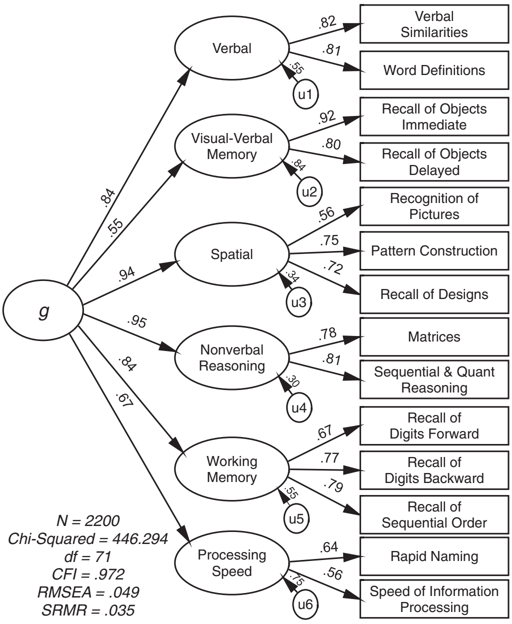

FIGURE 31.21. DAS-II higher-order model. This model includes additional tests and factors, compared to earlier models.

the DAS-II. This is the global composite, and it includes six subtests, with each subtest contributing equally to it. Therefore, in our model we include what is referred to as a "phantom variable" to represent the GCA. As shown in the model setup in Figure 31.22, there are arrows pointing directly to this phantom composite variable from the six subtests included in it, and all of the arrows are weighted by 1. This weighting simply means that this phantom variable is an equally weighted composite of these six subtests. The model is reestimated with this phantom variable, and we request the implied moments (covariances and correlations) in the output to obtain the correlation of the GCA composite with the *g* factor. Note that the correlation is not included in the actual model shown in the diagram; it is only produced in the implied moments output. Note also that model fit, *df*, and all other aspects of the model do not change at all. The implied correlation, or *g*-loading, of the GCA is .91 (see Table 31.6). The loading squared, or *g* saturation (or omega hierarchical), is .83 (Gignac, 2007, has referred to this as *phantom omega*). The estimate with a bifactor model using the phantom composite (not shown) is the same (*g*-loading = .91). These estimates are the same as the estimate from Reynolds, Floyd, and Niileksela (2013), who used the omega hierarchical calculations with output from a bifactor model.

Several other aspects of this model are worthy of comment. Note that we have included *all* of the available subtests in our CFA model (i.e., 14), to obtain what would be considered the best *g* estimates, but have only used the estimates from subtests included in the global composite (e.g., 6 from the DAS-II) to obtain the model-implied correlation (see also Reynolds, Floyd, & Niileksela, 2013; Reynolds & Keith, 2017). Including all of the subtests provides a more rigorous test of the CFA model (and the CFA model is important, since all of the estimates are obtained from the model) and likely results in the best possible estimate of a *g* factor. This view is consistent with the view that these estimates are closer to indices of validity. Note also that the estimates should reflect and be associated with the composite that is actually used. For example, a 14-subtest composite including every subtest included in the DAS-II is not available, so estimates associated with that composite are not that interesting. To summarize, we prefer to model all of the data to obtain the best estimates for the factors, but to use composites that reflect the actual composites on the test of interest. We follow this method for the rest of the analysis.

In addition to the *g*-loading, the relations of the other composites with their respective factors may be of interest. The DAS-II also includes Verbal, Nonverbal Reasoning, Spatial, Working Memory, and Processing Speed composites. The Working Memory composite does not include the Recall of Digits—Forward score, so it is not used in the calculation of the factor saturation in that composite, although it is included in the factor. All of the estimates are shown in Table 31.6. The first column shows the estimates using the higher-order model. Located in the column to the right of the higher-order model estimates (the "Unique" column) are the estimates where *g* has been removed from the first-order factors before each factor is correlated with its associated composite (here *g* has been partialed from the broad ability, but has not been partialed from the composite). In the model-implied correlation output, the correlations of the unit-weighted composite with the unique variance are interpreted (Unit variance identification should be used to scale the disturbances). For example, the model-implied u1 correlation with the Verbal composite (a unit-weighted composite of Verbal Similarities and Word Definitions) is interpreted. Recall that u1 represents Verbal ability

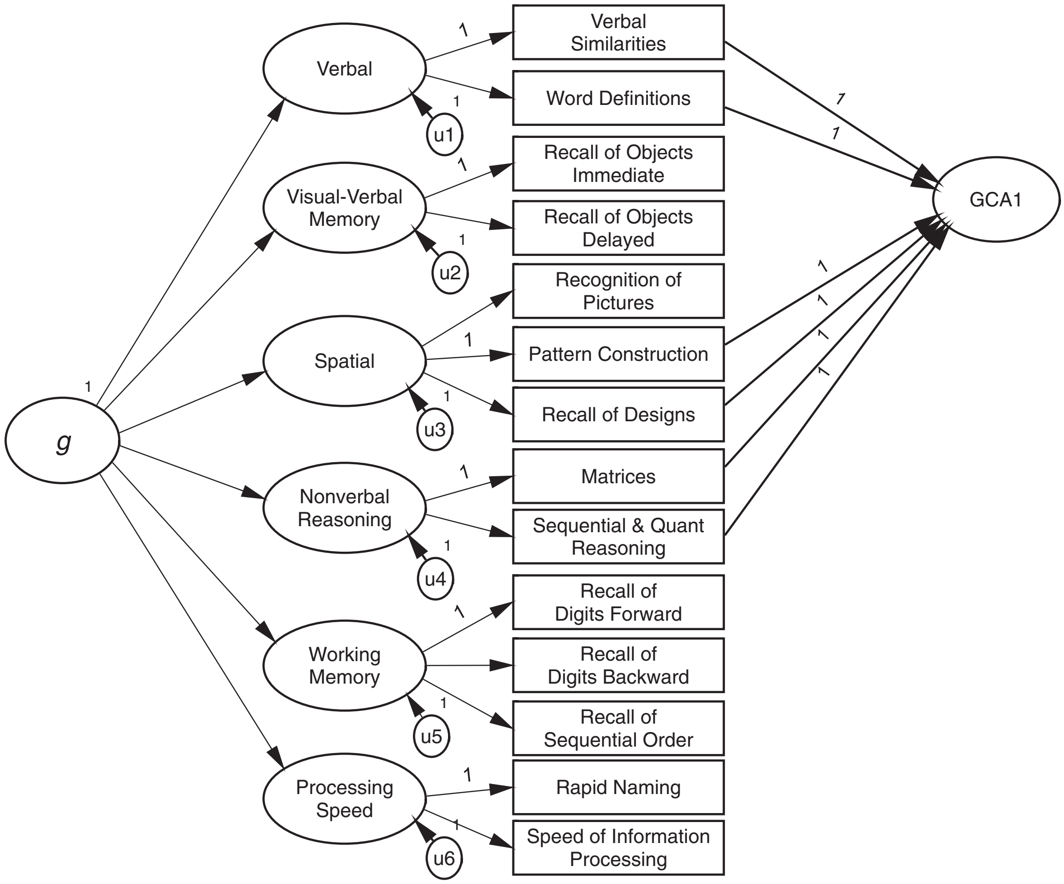

FIGURE 31.22. Setup to determine the model-implied correlation between the DAS-II GCA composite and *g*. Omega hierarchical (the correlation squared) estimates the GCA variance explained by *g*. The unique variances associated with the subtests have been removed for clarity, but are included in the analysis.

from which *g* has been partialed (or Verbal ability with *g* removed, if such a thing exists). Finally, also included are the bifactor model estimates. The unique estimates from the higher-order model are very similar to those from the bifactor model because, of course, *g* has been partialed from the subtests in the bifactor model. These estimates, sometimes referred to as *omega subscale,* of course will be lower than the estimates without *g* partialed.

One potential use of the estimation of the construct composite correlations is to see how the use of different subtests might affect the relation of the construct with that composite (see McDonald, 1999). For example, the DAS-II GCA may be considered an efficient measure of *g* because it only includes six subtests—and from three broad abilities that are traditionally associated strongly with *g*. Additional subtests in the composite, however, would seem to increase the *g* measurement in the composite because all of the subtests load positively on *g*. Would it be worth it to have a composite with additional subtests? As shown in the bottom portion of Table 31.6, including all 14 DAS-II subtests in a composite (e.g., a hypothetical unit-weighted composite of all 14 subtests) does not result in a substantial improvement in *g* measurement. Other potential composites are also tested—for example, one that includes a working memory and processing speed test, since most global composites from intelligence tests include measures of these constructs. Again, there is no improvement. Finally, we test a composite that is similar to the new seven-subtest composite on the WISC-V. It includes two Verbal subtests, two Nonverbal Reasoning subtests, and one subtest from each of the Spatial (Pattern Construction), Working Memory (Re-

TABLE 31.6. Model-Implied Correlations of DAS-II Composites with Their Corresponding Factors

	Correlation			Variance (correlation squared)		
Composite	Higher-order	Unique[a]	Bifactor	Higher-order	Unique[a]	Bifactor
GCA	.91		.91	.83		.83
Verbal	.89	.49	.50	.79	.24	.25
Spatial	.84	.29	.32	.71	.08	.10
Nonverbal Reasoning	.88	.27	.27	.77	.07	.07
Working Memory	.87	.48	.42	.76	.23	.18
Processing Speed	.73	.54	.54	.53	.29	.29
Possible alternative composites not on the DAS-2[b]						
All 14 DAS-2 subtests	.92		.92	.85		.85
GCA + DB/SIP	.92		.92	.85		.85
GCA WISC-V-like	.91		.91	.83		.83

Note. GCA, General Cognitive Ability; DB, Recall of Digits—Backward; SIP, Speed of Information Processing.

[a] The *g* factor has been partialed in the higher-order model.

[b] All of these unit-weighted composites are correlated with the *g* factor.

call of Digits—Backward), and Processing Speed (Speed of Information Processing) broad abilities. Again, a composite of these variables shows about the same relation with *g* as the six-subtest GCA does. It may be concluded that the six-subtest composite from the DAS-II is indeed an efficient measure of *g*. The additional subtests used here do not provide a noticeable improvement. Of course, we do not recommend simply adding and deleting tests to try to maximize the measurement of *g*. Theory is essential. For example, some believe that it is important to sample from a variety of broad abilities for *g* measurement. In that case, some may view the measurement of *g* by the DAS-II as lacking breadth. Others may think that it is more important to measure *g* from subtests and constructs that are more closely associated with *g*.

REFERENCE VARIABLES: COMBINING SAMPLES

A major difficulty in conducting CFA-guided intelligence test research is the time commitment involved for both researchers and participants. An individually administered test of intelligence will generally take an hour and a half to administer, and substantial sample sizes are needed (150 or more are useful, although for more detail on power analysis and sample size, see Brown, 2015; Keith, 2015; Kline, 2016). Research using tests from multiple batteries allows for powerful tests of competing theories (for a further discussion, see Keith & Reynolds, 2010). Data collection for such research also requires a considerable increase in time commitment. It also likely reduces participation rates; how many participants (or their parents) are willing to spend 3–4 hours taking tests to aid in a research project? Even if they were willing, examinee fatigue would probably become an issue, so data collection for one examinee would be likely to require multiple sessions. On the other hand, imagine how useful the inclusion of additional batteries or parts of batteries would be, allowing for more comprehensive tests of specific questions and even underlying theories. Needless to say, despite the appeal, such studies are quite rare.

One possible solution is the use of a *reference variable* approach (McArdle, 1994) as a way of combining data from different samples, if those samples share a subset of subtests given to all participants. McArdle (1994) outlined the approach as a method of reducing data collection requirements by instituting *planned missingness*. That is, a large number of measures could be administered to participants, but no one would take all measures. Instead, each participant might take one, two, or a few tests per factor measured, or subsets of participants would take different subsets of measures. The methodology builds on several topics already discussed, especially multisample analysis and invariance testing, and it requires expanding our thinking about what "latent" variables are. Cheung and Chan (2005) advocated the method as a way of combining correlation matrices for meta-analysis. Keith and colleagues (2010) illustrated the use of the method to conduct cross-age invariance testing when the structure of a test changes across age groups. Reynolds, Keith, and colleagues (2013) used the method to combine data from multiple batteries to test the validity of CHC theory and of those tests as measures of CHC constructs. Here, we likewise illustrate the method as a way of combining overlapping batteries from multiple samples, but on a smaller scale.

Stone (1992) conducted a cross-battery CFA of the original DAS (Elliott, 1990) and the second edition of the WISC, the Wechsler Intelligence Scale for Children—Revised (WISC-R; Wechsler, 1974). His primary purpose was to compare models similar in structure to those guiding the WISC-R to those guiding the DAS (the DAS-type structure was more strongly supported). The data presented by Stone, however, can also be used to test specific hypotheses about the abilities measured by either measure. As a huge help to those who might want to investigate further, he reported the correlation matrix among the tests in these two batteries, thus allowing us (or anyone else) to further analyze those data. We have used those data in previous versions of this chapter to illustrate cross-battery CFA and its utility in answering questions about the constructs measured by tests (viz., whether the Block Design subtest of the WISC-R measures visual processing [Gv] or fluid intelligence [Gf]).

As noted earlier, one enduring question concerning the Wechsler scales is what exactly is being measured by the Arithmetic test. In previous versions of the WISC, Arithmetic was a component of the Verbal scale, but it was often combined with Digit Span and Coding into a (probably misnamed) Freedom from Distractibility factor in EFA. In the WISC-IV, the WISC-V, and the Wechsler Adult Intelligence Scale—Fourth Edition (WAIS-IV), there is evidence that Arithmetic measures Gf (Benson, Hulac, & Kranzler, 2010; Keith, Fine, Reynolds, Taub, & Kranzler, 2006; Reynolds & Keith, 2017; Weiss, Keith, Zhu, & Chen, 2013), but that it may also measure short-term memory (Gsm) and crystallized intelligence. A cross-battery CFA of the WISC-III with the WJ III Tests of Cognitive Abilities (WJ III COG) suggested that Arithmetic is best considered a measure of Gq, or mathematics achievement (Phelps, McGrew, Knopik, & Ford, 2005). Thus, although the Stone (1992) data do not focus on the most recent versions of the WISC and DAS, they may still be useful for helping us understand the construct measured by previous (and likely current) versions of the Arithmetic test.

The DAS includes two good measures of Gf, one of which (Sequential and Quantitative Reasoning) appears to measure quantitative reasoning (RQ). Thus a joint CFA of the WISC-R and the DAS could determine whether the Arithmetic test "fits" on the same factor with Sequential and Quantitative Reasoning. But what about alternative competing hypotheses? The original DAS also included three short measures of achievement (Basic Number Skills, Spelling, and Word Reading), so with a cross-battery CFA of the WISC, the DAS, and the DAS achievement scale, it should be possible to test whether the WISC Arithmetic test measures Gf, achievement, neither, or both. Because the two measures also include other measures of Gsm (each includes a digit span measure), it should also be possible to test whether Arithmetic measures short-term memory skills.

The second sample in this research is a portion of the original DAS standardization sample, ages 8–15 (the age range of the Stone DAS/WISC-R data), using the DAS cognitive and achievement tests. These data are accessible as age-related matrices in the DAS technical handbook (Elliott, 1990). Two samples are thus used in this example. The first sample includes 115 children ages 8–15 who were administered both the DAS and the WISC-R. The second sample includes children ages 8–15 in the standardization sample who were administered the DAS cognitive battery and the three DAS achievement tests. For both samples, the correlation matrix of tests and standard deviations have been used as input for the analysis.[10] The DAS serves as a "link" between DAS achievement and WISC-R tests.

Figure 31.23 shows the model developed and tested for the DAS/WISC-R data, and Figure 31.24 shows the model developed and tested for the DAS/achievement data (the Recall of Digits residual has been constrained, based on the results of the DAS/WISC data). As shown in the figures, both models fit the data well, and we are likely to accept them as reasonable (all factors have been correlated, although these are not shown in the figures in order to simplify them). Figure 31.25 shows the setup for the reference variable analysis, with the DAS/WISC-R sample on the top and the DAS/achievement sample on the bottom. This is a basic multi-

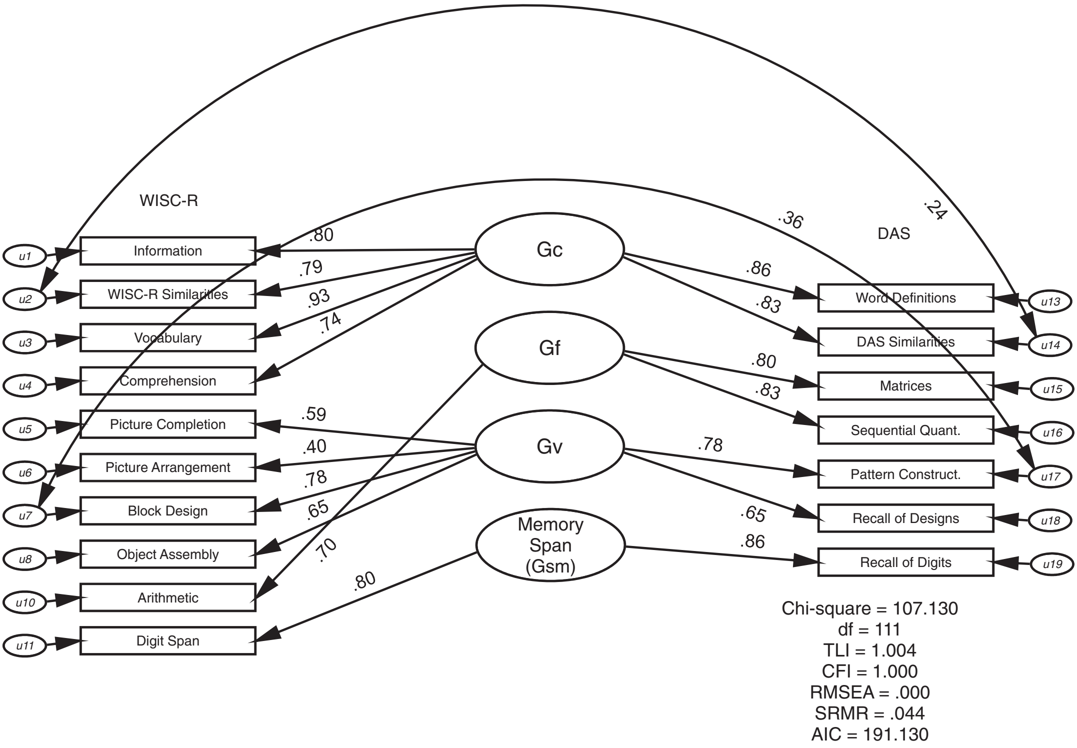

FIGURE 31.23. Cross-battery CFA of the DAS and the WISC-R.

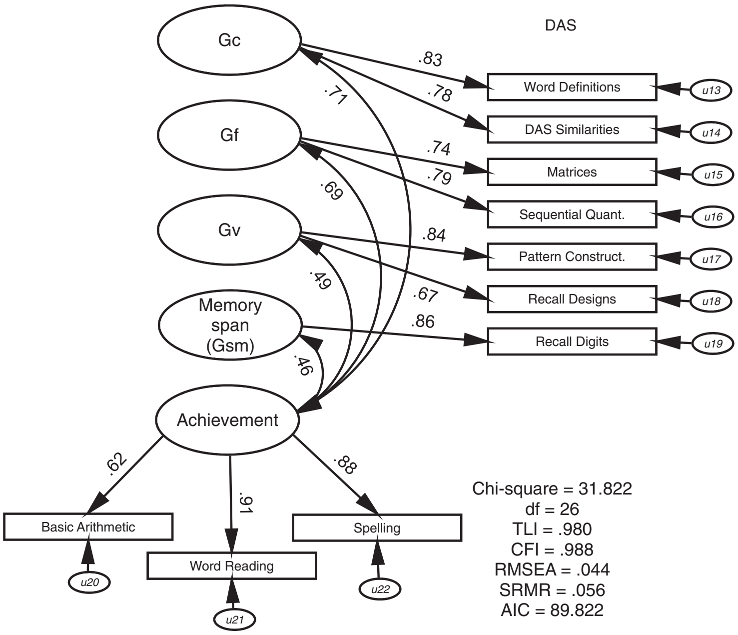

FIGURE 31.24. CFA of the DAS and the DAS achievement tests.

sample analysis, but with different models across samples. What is unusual in these are that some variables that are normally measured variables appear as latent variables in one sample (e.g., the subtests of the WISC-R in the lower portion of Figure 31.25). This may seem strange, but consider some alternative ways of thinking about latent variables: They are unmeasured or even imaginary variables, and an imaginary variable is also a *missing variable*. The latent variables Gc, or u13, do not appear anywhere in either dataset; they are missing. Likewise, in the DAS/WISC-R sample, there is no Basic Arithmetic variable, and thus it is missing, or latent (see the upper portion of Figure 31.25).

Both models will be underidentified (and therefore impossible to estimate) if analyzed separately, but they can be analyzed in tandem, with certain parameter constraints. These are also shown in Figure 31.25. Thus the path from achievement to Basic Arithmetic in the DAS/WISC-R sample is constrained to the value estimated in the DAS/achievement sample, and the path from Gc to Information in the DAS/achievement sample is constrained to the value estimated in the DAS/WISC-R sample, and so on. In fact, every parameter that has the same label across the two figures has been constrained to be equal across the groups. These include some of the factor loadings, factor variances, variances of residuals, and covariances among factors and residuals. The constrained parameters are those related to measured variables that do not exist in one sample versus the other.

These constraints are *required* for estimation, but are they reasonable? What if the DAS/WISC-R sample were very different from the DAS/achievement sample? In that case, assumptions concerning the equivalence of these parameters would not be justified. It is possible, however, to get an idea of the reasonableness of these assumptions by testing for invariance for the parts of the model that exist in *both* groups. The DAS cognitive battery was administered to both samples (these are the *reference variables*), and thus it is possible to go through the invariance testing steps for these portions of the models. Table 31.7 shows the results of such testing. The configural model is the model shown in Figure 31.25, with no cross-sample constraints beyond those required for identification and estimation. For the metric invariance model, the paths from the factors to the DAS cognitive tests have been constrained to be equal across groups. As shown in the table, these constraints do not result in a statistically significant decrement in model fit, and thus we are likely to accept these loadings as equal across groups. The table shows that the results of each level of invariance testing are plausible.[11] If the common structure is equivalent across groups, it makes sense to assume that the unmeasured/missing portions of that structure are equivalent also. As a result, we can now proceed confidently to use these combined data to test hypotheses of interest. If we were using raw data (and if intercept invariance were also tested and established), it would now also be reasonable to combine the two datasets and let the SEM program deal with the missing data. (Given that most SEM programs, by default, use maximum-likelihood methods for dealing with missing data, the results should be the same as in the reference variable approach, with structures estimated via maximum-likelihood estimation.)

The model shown in Figure 31.25, and those discussed so far in Table 31.7, have assumed that the WISC-R Arithmetic test is a measure of quantitative reasoning, and thus Gf, fluid intelligence. This categorization is consistent with the current version of the WISC, the WISC-V. With the Test Arithmetic 1 model, a cross-loading was also allowed for Arithmetic on the Achievement factor. As shown in the table, this model relaxation results in an improvement in χ^2, but that improvement is not statistically significant. We are likely to accept the stricter model, the one specifying that Arithmetic is a measure of RQ/Gf, over the one specifying that Arithmetic measures both Gf and achievement. Interestingly, in the model in which both loadings are allowed, neither is statistically significant (probably due to the smallish sample size), but they are of similar magnitude (.41 for Gf, .39 for Achievement). If we stopped our model testing here, we would be likely to conclude that Arithmetic is better considered a measure of RQ and Gf than of achievement.

The Test Arithmetic 2 model specifies that Arithmetic loads only on the Achievement factor. This model can also be compared to the Test Arithmetic 1 model. The difference is not statistically significant, suggesting that a model with Arithmetic loading only on the Achievement factor is better than a model allowing it to load on both Achievement and Gf. The model comparisons are not definitive in this case (e.g., AIC of 256.271 vs. 256.198), so it is still not clear whether Arithmetic is better considered a measure of Gf or of achievement. Larger sample sizes, additional measures of RQ, and additional measures of arithmetic achievement would help in making this determination.

TABLE 31.7. Comparisons of Reference Variable Models: Invariance and Hypothesis Testing

Model	χ^2	*df*	$\Delta\chi^2$	Δdf	*p*	RMSEA	SRMR	AIC
Configural	138.952	137				.008	.044	280.952
Metric	139.029	140	0.077[a]	3	.994	.000	.044	275.029
Subtest residual	143.471	147	4.442[a]	7	.728	.000	.045	265.471
Factor variances	143.675	150	0.204[a]	3	.977	.000	.046	259.675
Factor covariances	152.271	156	8.596[a]	6	.198	.000	.054	256.271
Test Arithmetic 1	150.431	155	1.840[a]	1	.175	.000	.052	256.431
Test Arithmetic 2	152.198	156	1.767[a]	1	.184	.000	.052	256.198
Test Gsm 1	151.351	155	0.920[b]	1	.337	.000	.053	257.351
Test Gsm 2	178.475	156	28.044[a]	1	<.001	.025	.074	282.475

[a] Compared to the previous model.

[b] Compared to the factor covariances model.

The WISC-IV included the Arithmetic test on a Working Memory Index, suggesting that it is a measure of the narrow ability working memory and the broad ability short-term memory (Gsm). Table 31.7 also shows two models testing this possibility. The results of these comparisons are more definitive. Allowing Arithmetic to cross-load on a Gsm factor does not improve model fit, and with a model allowing such cross-loading, the path from Gf to Arithmetic is statistically significant, whereas the path from Gsm to Arithmetic is not. In addition, a model allowing Arithmetic to load only on the Gsm factor fits statistically significantly worse than a model allowing cross-loadings does, and worse (based on the AIC) than a model allowing it to load only on a Gf factor does. The models suggest that Arithmetic (at least the version of Arithmetic on the WISC-R) likely measures Gf more than it measures Gsm. Of course, additional measures of Gsm and additional measures of working memory abilities on the Gsm factor would improve these comparisons as well. The issue is not settled by any means; current research with the WISC-V suggests that Arithmetic measures primarily general intelligence, with a small loading on a memory factor (Reynolds & Keith, 2017).

Figure 31.26 shows another way to specify this model (this is the configural invariance model). With this specification, variables that are measured in one sample but missing in the other simply are not included in that second sample. Note that the latent variable referencing achievement does appear in both, with its variance and covariances constrained to be equal across groups. Note that the fit statistics for this version of the model match those for the original configural invariance specification shown in Table 31.5.

Although these results and speculation are interesting, the main purpose of this example has been to illustrate the reference variable approach. Clearly, this is a useful approach for increasing the number of tests and broadening the factor representation in CFA. It can be useful for combining extant datasets, as we have done here, but a more useful approach would be to use this to plan data collection so that the breadth of measurement is increased without increasing the time commitment per participant. (For example, a useful plan would be that there would be one indicator variable per factor administered to all participants.) And the approach is not limited to two samples. Reynolds, Keith, and colleagues (2013), for example, combined data from four samples in a comprehensive test of CHC theory. This research also tested for measurement invariance in many of the major tests used (e.g., the WISC-IV, the WJ III, and the reference test, the KABC-II) against their standardization data, to ensure that the smaller cross-battery samples were representative of the underlying factor structures.

TESTING THEORIES OF INTELLIGENCE

Most of the examples used in this chapter are examples of CFA used to understand the constructs measured by specific tests. The method is equally applicable, however, for asking and answering questions about *theories* of intelligence. Of course, some analyses serve both functions.

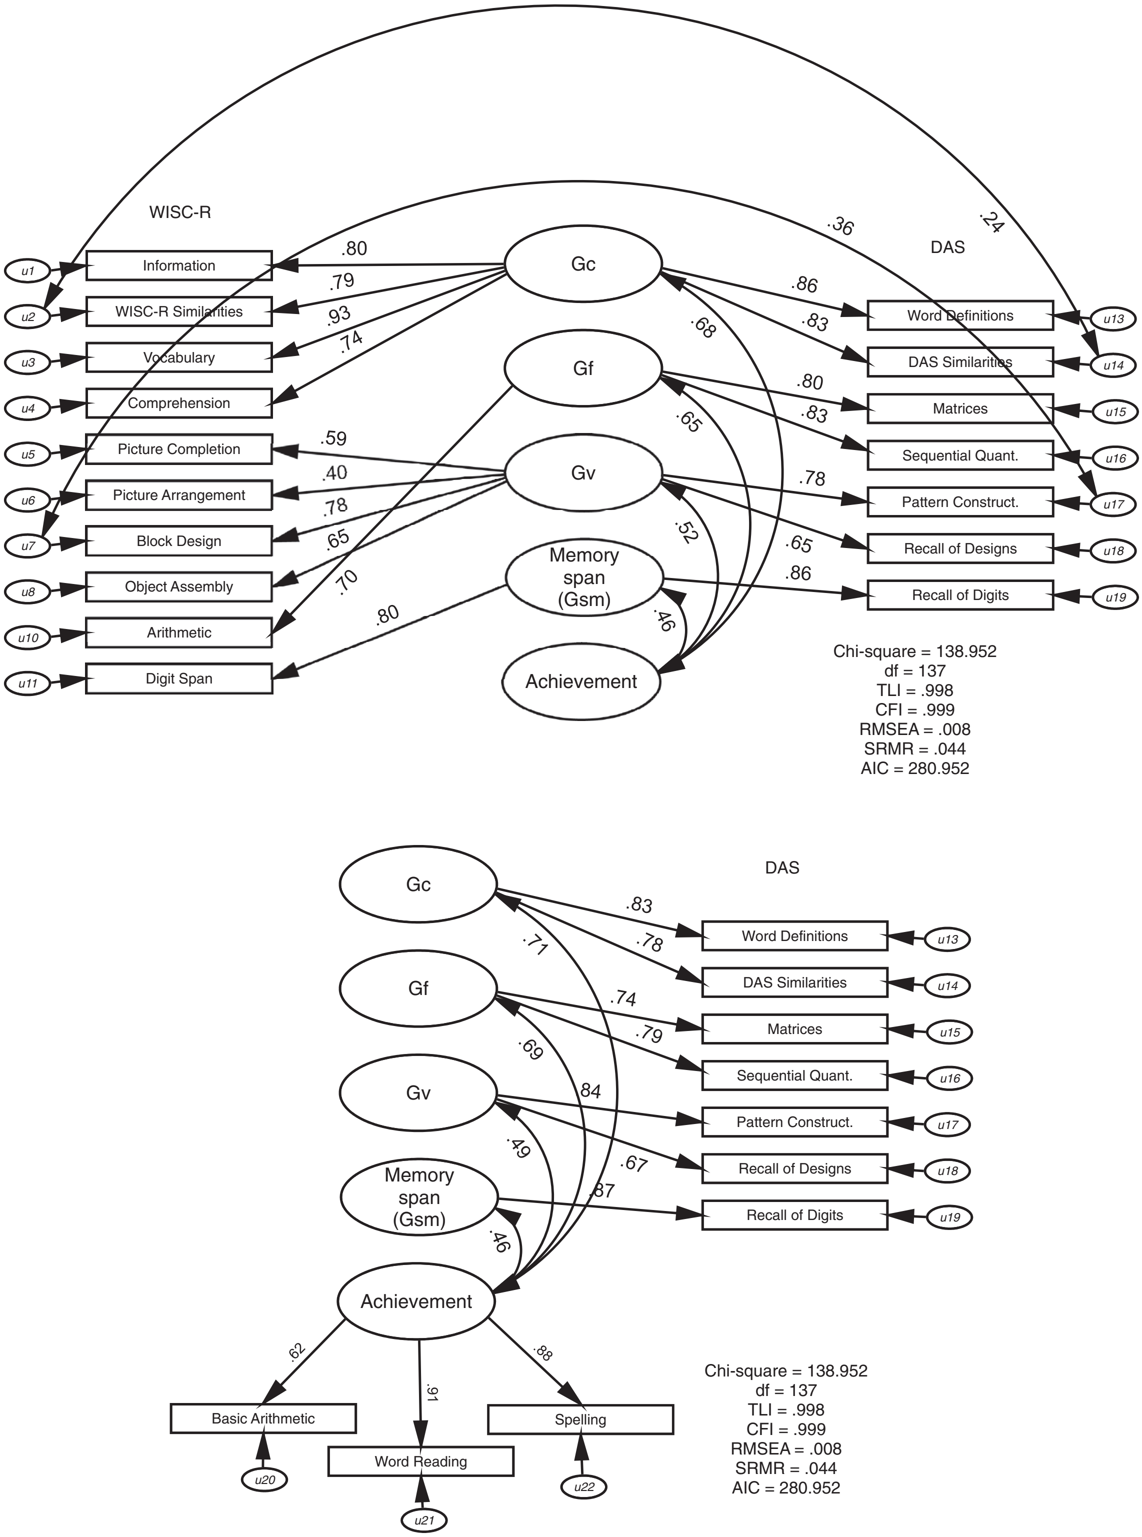

FIGURE 31.26. An alternative model specification for the reference variable approach.

CHC and Three-Stratum Theory

CHC theory is based, in part, on Carroll's three-stratum theory of cognitive abilities. Both theories posit a higher-order model of intelligence with narrow-order abilities at the bottom and the most general ability, *g*, at the apex. The theory is described in detail in Carroll (1993) and in Schneider and McGrew (2012; see also Schneider & McGrew, Chapter 3, this volume).

Carroll speculated that there might well be *intermediate* factors between his second-stratum (e.g., Gf, Gc, Gv) and third-stratum abilities, but left the task of describing this intermediate structure up to other researchers. Bickley, Keith, and Wolfle (1995) addressed the possibility of intermediate factors and tested one such model, and Keith (1997) explored several such possible models, but neither pursued the matter in depth. One difference between three-stratum theory and Gf-Gc theory (the other component of CHC theory) is the nature of quantitative reasoning and quantitative knowledge. Gf-Gc theory has traditionally treated quantitative skills as a separate achievement-related construct, Gq, whereas Carroll focused on quantitative reasoning (RQ) and found it to be a part of fluid or novel reasoning, Gf. To demonstrate CFA's applicability to testing theory, one model with intermediate factors is explored here, and several models exploring the nature of quantitative reasoning are tested.

The WJ III COG is based on CHC theory, and research suggests that it provides valid measures of CHC constructs (McGrew & Woodcock, 2001; Taub & McGrew, 2004), so it is a good tool for testing basic questions about CHC theory. A basic CHC model is shown in Figure 31.27 (cf. Floyd, Keith, Taub, & McGrew, 2007). The data used are from the matrix of correlations and standard deviations for children ages 9–13 from the WJ III standardization data (McGrew & Woodcock, 2001). Not all WJ III COG tests are used; the model includes three good measures of each factor. The sample sizes for tests in this matrix vary, so an overall sample size of 1,000 is used in these analyses (the expectation minimization algorithm was used to deal with incomplete data in the calculation of the matrices).

Figure 31.27 also shows the results of the analysis of this initial model for 9- to 13-year-olds in the WJ III standardization sample. As shown in the figure, the initial model provides a good fit to the WJ III data; the SRMR, RMSEA, TLI, and CFI all suggest an excellent fit to the data. The RMSEA information in the figure is a little different from that presented previously; the figure shows the point value of the RMSEA (.043) surrounded by the 90% confidence interval of the RMSEA (.039–.047).

The model shown in Figure 31.28 presents one possible set of intermediate factors between the second and third strata from CHC/three-stratum theory (in the model, these intermediate factors are second-order factors, and *g* is a third-order factor). Woodcock (1993) proposed a *cognitive performance model (CPM)* of abilities as a method of explaining how abilities work in concert to affect a person's overall functioning, and this model was refined and to some degree built into the scoring of the WJ III and the WJ IV. The CPM includes three intermediate factors between the broad abilities (Gf, Gc, etc) and *g*: *verbal ability, thinking ability,* and *cognitive efficiency.* Two of these intermediate factors are included in the model (as "Think" and "Effic"); verbal ability and Gc are the same, so there is no need to build a verbal ability intermediate factor into the model (an intermediate factor could be built into the model, but the fit would be the same as that for the more simple model shown).

As shown in the figure and in Table 31.8, this categorization of second-stratum abilities into thinking abilities and cognitive efficiency leads to an improvement in the fit of the model. In particular, the intermediate CPM factors produce a statistically significant decrease in χ^2, thus suggesting the division of some of the second-stratum abilities into thinking and cognitive efficiency as a worthwhile addition to the three-stratum theory.

One interesting aspect of this model is the essential equivalence of *g* and thinking ability. (The path from *g* to thinking ability is actually 1.02, but is not statistically significantly different from 1.) We have already discussed how such an equivalence is a common occurrence with *g* and Gf. A common fix would be to constrain the disturbance of the thinking ability factor to 0, which would fix the standardized loading to 1.0. Another, equivalent method for dealing with the issue would be to recognize that this means that one of the factors—*g* or thinking ability—is redundant. Shown in Figure 31.29 is a model in which the *g* and thinking ability factors are combined; this model is equivalent to one in which the thinking ability disturbance is set to zero. We have labeled the highest-order factor "Think" in the figure, but "g"

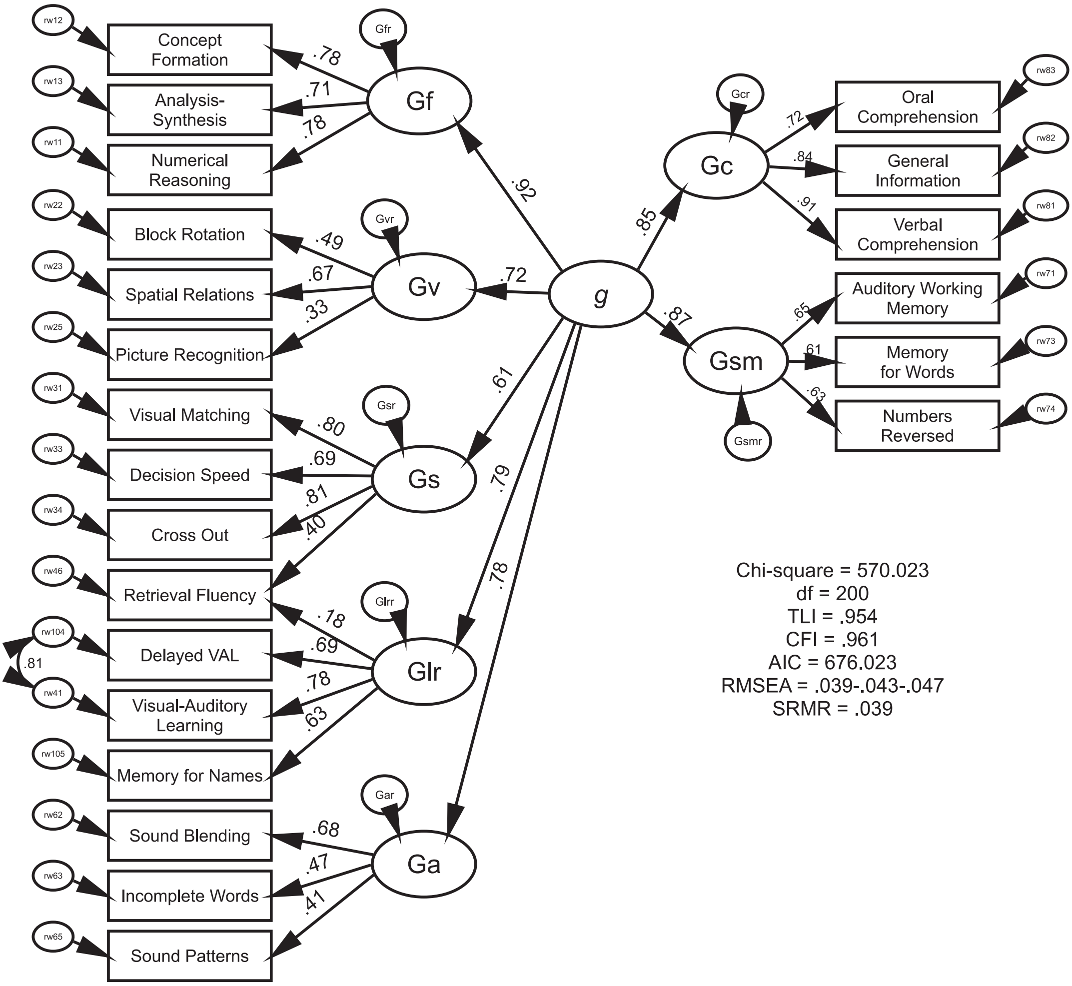

FIGURE 31.27. A three-stratum-theory-derived model of the WJ III COG. The model fits the data well.

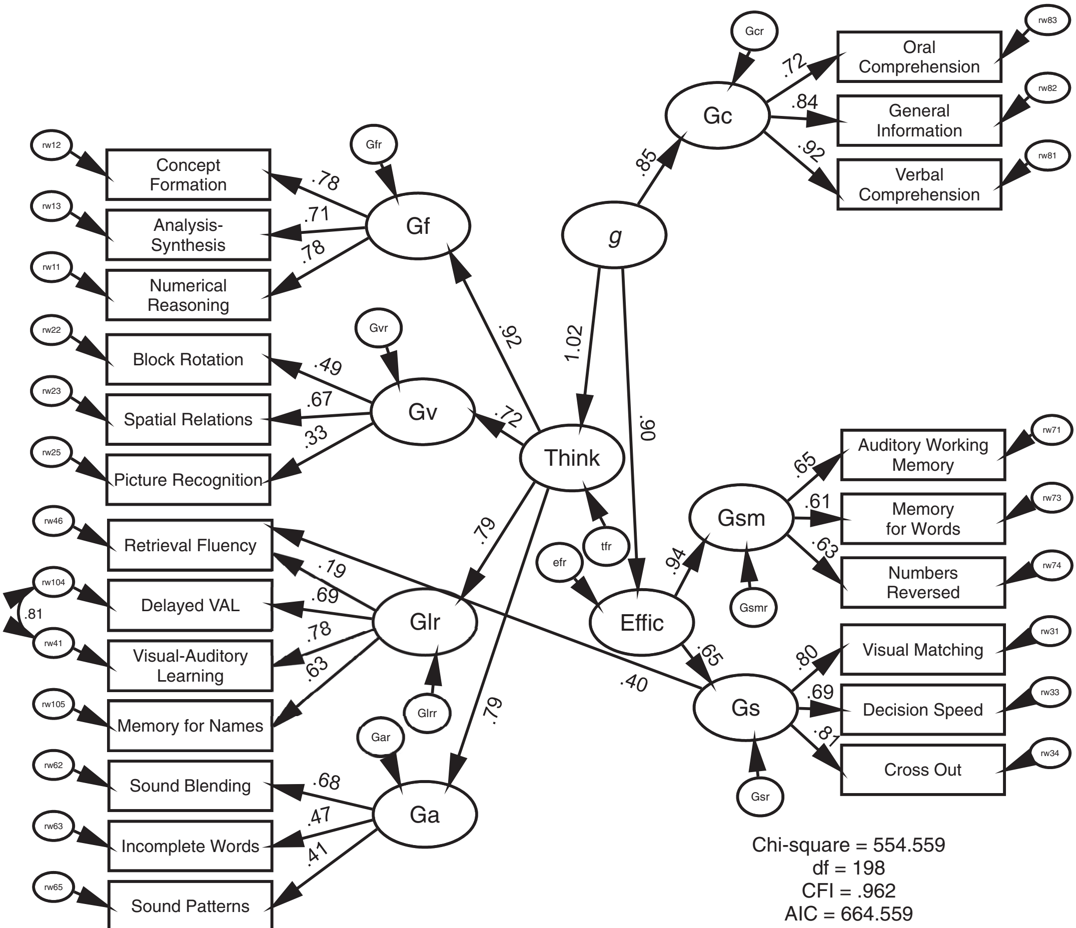
would be an equally valid label. As shown in Table 31.8, this model does not result in a statistically significant increase in χ^2, and thus is preferable as a more parsimonious version of the CPM. This modified model supports the combination of the Gs and Gsm factors into a hierarchical cognitive efficiency factor, but suggests that *g* and thinking ability are statistically indistinguishable.

One final variation of this model is mentioned briefly. One could argue that the path from cognitive efficiency to *g* should be reversed, so that efficiency affects *g* rather than the reverse. This modification could be based on the assumption that processing speed and short-term memory (and cognitive efficiency) are fundamental mental skills that influence one's level of general intelligence—essentially, gatekeepers of general cognitive ability (cf. Schneider & McGrew, 2012). Unfortunately, without further modification, this model is statistically equivalent to the modified CPM, and the two cannot be distinguished on the basis of fit statistics. The rules for generating equivalent and nonequivalent models (e.g., Keith, 2015, Ch. 13) could be used to develop some nonequivalent versions of these two alternative models, thus allowing a test of whether *g* should be considered an influence on cognitive efficiency, or an effect.

The final two models (Figures 31.30 and Figure 31.31) in this chapter test Carroll's contention that quantitative reasoning (RQ) is a part of Gf



Chi-square = 554.559
df = 198
CFI = .962
AIC = 664.559
RMSEA = .038-.042-.047
SRMR = .038

FIGURE 31.28. A test of possible intermediate factors between Carroll's stratum II and stratum III abilities. The model is based on Woodcock's cognitive performance model (CPM).

TABLE 31.8. Comparison of the Fit of Models Testing Different Intermediate-Level Factors in the Three-Stratum Theory, and the Relation of Gf and RQ

Model description	χ^2	*df*	$\Delta\chi^2$ (*df*)	Δ*df*	*p*	AIC
1. Initial model: No intermediate factors	570.023	200				676.023
2. Cognitive performance model (CPM)	554.559	198	15.464 (2)[a]	2	<.001	664.559
3. CPM 2	556.827	199	2.268 (1)[a]	1	.132	664.827
4. Initial Gf-RQ model: Separate factors	1914.426	198				2068.426
5. Gf subsumes Gf (narrow) and RQ	1873.621	197				2029.621

[a] Compared to the previous model.

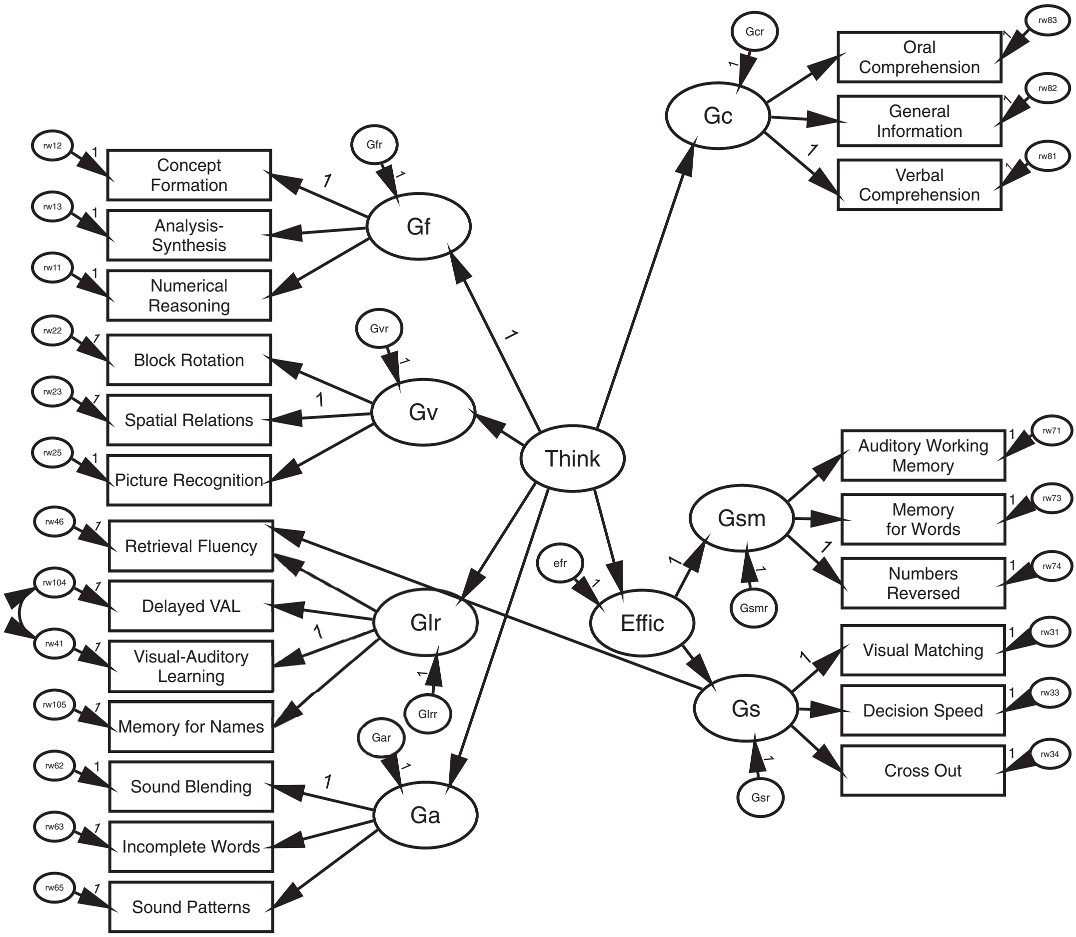


FIGURE 31.29. A simplified version of the CPM in Figure 31.28.

rather than a separate second-stratum factor. The models do not address the existence or nature of a Gq (quantitative knowledge) factor. These analyses have been conducted on over 5,000 participants from the WJ III standardization sample. The advantage of these data is that they include two clear measures of quantitative reasoning: number series and number matrices (these two tests were combined into a Numerical Reasoning test when the WJ III was first released). The sample is described in more detail by Keith and colleagues (2008).

The initial quantitative reasoning model, set up with separate Gf and RQ factors (in the upper part of the figure), is shown in Figure 31.30; the fit statistics for comparing models are shown in the figure and in the lower part of Table 31.8. As shown in the figure, the initial quantitative reasoning model provides a good fit to the data using common criteria. There are missing cases in the data, and Amos does not produce SRMR when there are missing data (some other programs, such as Mplus, do); thus SRMR is not reported.

There are several possible ways to test whether the RQ factor should be subsumed under a broader Gf factor. One common method—the most agnostic approach—would be to specify correlated errors for the disturbances of the Gf and RQ factors. Such a model suggests that these two factors measure something in common besides general intelligence. Figure 31.31 shows a model in which the narrow Gf (symbolized as “Gf narrow”) and

RQ factors are subsumed under a broader Gf factor. This model is in fact statistically equivalent to the correlated disturbance model, but better symbolizes the hypothesis of interest. A third method would be to delete the path from *g* to RQ and include one from Gf to RQ (this model is neither shown nor tested here). As shown in Table 31.8, the loading of the original Gf and RQ factors onto a broader Gf factor results in a considerable improvement in model fit over the initial quantitative reasoning model. Said differently, the broad Gf factor may be considered an intermediate factor between the narrow Gf and RQ factors and *g*. This preliminary investigation supports the contention that quantitative reasoning is a part of fluid/novel reasoning (Gf).

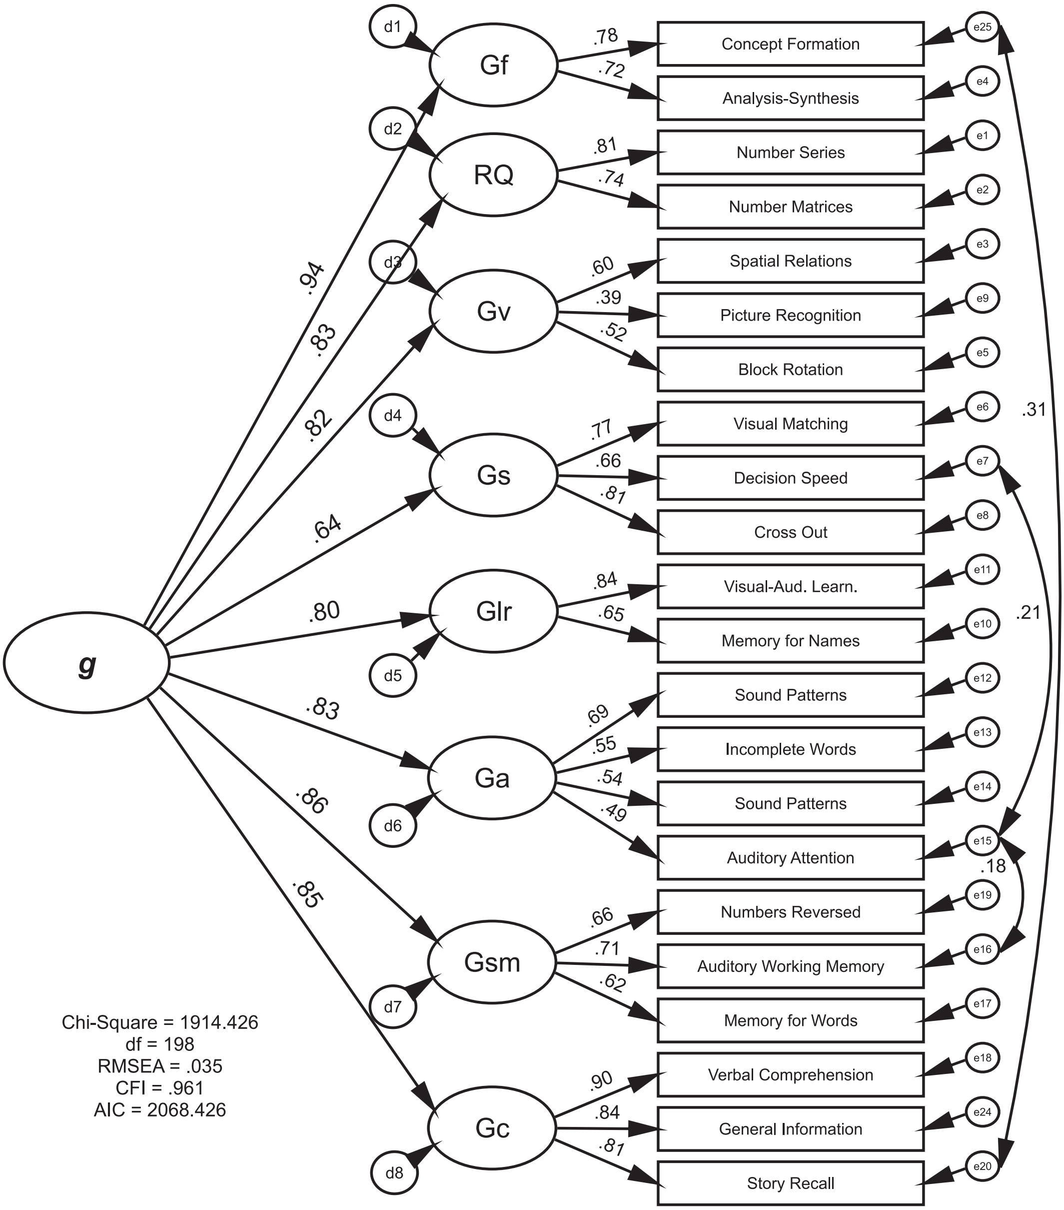

FIGURE 31.30. A model designed to probe the nature of the relation between Gf and RQ.

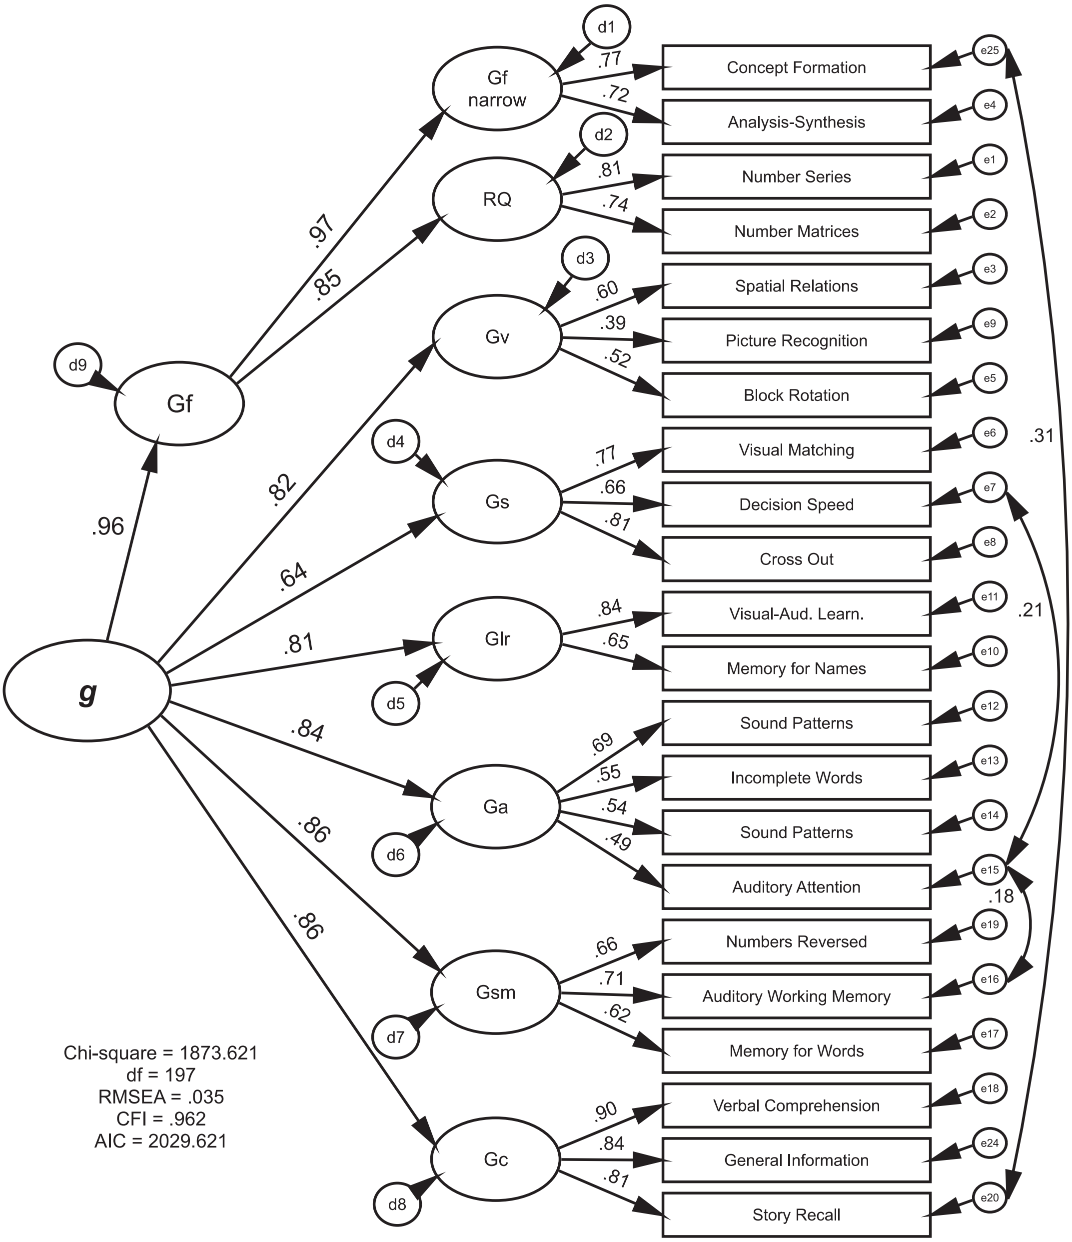

FIGURE 31.31. In this model, Gf subsumes RQ and a narrow Gf factor. The model shows an improvement in fit over the previous model.

SUMMARY

This chapter has provided an overview of and introduction to the method of CFA, with particular attention to the use of the method as an aid in understanding the constructs measured by modern tests of intelligence. The chapter has covered “simple” CFA—in other words, first-order CFA, a method that is fairly common in the factor-analytic/intelligence literature.

We believe, however, that additional uses of CFA are needed for a real understanding of intelligence constructs. Thus we encourage the comparison of *meaningful* alternative explanations to a researcher's pet theory through the testing and comparison of alternative factor models. This practice, too, is becoming more common, although alternative models are not always meaningful. We also encourage the use of carefully ordered nested models to test specific hypotheses concerning intelligence, intelligence constructs, and intelligence tests.

Many modern theories of intelligence are hierarchical in nature, with the most prominent example being the three-stratum theory, a "metatheory" developed and tested by John Carroll (and incorporated into CHC theory). Most tests of intelligence tacitly recognize a hierarchical nature of intelligence as well (Keith & Reynolds, 2010). We strongly believe that our research should therefore test these hierarchical notions of intelligence if we are to fully understand the constructs we are measuring. Put another way, a test of a first-order version of a hierarchical theory/test is not a complete test of that theory. Furthermore, higher-order hierarchical analysis provides a more thorough understanding of the first-order abilities (Carroll, 1993, Ch. 3). This chapter has demonstrated several variations of hierarchical CFA, using second- and even third-order factors.

We also encourage researchers to think about intelligence by using different types of models, even if they cannot be distinguished on the basis of fit. For example, in all of the models presented here, we have conceptualized *g* as affecting broad abilities or subtests. It may be that *g* does not give rise to the correlations among subtests or factors, but alternatively, it simply may arise from those correlations (Kovacs & Conway, 2016). If that is the case, the arrows should flow into *g* and not from *g*, and the nature of that variable would be likely to take on a whole different meaning.

This chapter has demonstrated several other important uses of CFA: to compare the constructs measured across different tests, and to compare the constructs measured by one test across different groups. Many of the most vexing problems in the intelligence field revolve around these issues, and CFA is an excellent method for answering these important questions. Cross-battery CFA can be a powerful method for answering questions about the nature of constructs measured by specific tests, and for understanding the nature of intelligence. Use of a reference variable approach can enable larger and more comprehensive tests of such theories. Multisample CFA provides an organized, effective method for testing for the equivalence of structures across groups, and for testing for construct bias across groups. Finally, CFA provides a powerful method for testing theory, and especially for testing competing theories of intelligence.

We have not covered or tried to cover all possible uses of CFA; those uses are limited primarily by the imagination of the researcher. In addition, CFA is a subset of a more general approach—SEM—and that broader approach is also useful for understanding the nature of the constructs measured by tests of intelligence. To mention only two examples, SEM provides an excellent method for testing the stability over time of intelligence *constructs,* independent of the method of measurement; the dynamic relations among intelligence constructs across time; and the presence of *predictive* bias in intelligence measures (cf. Borsboom, Romeijn, & Wicherts, 2008; Ferrer & McArdle, 2004; McArdle, 1994). Nevertheless, we hope that this chapter has provided enough of an overview to stimulate thought and further study, and to fire the imaginations of future CFA researchers. For those interested in additional study, there are numerous resources available (e.g., Brown, 2015; Keith, 2015; Kline, 2016; Loehlin & Beaujean, 2017; Reynolds & Keith, 2013).

NOTES

1. The factor model tested is one that matches the scoring structure of the KAIT, a good starting point for an informal theory of what a test measures. Other models (e.g., Flanagan & McGrew, 1998) are certainly plausible, but are not evaluated here.

2. Note that one reason the χ^2 is so small is that the sample size used is 143, the average sample size for each age level. If a value 10 times larger were used (1,430), the χ^2 would be almost 10 times larger and statistically significant, thus suggesting a poor fit. Furthermore, although a good fit may be indicated for the *overall* model, it does not mean that there are not some *local* areas of misfit related to specific parameters.

3. Without this constraint, this portion of the model would have been underidentified, meaning that we would not have enough information to solve for all of the parameters in the model. Although these kinds of equality constraints are common ways of dealing with underidentification, researchers should always report when these constraints are made.

4. Readers may want to go over this section several times. It is confusing in part because we first compare different theoretical models (via the figures), but then

change the order of model presentation in the table. The table is ordered as a series of hypotheses that can be tested via nested models by first adding a constraint (model 2), then relaxing two constraints (model 3), then adding three constraints (model 4). It doesn't help that we would come to different answers using ??2 versus the AIC. According to the AIC, model 4 (Figure 31.5) is the best-fitting of these models. This difference is also illustrative, however.

5. In SEM, these are known as *disturbances* and represent all other causes not included in the model. Thus, for the DAS-II example, f1 represents all causes of Verbal ability/Gc other than *g*.

6. The variance of the Gsm factor is nonsignificant for this model, but becomes statistically significant when these three loadings are also constrained to be equal. When UVI is used to scale the factors to check the statistical significance of the constrained loadings, all are statistically significant. If our purpose were an in-depth investigation of the bifactor structure of the DAS-II, we would investigate these anomalies in considerably more depth. For teaching purposes, and for comparison with a higher-order model, the model shown in Figure 31.14 serves well, however.

7. Another difference is that with the higher-order model, the effects of *g* are removed from the first-order factors; with the bifactor model, G is partialed at the subtest level. There are several different ways to obtain the partialed effects with a higher-order model. First, as noted, these can be calculated as the indirect effect of the factor disturbance on the subtest. Another method is to use the squared multiple correlations associated with the first-order factors, easily obtainable from any SEM/CFA program. As noted, one seeming advantage of the bifactor approach is that it produces estimates that look like a Schmid–Leiman transformation. In fact the approach outlined here with the higher-order model is much more similar to the Schmid–Leiman EFA technique.

8. Anyone who has had to explain IQ test scores to parents will probably note that it is much easier to talk about broad-ability scores than it is about the global composite because those tests are grouped together according to explainable, surface characteristics of tests. This is a reflection of the abstractness of *g* versus the broad abilities.

9. See Widaman and Reise (1997) for alternative specifications.

10. The DAS standardization sample included approximately 1,600 children, but the sample size has been set to 115 in the multisample analyses so as not to overwhelm the findings for the other group. The matrix reported in Stone did not include standard deviations, which are needed to test for later levels of invariance. For purposes of illustration, we have set these to the average *SD* for each test (10 for the DAS and 3 for the WISC-R). Information presented in the DAS manual (the source for these data) suggests that these values are likely to be reasonable.

11. The variance steps may be plausible, in part, because we have guessed at values for the subtest variances in the DAS/WISC-R sample. If our purpose were to rigorously test hypotheses instead of illustrate the method, this would be an important limitation. In this example, we are interested in the covariance structure and not the mean structure; thus we have not tested for intercept invariance or the equality of latent means. If questions of latent means were important, it would also be important to include these steps in the invariance testing.

CHAPTER 32

Functional Cattell–Horn–Carroll Nomenclature for Practical Applications

Richard W. Woodcock
Denise E. Maricle
Daniel C. Miller
Ryan J. McGill

The purpose of this chapter is to review the evolution of Cattell–Horn–Carroll (CHC) theory, in an effort to examine the state of the state of the art in this dominant theory defining the structure of cognitive abilities. The nomenclature associated with CHC theory has become more complex as scholars have elaborated upon the theory, introducing their additions and revisions to the taxonomy. With the publication of the Woodcock–Johnson IV (WJ IV), the preeminent instrument operationalizing CHC theory, change was seen in the conceptualization of CHC theory. In particular, the shift seemed to be toward a more "scientific" and less "functional" or clinician/consumer-friendly CHC nomenclature. This scientific taxonomy is exemplified by what is known as the *CHC periodic table of human abilities* (McGrew, LaForte, & Schrank, 2014; Schneider & McGrew, 2012). The application of CHC theory to measures of cognitive abilities, and the wide acceptance of the theory in research and clinical practice, have given rise to a specialized vocabulary (i.e., nomenclature or taxonomy) that can be difficult for consumers of the information, such as parents, clients, or educators, to understand. Scientific taxonomies are needed to provide precision and to guide scientific development, but more functional or user-friendly nomenclature would benefit consumers. Given recent changes in CHC theory, it seems appropriate to summarize the history of the theory, as well as to discuss current proposals for the continued evolution of the theory being presented by various factions within CHC. The chapter concludes with a description and discussion of a more functional and clinician/consumer-friendly CHC nomenclature.

HISTORICAL PRECEDENTS TO CHC THEORY

Spearman's Two-Factor Theory

Inspired by the statistical developments of his cousin Karl Pearson, British statistician Charles Spearman proposed the first unified theory of cognitive abilities with the 1904 publication of his paper "'General Intelligence,' Objectively Determined and Measured." Although Spearman did not label his theory, it is generally referred to in the contemporary literature as *g* theory. Spearman (1904) administered a battery of assessments to a sample of 60 school-age children in a small village in England. The tests measured subjects such as the classics, French, English, math, vocal pitch, and sound discrimination. He determined that all of the measures tended to correlate—a phenomenon later referred to as *positive manifold* (Thurstone, 1947). Spearman arranged all of the coefficients between the tests into a matrix that he then analyzed, using a primitive form of factor analysis called the method of *tetrad differences*. In his analysis, he found that 62.9% of the total variance between all of the tests was accounted for by a single factor, which he identified as a general factor or *g*. The remaining 37.1% of variance was attributed to specific factors unique to the individual tests themselves, which Spearman labeled *s*.

Spearman postulated that all tests of cognitive ability are composed of some form of *g* variance—an observation he referred to as the "indifference of the indicator" (Spearman, 1927, p. 197). However, he appeared to remain ambivalent about the exact nature of *s*, whose influence he stated was largely negated by the combination of individual test scores into larger composites.

Despite criticism, he resisted the notion of including additional common factors in his model because he felt it would open the door for the inclusion of an infinite number of hypothesized subordinate factors. By the end of his career, however, he acknowledged that cognitive ability may be better represented by a second-order *g* factor, with an underdetermined number of first-order common factors representing more discrete cognitive skills (Spearman & Jones, 1959).

The Rise of Multiple-Factor Theories

One of Spearman's critics was Edward L. Thorndike, a psychologist at Columbia University. Thorndike developed and facilitated the administration of a test to 63 primary and secondary school students that purported to measure several psychoeducational abilities, such as sensory discrimination, quantitative reasoning, and vocabulary development. After reviewing correlational data, he and his colleagues concluded that "there is nothing whatsoever common to all mental functions, or even half of them" (Thorndike, Lay, & Dean, 1909, p. 368). Thorndike rejected the notion of a general intelligence factor in favor of a model that emphasized multiple faculties of the mind.

Although Spearman spent the latter part of his career defending his theory from researchers like Thorndike, advances in research methodology and statistical techniques allowed for the discovery of group abilities in cognitive assessment data. Spearman eventually acknowledged these findings when specific cognitive tasks were found to load on group factors subordinate to *g*. These discoveries helped pave the way for the development of more empirically derived theories of mental ability.

L. L. Thurstone (1938) developed a model of mental ability derived from a statistical technique that allowed factors to be extracted from an extant dataset—a method known as *factor analysis*. Using data from a battery of 56 mental tests administered to 240 college students, he extracted seven factors that he described as visual–spatial, perception of visual detail, numerical, verbal logic, verbal words, memory, and induction. Thurstone called these factors *primary mental abilities*, and this term soon became associated with his model of intelligence. Thurstone eventually reconfigured his model to account for eight primary abilities. The influence of Thurstone's work on the modern-day understanding of the structure of human cognitive abilities cannot be underestimated, as many of the group factors that he identified served as the foundation for subsequent models of intelligence.

Thurstone's initial reluctance to acknowledge a general factor may have been an artifact of the methods he utilized to identify his group factors. Thurstone used rotation techniques in his factor analyses that left various broad abilities orthogonal (not correlated) to each other. With this method, it was almost impossible for a general factor to be derived because little common variance in the factors could be extracted. Although Thurstone later accepted the existence of a general factor, and subsequent research using oblique rotations indicated that his broad abilities were correlated (Jensen, 1998), he stated that the use of a single score to estimate overall mental ability was inadequate for clinical decision making; he encouraged the synthesis of an individual's profile of scores across several measures of cognitive functioning to determine individual cognitive strengths and weaknesses.

The Emergence of Gf-Gc Theory and the Fluid–Crystallized Model of Intelligence

A dichotomous model of intellectual ability, the *fluid–crystallized model* or Gf-Gc theory, was proposed by Raymond Cattell in the early 1940s. In a commentary discussing issues unresolved in the measurement of adult intelligence, Cattell (1943) postulated that cognitive ability was best represented by two general factors that he identified as fluid intelligence (Gf) and crystallized intelligence

(Gc). Cattell described fluid intelligence as a general facility in reasoning, wherein prior knowledge cannot be used to solve problems, and crystallized intelligence as the storage, retrieval, and use of prior knowledge. Two decades later, Cattell (1963) conducted the first experimental analysis of the theory by administering a series of nine cognitive tasks to a sample of 277 school-age individuals and then subjecting the results to a factor analysis. His results indicated that each of the tasks primarily loaded on one of the two factors.

Cattell chose not to include a general factor in his model, despite the fact that he acknowledged that Gf and Gc were highly correlated and that a third-order factor solution was tenable. Rather, Cattell posited that *g* operated largely through Gf, and he proposed *investment theory* as a vehicle for describing the interaction between Gf and Gc. According to Cattell (1987), fluid ability serves as a limiting factor in how much information individuals can acquire from the environment. Therefore, learning is a function of the interaction between inherited levels of fluid ability and interpersonal metacognitive factors (motivation, drive, personality) that regulate how much that fluid ability is invested by the individual within the environment. The product of that investment is later expressed in the form of developed crystallized ability. Cattell proposed that this interaction helped explain why Gf and Gc were so highly correlated.

The first replication of Gf-Gc theory was conducted by John Horn in his doctoral dissertation supervised by Cattell at the University of Illinois. Horn (1965) administered 31 cognitive and personality tasks to a sample of 297 adults. He extracted several second-order factors from the data, which he identified as fluid intelligence (Gf), crystallized intelligence (Gc), general visualization (Gv), general speediness (Gs), facility (a forerunner of long-term storage and retrieval), carefulness (general cognitive accuracy), premsia (PRM, literacy and artistic ability), and positive self-image (PSI). Horn then extracted two general factors that he did not identify further. The first general factor was composed of Gf, Gv, Gs, and facility. The second general factor was composed of Gc, Gf, and PSI. From their first joint publication (Horn & Cattell, 1966) through the late 1990s, Horn and Cattell collaborated in a systematic program of research aimed at validating and adding additional second-order factors to the Gf-Gc model. Specifically, Horn (1986) laid out an expansion of Gf-Gc theory designating eight broad abilities that were later modified and used to guide the organization of the WJ-R Tests of Cognitive Ability (Woodcock & Johnson, 1989). By the early 1990s, the Gf-Gc model had expanded to include nine broad second-order abilities: fluid intelligence (Gf), crystallized intelligence (Gc), short-term acquisition (Gsm), visual intelligence (Gv), auditory intelligence (Ga), long-term storage and retrieval (Glr), cognitive processing speed (Gs), correct decision speed (CDS), and quantitative knowledge (Gq). At about this time, Woodcock (1990) proposed the additional inclusion of a reading and writing ability factor (Grw).

One of the more consequential discoveries from this Gf-Gc research program has been the demonstration of differential declines in various broad abilities over the course of the human lifespan. In general, it has been demonstrated that Gc tends to increase throughout adulthood, with small declines emerging at around age 70 (Ackerman, 1996). Conversely, Gf skills have been shown to peak in early adulthood (i.e., ages 25–30) and then to decline throughout the rest of the lifespan (Verhaeghen & Salthouse, 1997). Using regression growth models, Noll and Horn (1998) estimated that the loss of Gf ability in adulthood was equivalent to 0.5 to 1.0 IQ units per decade. McGrew and Woodcock (2001) later argued that in spite of strong Gf-Gc correlations, such developmental validity evidence demonstrated that Gf and Gc were in fact orthogonal, unrelated abilities.

The Emergence of Hierarchical Models of Intelligence and Carroll's Three-Stratum Model

Philip Vernon (1950) is credited with articulating the first hierarchical model of cognitive abilities. He posited that a higher-order *g* factor presides over two lower-order factors, which he identified as verbal ability and spatial ability. In his model, the lower-order factors were composed of dozens of narrow abilities, such as psychomotor coordination, attention, fluency, reasoning, and reaction time. Vernon stated that his model was most likely underidentified and went on to hypothesize additional group factors beyond verbal reasoning and spatial thinking, which constituted a more complete model of cognitive ability. Vernon's model was an important reconciliation of Spearman's two-factor model and Thurstone's primary abilities. Additionally, Vernon's model provided empirical support for the verbal–nonverbal dichotomy of cognitive abilities, which was popular as a result of the publication of the Wechsler scales of intelligence (Wechsler, 1949).

A more direct hierarchical test of the nature of cognitive abilities was completed by Gustafsson (1984), who administered a battery of 16 tests to 1,000 sixth-grade students, and then utilized factor analysis to test the fit of several competing models. He reported that the model that best fit the data was a third-order *g* factor that reigned over the three group ability factors. Gustafsson found that the fluid reasoning factor was nearly identical to the third-order general ability factor; this finding has perpetuated the theory that fluid reasoning is largely a proxy for *g*.

A major breakthrough in applied psychometrics occurred with the publication of John Carroll's (1993) *Human Cognitive Abilities: A Survey of Factor-Analytic Studies*. Carroll assembled a collection of over 400 datasets of factor-analytic studies of cognitive abilities; reanalyzed them by utilizing varimax rotations of the principal factor matrices; and followed up with the Schmid–Lieman procedure (Schmid & Lieman, 1957), which further orthogonalized the factors for a more parsimonious interpretation of the resulting factor structure. Carroll concluded that a three-tier model best fit the data. This model later became known as the three-stratum model. In Carroll's model, *g* or general ability was placed at the apex of the model and was labeled stratum III. The next level, or stratum II, included such broad abilities as fluid intelligence (Gf), crystallized intelligence (Gc), general memory and learning (Glm), broad visual perception (Gv), broad auditory perception (Ga), broad retrieval ability (Gr), broad cognitive speediness (Gs), and reaction time/decision speed (Gt). Over 70 narrow cognitive abilities, organized according to their loadings on the broad factors, made up stratum I.

Carroll's three-stratum model was widely embraced by the scientific community and represented a major paradigm shift in the study of cognitive abilities. The most significant contribution of the model was that it provided the field with a standardized taxonomy to categorize and describe individual cognitive tasks. Many commentators consider Carroll's work the greatest accomplishment in all of applied psychology. Burns (1994, p. 35) stated, for example, "It is simply the finest work of research and scholarship I have read and is destined to be the classic study and reference work of human abilities for decades to come." In the 25 years since its publication, Carroll's work has yet to be seriously challenged.

THE ASCENDANCY OF CHC THEORY

The Birth of CHC Theory

In the late 1990s, Kevin McGrew negotiated the merger of Carroll's three-stratum theory with Cattell and Horn's Gf-Gc theory; he was thus instrumental in the ascendancy of the consolidated CHC model in the field of cognitive assessment. Although the two models were merged, there was not necessarily complete agreement between their creators. Horn refused to accept the validity evidence provided by Carroll for a general ability factor. Horn and Noll (1997) warned that "the problem for the theory of general intelligences is that the factors are not the same from one study to another. . . . The factors represent different mixture of measures, not one general intelligence" (p. 68). Horn (1986) very clearly argued against a single or unitary factor of intelligence, despite widespread opinion to the contrary. He thought that the evidence conclusively indicated several distinct intellectual abilities, each with differing genetic and environmental determinants, different developmental trajectories or courses of development, and different implications for understanding human cognition and achievement. There were also differences between the originators of the two models regarding the number of broad factors, as well as which broad factors were relevant. For instance, Carroll (2003) concluded that there were data to support 10 broad factors, but argued that Gq (quantitative reasoning) was a narrow ability subsumed under Gf and not a stratum II broad factor. He considered quantitative ability to be "an inexact, unanalyzed popular concept that has no scientific meaning unless it is referred to the structure of the abilities that compose it" (Carroll, 1993, p. 627).

Despite these differences, the two theories were consolidated into one theory with three strata: an optional broad general ability or *g* factor; nine broad-ability factors (crystallized knowledge or Gc, fluid reasoning or Gf, visual–spatial processing or Gv, auditory processing or Ga, short-term memory or Gsm, long-term storage and retrieval or Glr, processing speed or Gs, quantitative knowledge and reasoning or Gq, and reading–writing or Grw); and approximately 89 narrow abilities. In the past several years, Kevin McGrew has become the de facto standard bearer of research with CHC theory, and his classifications of CHC abilities (e.g., McGrew, 2005) have become the standard framework for discussing CHC theory in the empirical literature, although only seven broad CHC abilities constitute the predominant focus of much of the empirical research on human cognitive abilities. While recent work has demonstrated that some of the broad abilities are much more complex than previously thought (McGrew & Evans, 2004), the initial goal of CHC research was to refine the model into a more accurate and parsimonious summary of human cognitive abilities (McGrew, 2009; Wasserman, 2012).

In the years following the consolidation of the Carroll and Cattell–Horn models, CHC theory has had a visible impact on the development of new and revised individually administered intelligence tests (Keith & Reynolds, 2010). It has become the dominant interpretive framework for measures of intellectual functioning, and, according to Schneider and McGrew (2012, p. 109), "CHC theory has attained the status as the consensus psychometric model of the structure of human cognitive abilities." Despite the widespread representation of CHC within the cognitive testing landscape, the Woodcock–Johnson series has been the only test battery founded exclusively on CHC theory, and the only contemporary test to assess all of the nine broad-ability factors. Other tests, such as the Stanford–Binet Intelligence Scales, Fifth Edition (Roid, 2003); the Kaufman Assessment Battery for Children—Second Edition (Kaufman & Kaufman, 2004); the Differential Ability Scales—Second Edition (Elliott, 2007); and the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014), only provide representations of a few broad factors. The broad abilities of fluid reasoning (Gf), crystallized knowledge (Gc), visual–spatial processing (Gv), and short-term memory (Gsm) are widely represented. However, auditory processing (Ga) and long-term storage and retrieval (Glr) are underrepresented within most existing cognitive measures (Flanagan, Ortiz, & Alfonso, 2013).

Beyond CHC

In 2012, Schneider and McGrew proposed changes to CHC theory, which McGrew labeled as going "beyond CHC." McGrew and Schneider posited 16 cognitive domains grouped into five functional areas. The first functional area, cognitive knowledge, is composed of Gc, Grw, Gq, and Gkn. Cognitive operations is the second functional area and is made up of Gf, Glr, Gv, and Ga. The third functional area is cognitive efficiency and control, consisting of Gsm and Gs. The fourth functional area is sensory functions and consists of visual, auditory, and tactile (Gh), kinesthetic (Gk), and olfactory (Go) sensations. The final area is motor functions, consisting of strength, finger dexterity, and manual dexterity (Gp and Gps). Similar to all of the reconceptualizations discussed in this chapter, McGrew and Schneider's reconceptualization of CHC is theoretical; there is no research that currently would support the hypothesized changes, although the authors refer to a synthesis of the research literature in the past 10–15 years as supportive of their proposed changes.

Schneider and McGrew (2012) further reconceptualized the CHC broad and narrow abilities into five expanded domains, labeled motor (Gp), perception (Gv, Gk, Ga, Gh, Go), controlled attention (Gf, Gsm), knowledge (Gc, Gq, and Grw with a greater Gkn), and speed (Gps, Gt, Gs, and Glr). Subsequently, McGrew (2016) has suggested that the broad-ability domain of Glr may have been conceptualized incorrectly in the CHC literature since 1997. McGrew posits that Glr should be separated into two broad abilities: Gl (learning efficiency) and Gr (retrieval fluency). Learning efficiency is defined as "the ability to learn, store, and consolidate new information in long-term memory" (McGrew, 2016). Retrieval fluency is defined as the rate and facility with which individuals can generate and regain verbal and nonverbal information or ideas stored in long-term memory (McGrew, 2016). McGrew often refers to his current overview of CHC abilities as CHC model v2.3. Additionally, it has been suggested (e.g., Schneider & McGrew, 2012) that a joint neuropsychological and CHC perspective might be the new frontier for understanding cognitive constructs and assessment of cognitive performance and abilities. For the latest revisions and refinements to CHC theory, see Schneider and McGrew (Chapter 3, this volume).

A joint neuropsychological and CHC perspective has been conceptualized by Miller (2013) and articulated in his integrated school neuropsychology/CHC conceptual model. Miller's model is distinctive, as it uses neuropsychological, neuroanatomical, and neuroassessment research to theorize the model's components. In Miller's conceptual model, tasks are classified according to four broad classifications (basic sensorimotor functions; facilitators and inhibitors; basic cognitive processes; and acquired knowledge), and are then further segmented into second- and third-order classifications that denote the broad and narrow CHC constructs being assessed by various tasks. Miller (2015) and Miller, McGill, and Bauman Johnson (2016) have delineated the neuropsychological applications of the WJ IV, WISC-V, WISC-V Integrated, and Wechsler Individual Achievement Test—Third Edition specifically, as well as in relation to Miller's conceptual model. Further supporting a joint neuropsychological/CHC perspective is work by Flanagan, Alfonso, Ortiz, and Dynda (2010) and Flanagan and colleagues (2013), who present an integrated interpretive framework based on psychometric, neuropsychological, and Lurian perspectives, and provide a neurocognitive demand task analysis of the major test batteries using this framework. Flanagan and colleagues (2010, 2013) posit that specific neuropsychological domains correspond well with eight broad CHC abilities—fluid reasoning (Gf), comprehension–knowledge (Gc), processing speed (Gs), short-term memory (Gsm), long-term storage and retrieval (Glr), quantitative knowledge (Gq), reading and writing ability (Grw), and general knowledge ability (Gkn)—and fit well within a cross-battery conceptual framework.

The WJ IV, published in 2014 (Schrank, McGrew, & Mather, 2014) as a substantial revision of the WJ III, further confuses the issue of the structure of the CHC model. The WJ IV consists of three complementary batteries: the Tests of Cognitive Abilities, the Tests of Achievement, and the Tests of Oral Language. According to the authors of the WJ IV, the nine original CHC factors (Gf, Gc, Gv, Ga, Gsm, Gs, Glr, Gq, and Grw) are still measured, although there are slight reconceptualizations of some factors (such as Gsm, which has been renamed Gwm). However, the factor structure of the WJ IV based on reported factor analyses in the technical manual (McGrew et al., 2014) has recently been questioned (Dombrowski, McGill, & Canivez, 2017). The technical manual reported the results of exploratory cluster, factor, and confirmatory factor analyses. These analyses were conducted "during the early stages of WJ IV data collection" with subsections of the normative group and on the completed normative sample of 7,416 individuals (McGrew et al., 2014, pp. 149–150). The authors chose a model-generating approach to their analysis of the data, and they note that it was a major component in the multistage structural validity procedures utilized. Three different exploratory methods—cluster analysis, exploratory principal-components analysis, and multidimensional scaling analysis—were applied.

Dombrowski and colleagues (2017) have criticized the exploratory and confirmatory analyses described in the technical manual, noting that significant amounts of the data were imputed; that some analyses were extrapolated; and that the methods chosen for the analyses were not appropriate, incomplete, or less sophisticated. McGrew and colleagues (2014) note that the obtained structural models varied by methodology. In general, two consistent factor structures emerged. The first factor structure consisted of five factors (Gc, Gs, Grw, Gq-Gf, and Gwm). The second consisted of three factors that they labeled auditory–linguistic (Ga, Gc, and select Gwm tasks), visual–figural (Gv, Gf, Glr), and quantitative–numeric (Gq and select Gwm tasks). Confirmatory factor analyses were also conducted, and two factor structures were found that fit the data. From one of these analyses, the three-stratum hierarchical model emerged, including the general or *g* factor, broad-ability factors, and narrow abilities. From the other, McGrew and colleagues extracted a two-stratum factor structure consisting of the nine broad-ability factors and narrow abilities. Dombrowski and colleagues used the correlation matrices found in the technical manual to conduct several exploratory factor analyses on two age groups (9–13 and 14–19), using the cognitive tests of the WJ IV. Dombrowski and colleagues identified a four-factor solution as having the most parsimonious fit, but from their professional point of view, they suggest that the WJ IV is best viewed primarily as a measure of *g*, as it accounts for the majority of total and common variance. Such disparate and contradictory findings are confusing and create questions as to which latent theoretical structures should be applied interpretively.

A FUNCTIONAL REFINEMENT OF CHC THEORY

We suggest a more practical reconceptualization of CHC theory and functional nomenclature to describe CHC latent cognitive factors. We refer to this model as the *functional CHC model* (*F-CHC*; see Figure 32.1). We recommend grouping the cognitive abilities represented by CHC factors into three broad conceptual domains: acquired knowledge, thinking abilities, and cognitive efficiency. Additionally, a review of the CHC literature and research regarding broad and narrow abilities contributing to CHC factors suggests that each broad ability or CHC factor can be reduced to two primary narrow abilities, without loss of significant information needed for clinical utility.

Functional CHC nomenclature		**Scientific CHC nomenclature**	
Broad abilities	**Narrow abilities**	**Broad abilities**	**Narrow abilities**
Acquired knowledge		Acquired knowledge	
(Gc) Comprehension–knowledge	(Gc-VA) Verbal ability	Gc: Crystallized intelligence	LD: Language development LS: Listening ability VL: Lexical knowledge
	(Gc-K) Factual knowledge		KO: General verbal information
(Grw-R) Broad reading	(Grw-RS) Reading skills	Grw: Reading and writing	RD: Reading decoding
	(Grw-RC) Reading comprehension		RC: Reading comprehension RS: Reading speed
(Grw-W) Broad writing	(Grw-WS) Writing skills		SG: Spelling ability EU: English usage
	(Grw-WC) Writing composition		WA: Writing ability WS: Writing speed
(Gq) Broad mathematics	(Gq-C) Calculation	Gq: Quantitative knowledge	A3: Mathematical achievement
	(Gq-Ap) Applied math		KM: Mathematical knowledge
(Gp) Psychomotor abilities	(Gp) Handwriting		
Thinking abilities		Thinking abilities	
(Gv) Visual–spatial processing	(Gv-PP) Pictorial processing	Gv: Visual processing	CS: Closure speed
	(Gv-SP) Spatial processing		VZ: Visualization SR: Spatial relations SS: Spatial scanning
(Ga) Auditory processing	(Ga-SD) Sound discrimination	Ga: Auditory processing	US: Speech sound discrimination UR: Resistance to auditory stimulus distortion
	(Ga-Ph) Phonetics		U3: Sound discrimination PC: Phonetic coding
(Glm) Learning–memory	(Glm-IR) Immediate recall	Gl: Learning efficiency	MA: Associative memory MM: Meaningful memory M6: Free-recall memory MV: Visual memory
	(Glm-MR) Memory retrieval	Gr: Retrieval fluency	FI: Ideational fluency FA: Associational fluency FE: Expressional fluency SP: Sensitivity to problems/alternative solution fluency FO: Originality/creativity NA: Naming facility FW: Word fluency LA: Speed of lexical access FX: Figural flexibility

	(Gs-TS) Thinking speed		R9: Rate of test taking N: Number facility

FIGURE 32.1. *(continued)*

In the F-CHC nomenclature, the first domain, acquired knowledge, consists of comprehension–knowledge (Gc), reading and writing (Grw), and mathematics (Gq). In the extant CHC perspective, comprehension–knowledge (Gc) is composed of four narrow abilities: language development (LD), listening ability (LS), general verbal information (KO), and lexical knowledge (VL). The F-CHC nomenclature combines LD and LS into an ability called verbal ability (Gc-VA), and KO and VL into an ability called factual knowledge (Gc-K). In the F-CHC nomenclature, the reading and writing ability factor (Grw) is split into two broad abilities, reading (Grw-R) and writing (Grw-W), as these two areas are perceived by most people (including educators) as separate abilities. Reading consists of two abilities, reading skills (Grw-RS) and reading comprehension (Grw-RC); writing consists of writing skills (Grw-WS) and writing composition (Grw-WC). Finally, quantitative knowledge/reasoning (Gq) has been relabeled as mathematics, to better conceptualize the nature of this latent factor. Calculation (Gq-C) and applied math (Gq-AP) are the two primary abilities composing Gq in this reconfiguration.

Within the F-CHC nomenclature, the second domain, thinking abilities, consists of visual–spatial processing (Gv), auditory processing (Ga), learning–memory (Glm), and reasoning (Gr). In current CHC theory, Gv is composed of five narrow abilities: visualization (VZ), closure speed (CS), spatial relations (SR), spatial scanning (SS), and visual memory (VM). Within the F-CHC model of Gv, these five abilities are collapsed into pictorial processing (Gv-PP) and spatial processing (Gv-SP). For auditory processing (Ga), the narrow abilities of speech sound discrimination (US), resistance to auditory stimulus distortion (UR), sound discrimination (U3), and phonetic coding (PC) are reconceptualized as sound discrimination (Ga-SD) and phonetics (Ga-Ph).

Long-term storage and retrieval (Glr) is renamed in F-CHC as learning–memory (Glm), to better reflect the cognitive abilities being measured in this domain. Glr is consistently misinterpreted by clinicians as long-term memory, or long-term retrieval, when in reality it provides measures of learning, memory, and the ability to efficiently and effectively retrieve what has been encoded in memory or learned. In the extant CHC model, Glr has 13 narrow abilities, which are difficult to conceptualize and measure. In the F-CHC reconceptualization of the Glm factor, the two primary abilities are immediate recall (Glm-IR) and memory retrieval (Glm-MR).

Finally, fluid reasoning (Gf) has been renamed as simply reasoning (Gr), to better reflect the skills measured in this domain. The concept of *fluid* is not really meaningful in any context and historically seems to have been used as a synonym for novel problem solving. In the extant CHC nomenclature, Gf has three narrow abilities: quantitative reasoning (RQ, often misinterpreted as Gq), induction (I), and general sequential reasoning (RG). In the F-CHC nomenclature, the two primary narrow abilities for Gf are contextual reasoning (Gr-CR) and inductive/deductive reasoning (Gr-ID). Contextual reasoning essentially replaces quantitative reasoning. The Number Series subtest on the WJ IV COG would be a good example of a subtest ostensibly measuring quantitative reasoning, but in reality providing a comprehensive measure of contextual reasoning and abstract thinking. Sternberg (1990) has long argued that contextual reasoning and abstract thinking abilities are required in many areas of cognitive functioning, including reading or solving scientific equations.

The third domain, cognitive efficiency, includes conscious memory (Gcm), formerly Gsm/Gwm, and cognitive processing speed (Gs). Gsm has been a problematic factor within the CHC framework for many years. Initially called short-term memory (Gsm), it was reconceptualized recently in the WJ IV as short-term working memory (Gwm); however, neither term clearly represents what is being measured within this factor. Gsm incorporates memory span (MS), working memory (WM), working memory capacity (MW), and attention/concentration (AC). Within the F-CHC nomenclature, Gsm is renamed conscious memory (G*cm*) and is composed of memory span (Gcm-MS) and working memory (Gcm-WM). As currently conceptualized in CHC theory, processing speed (Gs) has four narrow abilities: perceptual speed (P), attention/concentration (AC), rate of test taking (R9), and number facility (N). In the F-CHC model, processing speed is renamed cognitive processing speed (Gs), and the primary abilities are perceptual speed (Gs-PS) and thinking speed (Gs-TS).

CONCLUSION

The CHC theory of cognitive functioning is theoretical, but has a solid research base and is supported by over 20 years of additional psychometric research. CHC theory has now been applied in some form or another to several contemporary measures of intellectual functioning. As such, it has been referred to as the consensus psychometric/theoretical model guiding interpretation of cognitive ability measures (see, e.g., Schneider & McGrew, 2012). In order for a good theory or model to stand the test of time, it must evolve as new knowledge is gained, while still retaining its foundation or core. For any revision or refinement of the model to be considered valid, it too must be subjected to rigorous research, with each suggested addition, subtraction, or substitution carefully weighed and considered.

The evolutionary advances proposed by McGrew and others, as well as changes in perspective given to current CHC constructs within measures such as the WJ IV and WISC-V, would suggest a need for practitioner's to re-conceptualize interpretation of CHC latent abilities. A good deal of attention in the WJ IV focuses on cognitive complexity (e.g., constructs that are cognitively complex and difficult to measure; tasks that are cognitively complex and thus measuring more than one latent ability).

CHC theory and its variants have also suffered from "descriptive messiness" of the latent constructs. For example, the construct of short-term memory (Gsm) has always been problematic and not reflective of the breadth and depth of our understanding of memory functions. For the most part, the CHC broad ability of Gsm was referring to short-term memory capacity or short-term working memory capacity, and most tasks measured this latent ability in the auditory domain only. With the advent of the WJ IV, an attempt was made to address the limitations of Gsm—primarily by renaming the factor and calling it Gwm, to better reflect the fact that tasks were measuring short-term working memory capacity. However, there is strong research to suggest that the neurocognitive constructs of short-term memory capacity, short-term working memory capacity, and working memory can be distinguished from each other, as well as, adequately independently measured in both auditory and visual domains. This descriptive messiness has now been extended by McGrew's concern that Glr (long-term storage and retrieval) has probably been misconstrued for the last 20 years, as well as his view that the importance of Ga (auditory processing) has been underrepresented.

For the average clinician attempting to apply the CHC framework to assessment and interpretation, the complexity of CHC theory and the human cognitive abilities it purports to describe, as well as the use of instruments supposedly measuring these abilities, is often challenging in and of itself. The need to possess in-depth understanding of latent neurocognitive factors, multiple narrow abilities, and variations in how tasks measure both latent abilities and narrow abilities, as well as proposed theoretical advances, can seem overwhelming to the average clinician. Many clinicians already find it difficult to describe and/or explain to clients current conceptualizations of CHC broad and narrow abilities and how they are measured by various tasks, as well as what all these things mean for their or their children's functioning. The effectiveness of communicating assessment results to consumers (clients, parents, teachers, etc.) is a direct function of the language and vocabulary being used. Our proposed F-CHC nomenclature provides a more parsimonious structure that is consistent with recent research (neuropsychological, cognitive, achievement), more functional for understanding the CHC theoretical constructs, more practical for the average clinician, and more understandable to consumers of the information.

CHAPTER 33

The Emergence of Neuropsychological Constructs into Tests of Intelligence and Cognitive Abilities

Daniel C. Miller
Denise E. Maricle

PERSPECTIVES ON NEUROCOGNITIVE ASSESSMENT

Baron (2004) has pointed out that "intelligence tests are not neuropsychological instruments" (p. 114). Historically, tests of intelligence were designed empirically to be predictive of academic achievement, and the lens through which they were viewed was very narrow. However, in the last 25 years there has been a rapid advance in theoretically driven intelligence tests, with the Lurian and Cattell–Horn–Carroll (CHC) theories being the primary approaches used in intelligence test development, construction, and interpretation. Consequently, intelligence tests today are being used differently, with a broader lens; less attention is being given to the concept of *g* (general intellectual ability) as a predictor of academic achievement, and more emphasis is being placed on combinations of cognitive constructs as predictors of academic achievement.

The Lurian and CHC theories provide unique perspectives on the assessment of cognitive abilities. The Lurian perspective is grounded in clinical neuropsychology with extensive empirical evidence stemming from strong brain–behavior research. Currently, Lurian theory provides the foundation for the Cognitive Assessment System—Second Edition (CAS2; Naglieri, Das, & Goldstein, 2014) and can be used as an alternative interpretive approach for the Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004). In contrast to Lurian theory, CHC theory is largely based on a factor-analytic cross-battery approach. The Woodcock–Johnson IV (WJ IV) Tests of Cognitive Abilities (WJ IV COG; Schrank, McGrew, & Mather, 2014), Tests of Oral Language (WJ IV OL; Schrank, Mather, & McGrew, 2014b), and Tests of Achievement (WJ IV ACH; Schrank, Mather, & McGrew, 2014a) serve as the preeminent instruments that operationalize CHC theory. CHC theory has also been applied to the Stanford–Binet Intelligence Scales, Fifth Edition (SB5; Roid, 2003), the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007), and the Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014), as well as being the preferred interpretive model for the KABC-II. CHC theory has thus become the "default" theoretical perspective in the majority of tests of cognitive ability.

Although there is significant psychometric research supporting CHC theory, one of its weaknesses is that there is no empirical evidence for the direct linkage between neuroanatomical functions and the cognitive constructs posited by the theory. As Baron (2004) has correctly pointed out, current intelligence tests have typically not been validated with respect to brain function. We agree with Baron that intelligence tests are not neuropsychological instruments. Presently, neuroimaging studies linking brain function to concurrent measures of commonly used tests of cognitive abilities are not available. Perhaps it is best to view intelligence tests as packaged samples of behavior that (1) may be starting points for generating hypotheses about possible deficits in neuropsychological processing, and (2) may also be interpreted from a neuropsychological perspective.

Miller (2007, 2010, 2013; Miller & Maricle, 2012) has introduced the school neuropsychological conceptual model as a way of organizing cross-battery assessment data on school-age children. Miller (2013) has since expanded his conceptual model to further integrate neuropsychological constructs with CHC theory, and it is now called the *integrated school neuropsychology/Cattell–Horn–Carroll conceptual model* (integrated SNP/CHC model; see Figure 33.1). The purposes of this model are (1) to facilitate clinical interpretation by providing an organizational framework for assessment data; (2) to strengthen the linkage between assessment and evidence-based interventions; and (3) to provide a common frame of reference for evaluating the effects of neurodevelopmental disorders on neuropsychological processes. The complete integrated SNP/CHC model includes the integration of academic achievement and social-emotional functioning with the major neuropsychological assessment components (see Miller, 2013, for a complete review); however, in this chapter we focus only on the neurocognitive portions.

Flanagan, Alfonso, Ortiz, and Dynda (2010) have discussed the possible integration of the Lurian, CHC, and SNP models as a means of providing a common lens through which to examine neurocognitive constructs. For example, they have shown how neuropsychological constructs such as concept formation or working memory can be classified according to the three perspectives. Thus Flanagan and colleagues provide a much-needed framework for translating and integrating the concepts, principles, and nomenclature of the three models. Flanagan, Ortiz, and Alfonso (2013) have further integrated neuropsychological constructs from the major pediatric neuropsychological tests with tests of cognitive and academic achievement in the third edition of their *Essentials of Cross-Battery Assessment*.

Historically, clinical neuropsychological assessment has attempted to link the cognitive and behavioral manifestations of neuropsychological processing with known brain structures or functions; it has relied on both quantitative and qualitative aspects of performance. Traditional neuropsychological tests consist of specifically designed tasks used to measure psychological functions known to be linked to particular brain structures or pathways. The tests are typically used to assess impairment after an injury or illness known to affect neurocognitive functioning, or are used in research to compare neuropsychological abilities across experimental groups. In contrast, tests of cognitive abilities have traditionally focused almost exclusively on quantitative measures of cognitive performance, while ignoring qualitative behaviors. Baron (2004) has stated that this limitation prevents the clinical detection of meaningful performance patterns, such as strategy selection, analysis of error patterns, and response latency.

In response to such limitations, test publishers have begun to gather the prevalence rates of observable qualitative behaviors and to provide practitioners with useful base rate data. Starting with the original CAS (Naglieri & Das, 1997), followed by the Wechsler Intelligence Scale for Children—Third Edition as a Process Instrument (Kaplan, Fein, Kramer, Delis, & Morris, 1999), the Wechsler Intelligence Scale for Children—Fourth Edition Integrated (WISC-IV Integrated; Wechsler et al., 2004), and the WISC-V Integrated (Wechsler & Kaplan, 2015) test authors and publishers have provided bridges between the fields of cognitive and neuropsychological assessment by including qualitative behaviors in tests of cognitive functions.

An emerging trend in both cognitive and neuropsychological assessment is the development of computer-based assessment (CBA). Technological innovation is driving the use of computer-based assessment devices, such as tablets for the adaptation of examiner-administered tests with scoring and interpretation. CBA ranges from stand-alone computer-administered versions of established examiner-administered tests, such as the Wisconsin Card Sorting Test (Heaton & PAR Staff, 2003) or the WISC-V, to fully web-integrated applications (such as CNS Vital Signs; see below). CBA is viewed as less time- and resource-intensive than traditional examiner-administered tests, and thus more cost-effective.

Currently the assumption is being made that if an established examiner-administered test is adapted to computer-based administration, the normative and psychometric data provided by

the two versions are equivalent. However, Bauer and colleagues (2012) clearly state that even when a traditional examiner-administered test is programmed for computer administration, it "becomes a new and different test" (p. 366) and is not just the existing test in a slightly different format. Equivalency, reliability, and validity data for computer-based assessment are scarce.

Publishers have long offered computer- program or web-based scoring for numerous cognitive, academic, behavioral, and personality assessments. More recently, publishers are moving to computer-based or online platforms for the administration of previous examiner administered assessments. For example, Pearson offers the Q-global Web-Based Administration, Scoring, and Reporting (online system), Q-interactive (tablet-based system), and Q Local Scoring and Reporting Software (desktop-based system) options for administering, scoring, and reporting the results of more than 30 instruments—including cognitive measures such as the WISC-V, achievement measures such as the Wechsler Individual Achievement Test—Third Edition (WIAT-III), and personality measures such as the Minnesota Multiphasic Personality Inventory–2—Restructured Form (MMPI-2-RF). Psychological Assessment Resources (PAR) uses PARiConnect (*www.pariconnect.com*), which is an online assessment, scoring, and reporting platform for numerous instruments that PAR publishes. Similarly, Multi-Health Systems (MHS) has an Online Assessment Center (*www.mhs.com/infocenter.aspx?gr=mhs&prod=service&id=Overview*), where users can administer, score, and obtain reports on the instruments that MHS publishes.

Integrated neuropsychological assessments designed for computer-based administration include the Cambridge Neuropsychological Test Automated Battery (CANTAB; *www.cambridgecognition.com*), the Automated Neuropsychological Assessment Metrics—Version 4 (ANAM 4; *vistalifesciences.com*), CNS Vital Signs (*www.cnsvs.com*), MicroCog: Assessment of Cognitive Functioning Windows Edition 2004 (Powell et al., 2004), NeuroTrax: Innovative Science for Brain Health (*www.neurotrax.com*), and ImPACT Concussion Assessment and Management (*www.impact.com*).

The CANTAB advertises itself as including the world's most validated and sensitive touchscreen tests of cognitive functioning. The publisher cites over 1,600 peer-reviewed papers in a bibliography on the website (see URL above). The CANTAB is the most recent version of the Cambridge Neuropsychological Test Automated Battery developed at Cambridge University by neuroscientists Sahakian and Robbins in the 1980s. Areas covered include memory, executive functions, attention, decision making, and social cognition. For example, subtests included in the memory section are Paired Associates Learning, Delayed Matching to Sample, Graded Naming Test, Pattern Recognition Memory, Spatial Recognition Memory, Verbal Recognition Memory, Spatial Span and Spatial Working Memory. Reviews suggest that the CANTAB subtests demonstrate strong reliability and validity across a variety of age ranges and disability groups (Luciana, 2003).

The ANAM 4 is a library of 22 computer-based cognitive assessments developed by the U.S. military. It provides measures of attention, concentration, reaction time, memory, processing speed, and decision making, but is not considered to include a measure of intelligence. The ANAM 4 is intended to measure an individual's neurocognitive status at a point in time, as well as changes in cognitive status over time. The tasks of the ANAM 4 are sensitive to cognitive changes associated with injury (e.g., trauma, blast), illness, exposure or risk factors (e.g., toxins, fatigue), and interventions (e.g., medications). ANAM 4 is based on decades of clinical and laboratory research, and is referenced in more than 300 peer-reviewed independent research studies. It has the most comprehensive military research and clinical application record of any cognitive assessment technology, with researchers from many federal agencies contributing to its development (see URL above).

CNS Vital Signs touts itself as a world leader in the development and design of neurocognitive and behavioral assessment technologies and tools. A customizable battery can be developed from 10 normed (and 26 un-normed) neuropsychological tests and more than 50 evidence-based rating scales. CNS Vital Signs tests are suitable for clients ages 8–89 and can be customized for more than 50 languages. Reviews of CNS Vital Signs (Gualtier & Johnson, 2006) suggests strong validity and reliability for the 7 subtests of the Brief Clinical Battery. Numerous research studies are listed on the CNS Vital Signs website (see URL above).

The technological revolution is inevitable, and it can be predicted that many currently examiner-administered tests will migrate to computer-based platforms for administration, scoring, and interpretation or reporting of results. It is imperative that researchers examine the equivalency, reliability, and validity of these computer-based formats before computer-based measures of cognition and neuropsychological functioning enter widespread clinical use. Although technology is being systematically integrated into the field, it is still necessary to have a conceptual or theoretical framework to aid in clinical interpretation.

THE INTEGRATED SNP/CHC MODEL

The emerging subspecialization of school neuropsychology bridges the gap between traditional psychoeducational approaches and clinical neuropsychological approaches, allowing for both quantitative and qualitative assessment of performance. Miller's (2013) integrated SNP/CHC model provides a framework for school psychologists to integrate quantitative and qualitative performance from commonly used tests of cognitive abilities and to interpret performance from a neuropsychological perspective. See Miller (2015) and Miller, McGill, and Bauman Johnson (2016) for a complete classification of all subtests from the WJ IV, WISC-V, WISC-V Integrated, and WIAT-III into the integrated SNP/CHC model. The bulk of this chapter is structured to provide information about how neuropsychological constructs are measured in traditional neuropsychological tests and current tests of cognitive ability. Within the integrated SNP/CHC model, tasks from the various instruments are classified on the basis of their underlying neurocognitive demands, the theoretical perspectives from which each originates, and psychometric data from cross-battery research.

One of the limitations of this chapter is that we are only looking at the conceptual overlap between traditional neuropsychological instruments and tests of cognitive functions. In order to fully assess all of the neuropsychological constructs within the integrated SNP/CHC model, practitioners would have to administer a broader array of instruments, such as specialized or targeted tests of learning and memory or of sensory–motor functions. The following constructs covered in common by traditional neuropsychological instruments and tests of cognitive ability are discussed: sensory–motor functions; cognitive processes (visual–spatial, auditory, learning and memory, and executive functions); and facilitators–inhibitors (attention, working memory, and speed and efficiency of processing).

Sensory–Motor Functions

One of the major contrasts between intelligence testing and neuropsychological assessment is related to the assessment of sensory–motor functions. Neuropsychological evaluations typically assess for sensory functions of vision, hearing, and the sense of touch, as well as fine and gross motor functions, whereas the major tests of cognitive ability have traditionally not included these neuropsychological functions as part of their core batteries. Only two neuropsychological constructs within the sensory–motor domain have been integrated into current tests of cognitive ability: motor sequencing and visual–motor integration (see Table 33.1).

Traditional neuropsychological assessment has multiple examples of tests designed to measure motor sequencing actions with both the dominant and nondominant hands. These measures stem from Alexander Luria's original investigations of motor functions (Christensen, 1975), and all re-

TABLE 33.1. Sensory–Motor Functions Measured on Traditional Neuropsychological Tests and Current Tests of Cognitive Abilities

Neuropsychological construct(s)	Traditional neuropsychological measures	Examples of neuropsychological measures in tests of cognitive abilities
Motor sequencing	• Finger Sequencing Test • Fist–Edge–Palm Test • NEPSY-II: Fingertip Tapping (dominant and nondominant hand combined), Imitating Hand Positions, and Manual Motor Sequences • Oseretskii Test of Reciprocal Coordination • TOMAL-2: Manual Imitations	KABC-II: Hand Movements
Visual–motor integration	• VMI • NEPSY-II: Design Copying • Rey Complex Figure Test and Recognition Trial	DAS-II: Copying

Note. For full names of abbreviated tests in this and later tables, see chapter text.

quire the placement of the hand in three or more successive positions after either a verbal command or visual modeling from the examiner. Traditional neuropsychological measures of motor sequencing include the Finger Sequencing Test (Welsh, Pennington, & Groisser, 1991), the Fist–Edge–Palm Test (Christensen, 1975), and the Oseretskii Test of Reciprocal Coordination (Buchanan & Heinrichs, 1989) (see Baron, 2004, for a review).

Various sensory–motor tasks (e.g., Fingertip Tapping, Imitating Hand Positions, and Manual Motor Sequences) have also been included in the NEPSY-II (Korkman, Kirk, & Kemp, 2007), which is a comprehensive neuropsychological battery designed for school-age children. The Test of Memory and Learning—Second Edition (TOMAL-2; Reynolds & Voress, 2007) also includes a Manual Imitations test. Among tests of cognitive ability, only the KABC-II includes a motor sequencing task called Hand Movements.

One of the classic neuropsychological measures of visual–motor integration is the Rey–Osterrieth Complex Figure Test (ROCF), developed in the 1940s by Rey (1941) and Osterrieth (1944). The test has been revised and restandardized multiple times (e.g., the Rey Complex Figure Test and Recognition Trial; Meyers & Meyers, 1995), but the purpose of the test remains the same: to assess for visual–spatial constructional ability. The ROCF requires copying a complex figure drawing with an added delayed-recall component. Other two-dimensional copying tasks that may be used to supplement tests of cognitive ability are the Beery–Buktenica Developmental Test of Visual–Motor Integration, Sixth Edition (VMI; Beery, Buktenica, & Beery, 2010) and the Design Copying test from the NEPSY-II.

Only one current test battery of cognitive ability includes a direct measure of visual–motor integration: the Copying test from the DAS-II. Although other current tests of cognitive ability do not include measures of visual–motor integration, it is common practice in psychoeducational assessment to include an additional test like the Beery VMI, to rule out the presence of any sensory–motor deficit that could explain a learning difficulty. For example, before a specific learning disability can be diagnosed, the Individuals with Disabilities Education Improvement Act of 2004 (IDEA; 2004) requires that any sensory–motor impairment be ruled out as a primary causal factor.

Since many childhood disorders are known to have associated sensory–motor deficits (see Decker & Davis, 2010, for a review; see also Decker, Strait, Roberts, & Ferraracci, Chapter 24, this volume), clinicians must not rely on using tests of cognitive ability alone. Tests of cognitive ability do not include other important sensory–motor constructs that should be measured, such as speed and accuracy of motor output, both of which have a direct impact upon a learner's achievement (Miller, 2013). When the referral questions raise serious concerns about sensory–motor functions, an appropriately trained clinician is encouraged to include the sensory–motor subtests from the NEPSY-II or to administer the sensory–motor portions of the Dean–Woodcock Neuropsychological Battery (Dean & Woodcock, 2003). The latter include eight measures of sensory functioning, nine measures of motor functioning, and one measure of lateral dominance or preference.

Cognitive Processes

In the integrated SNP/CHC model (Miller, 2013), four core sets of cognitive processes/functions have been delineated: visual–spatial processes, auditory processes, learning and memory processes, and executive functions. These four cognitive processes are influenced by the basic sensorimotor functions and are enhanced or inhibited by the facilitators and inhibitors, respectively. In what follows, the neuropsychological and cognitive ability tests designed to measure these broad constructs are highlighted.

Visual–Spatial Processes

In the integrated SNP/CHC model (Miller, 2013), visual–spatial processes are influenced both by basic sensory–motor functions and by facilitators–inhibitors (discussed later in this chapter). The tests of visual–spatial processes are conceptually divided into two categories: (1) tests that require visual–spatial perception and (2) tests that require visual–spatial reasoning (see Table 33.2).

Visual–Spatial Perception

Visual–motor three-dimensional construction abilities are measured by both neurocognitive and cognitive instruments (see Table 33.2). The Block Construction test on the NEPSY-II is an example of a neuropsychological measure that requires three-dimensional construction of blocks. Similar visual–motor, constructional tasks on tests of cognitive ability include Pattern Construction on the DAS-II; Triangles on the KABC-II; Block De-

sign and Block Design—No Time Bonus on the WISC-V; Block Design Process Approach on the WISC-V Integrated; and Block Design and Object Assembly on the Wechsler Preschool and Primary Scale of Intelligence—Fourth Edition (WPPSI-IV; Wechsler, 2012).

Visual–Spatial Reasoning

In the integrated SNP/CHC model (Miller, 2013), visual–spatial reasoning tasks are divided into three groups, based on the neurocognitive demands of the task: (1) tasks requiring the recognition of spatial configurations, (2) tasks requiring part-to-whole analysis–synthesis or visual gestalt closure, and (3) tasks requiring visual–spatial analyses with and without mental rotations (see Table 33.2). These three neurocognitive constructs are shared between neuropsychological measures and tests of cognitive ability.

The Judgment of Line Orientation test (Benton, Hamsher, Varney, & Spreen, 1983) is a classic neuropsychological test designed to measure a person's ability to match the angle and orientation of line in space, or recognition of spatial configurations. Tests of cognitive ability designed to measure recognition of spatial configurations include Matching Letter-Like Forms from the DAS-II; Block Counting from the KABC-II; Visual Puzzles from the WISC-V; and Visualization from the WJ IV COG.

The Hooper Visual Organization Test (HVOT; Hooper, 1958) is a classic neuropsychological test designed to measure visual analysis and synthesis, conceptual reorganization, and mental rotation. The HVOT consists of sets of line drawings of familiar objects that have been divided into fragments. The examinee is asked to reassemble each set of fragments mentally and then name the object. Tests of cognitive ability designed to measure similar neurocognitive constructs include Gestalt Closure from the KABC-II and What's Missing from the Reynolds Intellectual Assessment Scale, Second Edition (RIAS-2; Reynolds & Kamphaus, 2015).

The third neurocognitive construct shared between neuropsychological measures and tests of cognitive ability is visual–spatial analysis with and without mental rotation. Examples of neuropsychological tests that measure this neurocognitive ability include the Geometric Puzzles test from the NEPSY-II and the Matching test from the Wide Range Assessment of Visual–Motor Abilities (WRAVMA; Adams & Sheslow, 1995). One test of cognitive ability that measures this same construct is the Nonverbal Visual–Spatial Processing test from the SB5.

Auditory Processes

In the integrated SNP/CHC model (Miller, 2013), auditory processes are considered as core cognitive processes, which are influenced both by basic sensory–motor functions and by facilitators–inhibitors (again, the latter are discussed later in this chapter). The tests of auditory processes are conceptually divided into two categories: (1) tests that require basic sound discrimination skills and (2) tests that require auditory/phonological processing abilities (see Table 33.3).

There are two traditional neuropsychological tests designed to measure basic auditory discrimination skills: the Seashore Rhythm Test from the Halstead–Reitan Neuropsychological Test Battery (Reitan & Wolfson, 1985) and the Wepman's Auditory Discrimination Test (Wepman & Reynolds, 1986) (see Table 33.3). The Sound Awareness test on the WJ IV OL battery is also designed to measure basic auditory discrimination skills.

In regard to auditory/phonological processing, the Phonological Processing test on the NEPSY-II is a contemporary neuropsychological measure of both higher-order phonemic awareness and phonemic manipulation (e.g., blending or deleted sounds). Tests of cognitive ability that measure this same auditory processing construct include Phonological Processing on the DAS-II; Nonword Repetition and Phonological Processing on the WJ IV COG; and Segmentation and Sound Blending on the WJ IV OL.

Learning and Memory

Learning and memory tasks have been classified in many ways. Conceptualizations of memory and learning have recently been shifting away from traditional information-processing models to models based on neuroscience. The integrated SNP/CHC model (Miller, 2013) classifies tests of memory and learning from neuropsychological tests and cognitive measures into three broad categories: (1) rate of learning, (2) immediate memory, and (3) delayed recall and recognition (see Figure 33.1). The constructs of immediate memory and of delayed recall and recognition are shared between neuropsychological tests and tests of cognitive ability.

Rate of Learning

Rate of learning is measured by the change in the number of correctly recalled words from a fixed list of words repeated over multiple trials. The major tests of cognitive ability do not include tests that are designed to measure rate of learning. However, several neuropsychological batteries or comprehensive tests of memory and learning provide assessments of rate of learning. Examples include the Word Pairs—Learning and Word Lists—Learning scores from the Children's Memory Scale (CMS; Cohen, 1997); the List Memory Learning Effect score from the NEPSY-II; and the Word Selective Reminding score from the TOMAL-2 (Reynolds & Voress, 2007). The California Verbal Learning Test—Children's Version (Delis, Kramer, Kaplan, & Ober, 1994) is a targeted rate-of-learning measure that is often administered by both neuropsychologists and school psychologists.

Immediate Memory

Immediate memory can be further subdivided according to the neurocognitive demands of a particular task. The first subdivision of immediate memory tasks takes into consideration the sensory input modality required to complete the task. As a result, these tasks can be subdivided into verbal immediate memory, visual immediate memory, and verbal–visual associative memory categories. In addition, the verbal and visual immediate memory tasks can be further subdivided according to the use of contextual cues. For example, a simple memory-for-digits task is a verbal immediate memory task without contextual cues, whereas a memory-for-stories task is a verbal immediate memory task with contextual cues.

Verbal Immediate Memory with No Contextual Cues. Verbal immediate memory tasks with no contextual cues are common to both neuropsychological tests and tests of cognitive ability (see Table 33.4). Strings of numbers, letters, or unrelated words are often used as stimuli in these types of tasks, and the examinee is asked to recall increasingly longer spans of stimuli. Neuropsychological measures of verbal immediate memory that do not include contextual cues include Word Lists—Immediate Recall and Word Pairs—Immediate Recall on the CMS; Word List Interference—Repetition on the NEPSY-II; and Digits Forward, Letters Forward, and Word Selective Reminding on the TOMAL-2.

The major tests of cognitive ability that include measures of verbal immediate memory tasks without contextual cues are Word Series on the CAS2; Recall of Digits—Forward on the DAS-II; Number Recall, Word Order, and Word Order (without color interference) on the KABC-II; Digit Span—Forward on the WISC-V; and Memory for Words on the WJ IV COG.

Verbal Immediate Memory with Contextual Cues. Verbal immediate memory tasks with contextual cues are also found on neuropsychological tests and tests of cognitive ability, but to a lesser degree than the verbal immediate memory tasks without contextual cues (see Table 33.4). Sentences of increasing length and stories with increasing complexity are used as stimuli in these types of tasks. Neuropsychological measures of verbal immediate memory tests that include contextual cues are Stories—Immediate Recall on the CMS; Narrative Memory and Sentence Repetition on the NEPSY-II; Memory for Stories on the TOMAL-2; and Sentence Memory and Story Memory on the Wide Range Assessment of Memory and Learning, Second Edition (WRAML2; Sheslow & Adams, 2003).

Two major tests of cognitive ability that include measures of verbal immediate memory with added contextual cues are the Verbal Memory test on the RIAS-2; the Story Recall test on the WJ IV COG; and Sentence Repetition on the WJ IV OL.

Visual Immediate Memory with No Contextual Cues. The types of stimuli used for visual immediate memory tasks with no contextual cues vary, but can include abstract designs, faces, objects, or pictures (see Table 33.4). Examinees are typically shown visual stimuli for a brief exposure and then asked to motorically reproduce the details of what was seen, or are asked to match, nonverbally or verbally, a newly presented visual stimulus with that previously seen.

Neuropsychological tests that require visual immediate memory for abstract designs include Memory for Designs on the NEPSY-II; Abstract Visual Memory and Visual Sequential Memory on the TOMAL-2; and Design Memory on the WRAML2. Tests of cognitive ability that measure a comparable construct include Figure Memory on the CAS2 and Recall of Designs on the DAS-II.

Neuropsychological tests requiring visual immediate memory for numbers, faces, objects, or pictures (see Table 33.4) include Faces—Immediate Recall on the CMS; Memory for Faces—Immediate Recall on the NEPSY-II; and Facial Memory on the TOMAL-2. The major tests of cognitive ability that include visual immediate memory for numbers, faces, objects, or pictures are Recognition of Pictures on the DAS-II; Face Recognition on the KABC-II; Nonverbal Memory on the RIAS-2; Object Memory on the Universal Nonverbal Intelligence Test—Second Edition (UNIT2; Bracken & McCallum, 2016); Coding Recall on the WISC-V Integrated; and Picture Recognition on the WJ IV COG.

Neuropsychological tests requiring visual immediate memory for spatial locations (see Table 33.4) include Dot Locations—Immediate Recall on the CMS and the Memory for Locations and Visual Selective Reminding tests on the TOMAL-2. The major tests of cognitive ability that include visual immediate memory for spatial locations are Spatial Memory on the UNIT2 and Spatial Span on the WISC-V Integrated.

TABLE 33.4. Learning and Memory Processes Measured on Traditional Neuropsychological Tests and Current Tests of Cognitive Abilities

Neuropsychological construct(s)	Traditional neuropsychological measures	Examples of neuropsychological measures in tests of cognitive abilities
	Immediate memory	
Verbal immediate memory for numbers, letters, or words (no contextual cues)	• CMS: Word Lists—Immediate Recall and Word Pairs—Immediate Recall • NEPSY-II: Word List—Interference Repetition • TOMAL-2: Digits Forward, Letters Forward, and Word Selective Reminding	• CAS2: Word Series • DAS-II: Recall of Digits—Forward • KABC-II: Number Recall, Word Order, and Word Order (without color interference) • WISC-V: Digit Span—Forward • WJ IV COG: Memory for Words

Visual immediate memory for spatial locations	• CMS: Dot Locations—Immediate Recall • TOMAL-2: Memory for Locations and Visual Selective Reminding	• UNIT2: Spatial Memory • WISC-V Integrated: Spatial Span
Visual immediate memory with contextual cues	• CMS: Family Pictures—Immediate Recall • WRAML2: Picture Memory	• UNIT2: Symbolic Memory
Verbal–visual associative learning	• NEPSY-II: Memory for Names—Immediate Recall • TOMAL-2: Object Recall and Paired Recall • WRAML2: Sound–Symbol	• DAS-II: Recall of Objects—Immediate • KABC-II: Atlantis and Rebus • WISC-V: Immediate Symbol Translation • WJ IV COG: Visual–Auditory Learning
	Delayed recall and recognition	
Verbal–visual associative delayed recall	• NEPSY-II: Memory for Names—Delayed Recall • WRAML2: Sound–Symbol—Delayed	• DAS-II: Recall of Object—Delayed • KABC-II: Atlantis—Delayed and Rebus—Delayed • WISC-V: Delayed Symbol Translation • WJ IV COG: Visual–Auditory Learning—Delayed

Visual Immediate Memory with Contextual Cues. There are only a few neuropsychological and cognitive tests designed to measure visual immediate memory with added contextual cues. Neuropsychological measures requiring visual immediate memory with added contextual cues include Family Pictures—Immediate Recall on the CMS and Picture Memory on the WRAML2. The Symbolic Memory test on the UNIT2 is the only test on a major cognitive test battery to measure visual immediate memory with added contextual cues.

Verbal–Visual Associative Learning. Verbal–visual associative learning tasks have been included on both neuropsychological and cognitive ability tests in the past decade. Each of the tasks requires the examinee to learn to associate a verbal label with either a picture, object, symbol, or face, often with corrective feedback. Neuropsychological tests requiring verbal–visual associative learning (see Table 33.4) include Memory for Names—Immediate Recall on the NEPSY-II; Object Recall and Paired Recall on the TOMAL-2; and Sound–Symbol on the WRAML2. The major tests of cognitive ability designed to measure verbal–visual associative learning include Recall of Objects—Immediate on the DAS-II; Atlantis and Rebus on the KABC-II; Immediate Symbol Translation on the WISC-V; and Visual–Auditory Learning on the WJ IV COG.

Delayed Recall and Recognition

Tests of cognitive ability do not typically include measures of delayed recall or recognition. A clinician who needs to assess delayed recall or recognition will need to use stand-alone tests of memory and learning (e.g., the WRAML2, TOMAL-2, or CMS) or the Memory and Learning tests from the NEPSY-II.

Verbal–Visual Associative Delayed Recall. All of the tests mentioned in the section above on verbal–visual associative learning, except for the Object Recall and Paired Recall tests on the TOMAL-2 and Visual-Auditory Learning on the WJ IV, have a delayed-recall portion of their tests (see Table 33.4). The purpose of these tests is to assess long-term memory, or the degree of consolidation, for paired verbal–visual stimuli.

Executive Functions

Among all neurocognitive constructs, the construct of executive functions has generated the most attention, interest, and research. Practitioners and researchers often equate executive functions with intelligence (Blair, 2006; Friedman et al., 2006). As a result, test publishers have included a broad array of executive function tasks on the major tests of cognitive ability.

However, Maricle, Johnson, and Avirett (2010) point out that there is not "a mutually agreed upon list of cognitive components which comprise executive functions" (pp. 599–600). The SNP model (Miller, 2013) classifies tests of executive functions from neuropsychological and cognitive measures into four broad categories: (1) cognitive flexibility (set shifting); (2) concept recognition and generation; (3) planning, problem solving, and reasoning; and (4) response inhibition (see Table 33.5).

Classic neuropsychological tests requiring the executive functions of cognitive flexibility or set shifting include the Halstead–Reitan Category Test (Reitan & Davidson, 1974); the Wisconsin Card Sorting Test (Grant & Berg, 1993); Color–Word Interference—Condition 4, Verbal Fluency—Condition 3, and Design Fluency—Condition 3 from the D-KEFS (Delis, Kaplan, & Kramer, 2001); and the Inhibition (switching condition) from the NEPSY-II. There are no similar cognitive flexibility measures specifically included on major tests of cognitive ability.

Concept Recognition and Generation

Concept recognition or generation tasks typically require the examinee to classify objects or pictures into groups that share a common attribute (e.g., the same color or shape). The goal of these tasks is to identify as many classifications as possible; this requires divergent thinking and concept formation. Neuropsychological tests requiring concept recognition or generation (see Table 33.5) include Sorting and Twenty Questions on the D-KEFS and Animal Sorting on the NEPSY-II. Tests of cognitive ability that include measures of concept recognition or generation are Picture Similarities and Verbal Similarities on the DAS-II; Similarities on the WISC-V; Similarities Multiple Choice on the WISC-V Integrated; and Similarities on the WPPSI-IV.

Planning, Problem Solving, and Reasoning

Despite the multiple classification schemas developed for executive functions, most researchers and theorists agree that executive functions include measures of planning, problem solving, and reasoning. More recent neuropsychological tests

TABLE 33.5. Executive Functions Measured on Traditional Neuropsychological Tests and Current Tests of Cognitive Abilities

Neuropsychological construct(s)	Traditional neuropsychological measures	Examples of neuropsychological measures in tests of cognitive abilities
Concept recognition and generation	• D-KEFS: Sorting and Twenty Questions • NEPSY-II: Animal Sorting	• DAS-II: Picture Similarities and Verbal Similarities • WISC-V: Similarities • WISC-V Integrated: Similarities Multiple Choice • WPPSI-IV: Similarities
Planning, problem solving, and reasoning	• D-KEFS: Tower, Color Word Interference—Condition 4, Proverbs, Verbal Fluency—Condition 3, and Word Context • NEPSY-II: Clocks and Inhibition (Switching Condition)	• CAS2: Matrices and Planned Connections • DAS-II: Matrices, and Sequential and Quantitative Reasoning • KABC-II: Pattern Reasoning, Rover, and Story Completion • RIAS-2: Guess What, Odd-Item Out, and Verbal Reasoning • SB5: Verbal Fluid Reasoning and Nonverbal Fluid Reasoning • UNIT2: Analogic Reasoning, Cube Design, and Mazes • WISC-V: Comprehension, Figure Weights, Matrix Reasoning, and Picture Concepts • WISC-V Integrated: Comprehension Multiple Choice and Figure Weights Recall • WPPSI-IV: Comprehension, Matrix Reasoning, Picture Concepts • WJ IV ACH: Number Matrices • WJ IV COG: Concept Formation, Analysis–Synthesis, Number Series
Response inhibition	• D-KEFS: Color Word Interference—Condition 3 (Inhibition) • NEPSY-II: Inhibition—Condition 2 and Statue • Stroop Color–Word Test	• CAS2: Expressive Attention

measuring planning, problem solving, or response inhibition include Tower, Color Word Interference—Condition 4 (Switching), Proverbs, Verbal Fluency—Condition 3 (Switching), and Word Context on the D-KEFS; and Clocks and Inhibition (Switching Condition) on the NEPSY-II.

Tests of cognitive ability that are designed to measure similar executive function constructs are Matrices and Planned Connections on the CAS2; Matrices, and Sequential and Quantitative Reasoning, on the DAS-II; Pattern Reasoning, Rover, and Story Completion on the KABC-II; Guess What, Odd-Item Out, and Verbal Reasoning on the RIAS-2; Verbal Fluid Reasoning and Nonverbal Fluid Reasoning on the SB5; Analogic Reasoning, Cube Design, and Mazes on the UNIT2; Comprehension, Figure Weights, Matrix Reasoning, and Picture Concepts on the WISC-V; Comprehension Multiple Choice and Figure Weights Recall on the WISC-V Integrated; Comprehension, Matrix Reasoning, and Picture Concepts on the WPPSI-IV; Number Matrices on the WJ IV ACH; and Concept Formation, Analysis–Synthesis, and Number Series on the WJ IV COG.

Response Inhibition

Response inhibition is the ability to withhold responding to distractor stimuli while focusing on target stimuli. Response inhibition tasks typically involve the ability to inhibit a response after a particular response set has been established. For example, in the classic Stroop test, the examinee is asked to name the color of the ink that a color word (e.g., *red*, *green*, or *blue*) is printed in, rather than reading the word itself.

The neuropsychological tests designed to measure response inhibition are Color Word Interference—Condition 3 (Inhibition) on the D-KEFS; the Inhibition—Condition 2 (Inhibition) and Statue tests on the NEPSY-II; and the numerous versions of the Stroop Color–Word Test (e.g., Golden & Freshwater, 2002). The only measure of cognitive ability that includes a response inhibition task is Expressive Attention on the CAS2, which is modeled after the Stroop test.

Facilitators–Inhibitors of Cognitive Processes

In the integrated SNP/CHC model, Miller (2013) introduced a broad classification called *facilitators–inhibitors,* which included the second-order classifications: (1) allocating and maintaining attention; (2) working memory; and (3) speed, fluency, and efficiency of processing. These three processes are thought either to facilitate or to inhibit other cognitive processes and acquired knowledge skills. For example, learning and memory can be helped or hurt by good or poor attentional skills, respectively. The quality of a person's working memory skills has a major positive or negative impact on many aspects of academic achievement or acquired knowledge (Dehn, 2015). Processing speed, fluency, and efficiency also influence other cognitive processes and acquired knowledge in a positive or negative manner. In what follows, we discuss how neuropsychological tests and tests of cognitive ability assess these facilitators and inhibitors.

Attentional Processes

Attentional processes and executive functions are often intertwined, and some neuropsychological tests such as the NEPSY-II combine these processes into a single domain for interpretation. In Miller's (2013) integrated SNP/CHC model, attentional processes are interpreted separately from executive functions. Consistent with prevailing neuropsychological theories of attention (see Riccio, Reynolds, & Lowe, 2001, for a review), the integrated SNP/CHC model views attention as multidimensional, with two major subcomponents: (1) selective/focused attention, and (2) sustained attention. A third subcomponent included in the model (Miller, 2013) is attentional capacity, which is a duplication of immediate memory tasks with the interpretive focus placed on the attentional load factor of the tasks. Miller (2010) has stated, "While attention is most probably multidimensional, many of the tests that are designed to measure attention . . . do not isolate the subcomponents of attention very well. Many of the common tasks of attention measure, as one unit, multiple subcomponents of attention such as selective and sustained attention" (pp. 95–96).

It is understood that some aspect of attentional processing is a basic requirement to perform almost any cognitive task. As an example, it is difficult to perform well on a memory task if attention is lacking during the encoding process. However, several current tests of cognitive ability are specifically designed to measure one or more of the attentional subcomponents (see Table 33.6).

Selective and/or Sustained Attention

Traditional neuropsychological measures of selective and sustained attention include the d2 Test of Attention (Brickenkamp & Zilmer, 1998) and the Ruff 2 & 7 Selective Attention Test (Ruff & Allen, 1996). Both of these tests require the examinee to choose target stimuli quickly from a visual array. The NEPSY-II Auditory Attention and Response Set tests measure aspects of selective, sustained, and shifting attention. Continuous-performance tests (CPTs) measure sustained attention and are used by both neuropsychologists and school psychologists in the diagnosis of attention-deficit/hyperactivity disorder (ADHD). Examples of CPTs include the Conners Continuous Performance Test 3rd Edition (Conners, 2014) and the Integrated Visual and Auditory Continuous Performance + Plus Test (Sandford & Turner, 1993–2010).

TABLE 33.6. Attentional Processes Measured on Traditional Neuropsychological Tests and Current Tests of Cognitive Abilities

Neuropsychological construct(s)	Traditional neuropsychological measures	Examples of neuropsychological measures in tests of cognitive abilities
Selective and sustained attention	• d2 Test of Attention • Ruff 2 & 7 Selective Attention Test • Continuous-performance tests • NEPSY-II: Auditory Attention and Response Set	• CAS2: Number Detection and Receptive Attention • WJ IV COG: Pair Cancellation

Several tests of cognitive ability have included measures of selective and sustained attention. The CAS2 has two tests, Number Detection and Receptive Attention, and the WJ IV COG includes the Pair Cancellation test.

Attentional Capacity

Attentional capacity has a direct relationship with the cognitive capacity or load required on memory tasks. As the stimuli to be recalled increase in length (e.g., in number of digits or letters), and as the semantic loading increases from words to sentences to stories, there are concurrent changes in the attentional demands of the tasks. Figure 33.2 illustrates the relationship of attentional capacity to memory tasks. Attentional capacity, or immediate short-term memory for numbers, letters, or visual sequences, is measured on common tasks in both neuropsychological tests and tests of cognitive functions.

Two classic neuropsychological visual span tests are the Corsi Block Span test (Milner, 1971) and the Knox Cube Test (Arthur, 1947; Knox, 1914). Only one cognitive ability test, the CAS2, includes a Visual Digit Span test. Two tests of memory and learning for children include measures of digit or visual sequence spans: Digits Forward on the TOMAL-2 and the Finger Windows and Number/Letter tests on the WRAML2. Digit span tests are routinely included in tests of cognitive ability, such as the Recall of Digits—Forward test on the DAS-II; the Number Recall test on the KABC-II; and the Digit Span test on the WISC-V.

Attentional capacity and contextual cues increase with memory for words and sentences. Among neuropsychological assessment tasks, the NEPSY-II and the WRAML2 both have sentence memory tests. There are similar memory-for-words tasks on three tests of cognitive ability: Word Series on the CAS2; Word Order (without interference) on the KABC-II; Memory for Words on the WJ IV COG; and Sentence Repetition on the WJ IV OL.

Finally, attentional capacity is maximized with increased cognitive load and semantic content with memory for stories. The three major standalone tests of memory and learning—the CMS, the TOMAL-2, and the WRAML2—all contain tests that assess memory for stories. The WJ IV COG is the only major test of cognitive ability that has a Story Recall test.

Working Memory

Working memory can be assessed according to the input modality, verbal or visual. Table 33.7 presents examples of tests designed to measure verbal working memory included in neuropsychological batteries (e.g., the NEPSY-II) or tests of memory and learning (e.g., the CMS, TOMAL-2, or WRAML2). All of these measures have in common the neurocognitive processing demand of active manipulation of information in immediate memory, which is the core requirement of a working memory task. An example of a working memory task is recalling a string of numbers or letters in reverse order after hearing them presented sequentially.

	Neuropsychological Measures	Neuropsychological Measures in Tests of Cognitive Abilities	
Memory for numbers, letters, or visual sequences	• Corsi Block Span test • Knox Cube Test • TOMAL-2: Digits Forward and Letters Forward • WRAML2: Finger Windows, Number/Letter	• CAS2 Brief: Successive Digits • DAS-II: Recall of Digits—Forward • KABC-II: Number Recall • WISC-V: Digit Span • WISC-V Integrated: Spatial Span Forward	↓ Increase in Attentional Capacity and Cognitive Load
Memory for words and sentences	• NEPSY-II: Sentence Repetition • WRAML2: Sentence Memory	• KABC-II: Word Order (without interference) • WJ IV COG: Memory for Words • WJ IV OL: Sentence Repetition	
Memory for stories	• NEPSY-II: Narrative Memory • TOMAL-2: Memory for Stories • WRAML2: Story Memory	• WJ IV COG: Story Recall	

FIGURE 33.2. Relationship of attentional capacity to memory tasks in the integrated SNP/CHC model.

TABLE 33.7. Working Memory Measured on Traditional Neuropsychological Tests and Current Tests of Cognitive Abilities

Neuropsychological construct(s)	Traditional neuropsychological measures	Examples of neuropsychological measures in tests of cognitive abilities
Verbal working memory	• CMS: Numbers Backwards and Sequences • NEPSY-II: Word List Interference—Recall • TOMAL-2: Digits Backwards and Letters Backwards • WRAML2: Verbal Working Memory	• DAS-II: Recall of Digits—Backward and Recall of Sequential Order • KABC-II: Word Order (with color interference effect) • SB5: Verbal Working Memory • WISC-IV: Arithmetic, Digit Span—Backward, and Letter–Number Sequencing • WJ IV COG: Numbers Reversed, Object–Number Sequencing, and Verbal Attention
Visual working memory	• WRAML2: Symbolic Working Memory	• SB5: Nonverbal Working Memory

The major tests of cognitive ability that include verbal working memory tests are Recall of Digits—Backward and Recall of Sequential Order on the DAS-II; Word Order (with color interference effect) on the KABC-II; Verbal Working Memory on the SB5; Arithmetic, Digit Span—Backward, and Letter–Number Sequencing on the WISC-V; and Numbers Reversed, Object–Number Sequencing, and Verbal Attention on the WJ IV COG.

There are very few tests designed to measure visual working memory. The WRAML2 provides a measure of visual working memory with its Symbolic Working Memory subtest. The Nonverbal Working Memory test (Block Tapping) on the SB5 is the only test on a major cognitive ability battery designed to measure visual working memory. The SB5 Nonverbal Working Memory test starts out measuring immediate visual memory capacity, but then shifts to measuring visual working memory at later levels, which makes overall classification of the test difficult.

Speed, Fluency, and Efficiency of Processing

In the current conceptualization of the integrated SNP/CHC model, speed, fluency, and efficiency of processing are classified together as a type of facilitator–inhibitor. This overall factor is conceptualized as having four major second-order subcomponents: (1) performance fluency, (2) retrieval fluency, (3) acquired knowledge fluency, and (4) accuracy as a function of speed (see Figuree 33.3).

Performance Fluency

Performance fluency is defined as "the ability to quickly perform simple, repetitive tasks" (Miller, 2013, p. 399). There are several types of performance fluency: (1) psychomotor fluency, (2) perceptual fluency, (3) figural fluency, (4) naming fluency, and (5) oral–motor fluency.

Psychomotor fluency tasks require rapid motor output. Table 33.8 presents examples of neuropsychological tests designed to measure psychomotor fluency, including Trail Making—Condition 5 (Motor Speed) from the D-KEFS and the Visuomotor Precision test (Total Completion Time) from the NEPSY-II. The only test from a cognitive ability battery designed to assess performance fluency is Coding Copy from the WISC-V Integrated.

Perceptual fluency is defined as the ability to quickly distinguish similar but different visual patterns and maintain attention under timed conditions (Horn & Blankson, 2012). There are no widely used neuropsychological measures that are specifically designed to measure perceptual fluency. However, Table 33.8 lists many tests from cognitive ability batteries that are designed to measure perceptual fluency.

Figural fluency refers to the ability to connect dots with unique line patterns while following rules and performing under time constraints. Two neuropsychological tests measure this construct: the Design Fluency tests on the D-KEFS and the NEPSY-II. There are no comparable tests on batteries of cognitive ability that measure figural fluency.

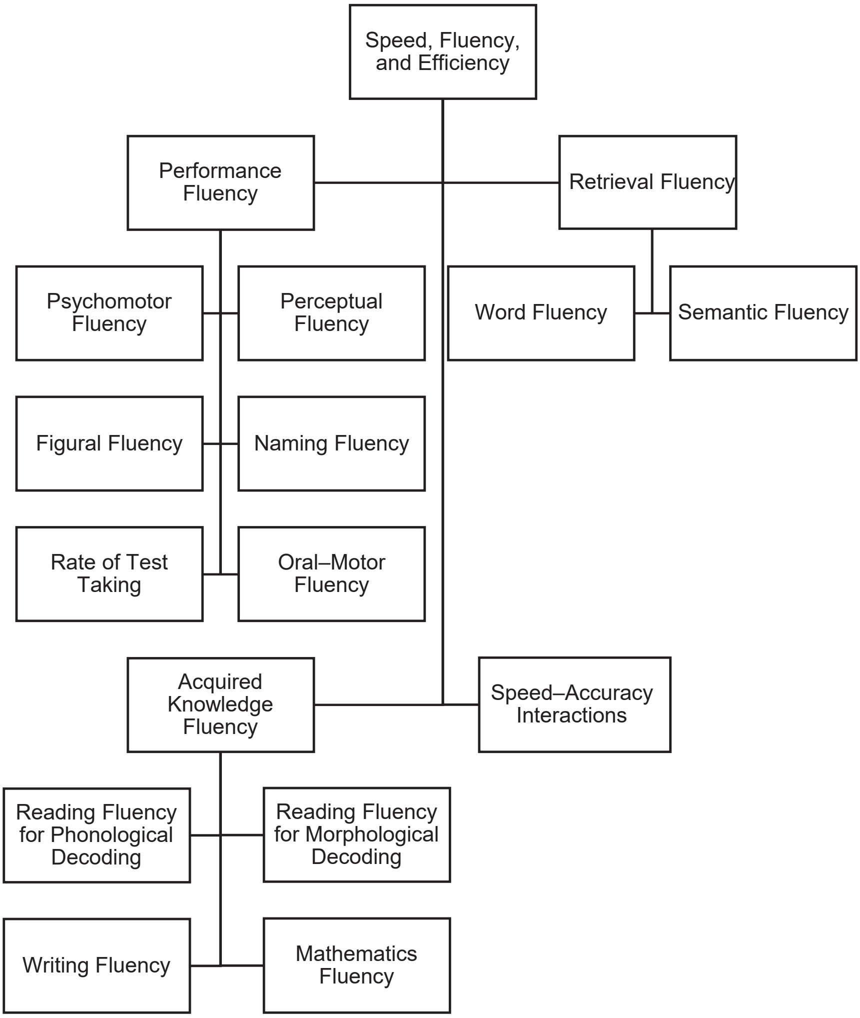

FIGURE 33.3. Speed, fluency, and efficiency of processing in the integrated SNP/CHC model.

Naming fluency is often referred to as rapid automatized naming (RAN). These tasks require an examinee to name common objects, colors, word, or letters quickly. The Rapid Automatized Naming and Rapid Alternating Stimulus Tests (RAN/RAS; Wolf & Denckla, 2005) are considered to be the gold standards in neuropsychological tests designed to measure naming fluency. Other neuropsychological tests that measure naming fluency include Color Word Interference—Conditions 1 and 2 from the D-KEFS and Speed Naming from the NEPSY-II. Several cognitive ability tests are also designed to measure naming fluency, including Rapid Naming on the DAS-II; Naming Speed Literacy and Naming Speed Quantity on the WISC-V; and Rapid Picture Naming on the WJ IV COG.

Oral–motor fluency tasks require the examinee to repeat words that are not real words quickly. The NEPSY-II has two tests, Oral Motor Sequences and Repetition of Nonsense Words, that require oral–motor fluency. Several achievement test batteries include tests that are designed to measure oral–motor fluency, but tests of cognitive ability do not include these types of measures.

Retrieval Fluency

Retrieval fluency is the ability to recall information quickly and accurately from long-term mem-

TABLE 33.8. Speed, Fluency, and Efficiency of Processing Measured on Traditional Neuropsychological Tests and Current Tests of Cognitive Abilities

Neuropsychological construct(s)	Traditional neuropsychological measures	Examples of neuropsychological measures in tests of cognitive abilities
	Performance fluency	
Psychomotor fluency	• D-KEFS: Trail Making—Condition 5 (Motor Speed) • NEPSY-II: Visuomotor Precision—Total Completion Time	• WISC-V Integrated: Coding Copy
Perceptual fluency		• CAS2: Planned Number Matching • DAS-II: Speed of Informational Processing • WISC-V: Cancellation • WPPSI-IV: Cancellation • WISC-V: Coding and Symbol Search • WPPSI-IV: Animal Coding and Bug Search • WJ IV COG: Number–Pattern Matching
Figural fluency	• D-KEFS: Design Fluency • NEPSY-II: Design Fluency	
Naming fluency	• D-KEFS: Color Word Interference—Conditions 1 and 2 • NEPSY-II: Speed Naming • RAN/RAS	• DAS-II: Rapid Naming • WISC-V: Naming Speed Literacy and Naming Speed Quantity • WJ IV COG: Rapid Picture Naming
Oral–motor fluency	• NEPSY-II: Oral Motor Sequences and Repetition of Nonsense Words	
	Retrieval fluency	
Word and semantic fluency	• D-KEFS: Verbal Fluency—Condition 1 (Letter Fluency) and Condition 2 (Category Fluency) • NEPSY-II: Word Generation—Initial Letter Total and Semantic Total	• WJ IV COG: Retrieval Fluency

ory. According to Miller (2013), the efficiency of retrieval strategies is what makes retrieval fluency an executive function, rather than just a measure of long-term memory. On neuropsychological tests, retrieval fluency is measured by using either verbal or nonverbal stimuli. Typically, verbal retrieval fluency tasks require the examinee to recall words that start with a particular letter or fit within a specific semantic category (e.g., food, pieces of furniture); nonverbal fluency tests usually require the examinee to generate unique designs or patterns quickly, using structured or unstructured visual arrays.

The neuropsychological tests that measure verbal retrieval fluency are Verbal Fluency (Conditions 1 and 2) on the D-KEFS and Word Generation on the NEPSY-II (see Table 33.8). Nonverbal retrieval fluency measures include the Design Fluency test on both the D-KEFS and the NEPSY-II. The only test of cognitive ability with a measure of retrieval fluency is the WJ IV COG.

Acquired Knowledge Fluency

Acquired knowledge fluency represents the automaticity of processing for rapid reading, writing, and math calculations. Neuropsychological and cognitive ability measures do not contain these types of tests, which are typically found on tests of achievement.

Speed–Accuracy Interactions

The interaction between speed and accuracy is an important consideration when assessment results are interpreted. Any time a test generates separate scores for completion time and accuracy (either the number of errors or the number correct), the speed–accuracy interaction can be examined. The best response on a test is average to above completion time with good accuracy. Some examinees rush through items, and accuracy suffers. Other examinees have learned to slow down to improve accuracy. Finally, some examinees with the most impairment are very slow and inaccurate. The following neuropsychological tests offer these types of comparisons: the D-KEFS Color Word Interference Test and the NEPSY-II Speeded Naming, Visuomotor Precision, and Inhibition tests. Perhaps the closest test on a cognitive ability battery designed to measure this same construct would be the WISC-V Block Design test with and without the time bonus.

CONCLUSIONS AND FUTURE DIRECTIONS

The major premise of this chapter—that the integration of neurocognitive constructs into tests of cognitive ability is somehow a new or emerging development—is false. In fact, many of these neurocognitive constructs have been found all along in tests of cognitive ability. Early researchers in cognitive assessment (e.g., Binet, Norsworthy, Terman, Wechsler, and Woodcock) were interested in measuring such cognitive constructs as processing speed, memory, or executive functions, but advances in psychometrics and test development led to an emphasis on empirical measurement within the field of cognitive assessment. As a result, there was an interpretive overemphasis on a singular global score as the best measure of intellectual functioning or the best predictor of academic achievement. Other developments within the field of psychology were also influential in the evolution of cognitive assessment. For example, as psychology moved away from the medical model, training programs in school, counseling, and clinical psychology gave less emphasis to the biological bases of behavior. For the most part, training programs in neuropsychology were the exceptions in this trend. In addition, because of the natural expansion in the knowledge base within the field (as well as a certain amount of territorialism/protectionism), psychology became more specialized or fractured, and the transfer of knowledge between related disciplines became less common. In cognitive assessment, this led to a narrow lens through which cognitive abilities were viewed and interpreted.

In actuality, there is far more integration between the disciplines of neuropsychology and cognitive assessment than many professionals realize. For example, many current tests of cognitive ability are composed of tasks that measure commonly identified neurocognitive constructs. In addition, current trends in interpretation of intellectual abilities are more theoretically driven than in the past and are being influenced by research on cognitive constructs of intelligence, which lends itself to a common nomenclature with the field of neuropsychology. Finally, the surge of interest in the neurosciences resulting from remarkable findings in brain science has generated a corresponding surge of research in the applicability of neuropsychology to cognitive assessment, bringing the field back to its historical origins.

To progress as a discipline, the next major advance in the integration of neuroscience and cognitive assessment has to be the use of neuroimaging techniques to validate associations between cognitive constructs and neurological functioning or brain structure, and then to validate the applicability of the various tasks or subtests being used to measure these neurocognitive constructs. This research should lead to more definitive conclusions about the connection between theoretical cognitive constructs and brain functioning, as well as to better identification of neurocognitive deficits with more targeted and applicable measures. Assessing neurocognitive functioning more accurately and parsimoniously should ideally lead to greater applicability for recommendations and interventions to address the manifestation of neurocognitive deficits in real-world settings.

In the meantime, best practice in assessment would suggest that individuals conducting cognitive and neurocognitive assessments need to (1) realize that current cognitive instruments are limited in their comprehensiveness, measuring only limited aspects of cognitive or neurocognitive constructs, and interpret them with this in mind; (2) understand that current cognitive instruments are best used as screeners for neurocognitive functioning, and that further assessment with more targeted measures (in the use of which they must be trained) may be required in the presence of suspected neurocognitive deficits; (3) recognize that a strong foundation or knowledge base in the neurosciences is necessary to use and interpret cognitive measures correctly from a neuropsychological perspective; and (4) appreciate the need for a theoretically based interpretive framework (Luria's theory, CHC theory, the integrated SNP/CHC model, Flanagan and colleagues' integrative interpretive model) within which to draw their conclusions.

The disciplines of cognitive assessment and neuropsychology have been, are, and will continue to be intertwined. Cognition, by definition, is brain-based; therefore, the assessment of cognition needs to be a brain-based endeavor. As the

21st century progresses, these two fields will evolve together, and perhaps psychologists in the future will express surprise that they were ever considered separate fields of study.

CHAPTER 34

Enhancing the Identification of Reading Disorders with Neuropsychological Tests

Marlene Sotelo-Dynega

A survey regarding the cognitive assessment practices of school psychologists (Sotelo-Dynega & Dixon, 2014) found that fewer than 40% of those sampled *always* interpreted the general/global ability score, and that "the majority of respondents reported that they typically used more than one test of intelligence or cognitive abilities during evaluations, mostly to follow up on hypotheses and/or aberrant score performances based on the results of the intelligence tests that were administered" (p. 1036). These data suggest that school psychologists may have begun to move away from traditional psychoeducational assessment methods that involve the interpretation of global ability scores, and toward more specific, diagnostic testing. According to Decker, Hale, and Flanagan (2013),

> Research has demonstrated that cognitive processes in many academic learning tasks are surprisingly complex. Most academic learning tasks require general cognitive processes such as attention, language, and memory. As such, low scores on any academic task could be the result of numerous factors. Not surprisingly, academic learning often involves numerous cognitive processes as well as cultural learning opportunities. Administering specific narrowly defined cognitive tasks helps to systematically isolate the underlying problem. The purpose of administering the tests is not to get an IQ score, but to help understand learning problems . . . and develop effective interventions. . . . This is an important distinction from viewing testing for the purpose of predicting achievement . . . (p. 303)

In fact, Decker and colleagues add that "school psychologists are in a unique position to take the lead role in the translation of brain research, cognitive neuroscience, and neuropsychological research related to neurodevelopmental disabilities into educational practice" (p. 303).

To bridge the gap between the literature and educational practice, school psychologists will have to expand upon their traditional, standard-battery-based testing approaches to include more comprehensive cognitive, neuropsychological, and diagnostic academic achievement measures. In 2010, a panel of experts on learning disabilities published a white paper that summarized their consensus opinions regarding the identification of specific learning disabilities (SLD), along with citations to support the rationales for their beliefs (Hale et al., 2010). Hale and colleagues (2010) stated that

> a strengths and weaknesses model makes good empirical, clinical, and legal sense because it ensures children identified with SLD demonstrate one or more processing deficits that interfere with academic achievement, the core characteristic of SLD . . . Not only does this processing strength and weaknesses approach make sense for SLD identification purposes, but processing assessment could also lead to more

> effective individualized interventions for children who do not respond adequately to intensive interventions in an RTI approach . . . (p. 229)

Considering that traditional assessment methods typically involve the use of a standard testing battery (i.e., the same tests are used regardless of the reason for a child's referral), a practitioner may sometimes have to use a more comprehensive cognitive or neuropsychological battery to identify a student's processing weaknesses. Although the most recent versions of the most popular intelligence/cognitive tests (the Wechsler scales, the Woodcock–Johnson IV [WJ IV], etc.) are more comprehensive than ever before, they are not necessarily exhaustive and lack comprehensive measures of neuropsychological processes. Therefore, once a detailed reason for testing is established, the practitioner should select an individualized battery of tests to assess the abilities or processes that have been found to be associated with the reported weaknesses. For example, if the child is having difficulty concentrating, then measures of attentional processes should be added to the battery. Although this approach to test selection is an ideal practice, is it practical or even reasonable to suggest that practitioners engage in more testing, given that school psychologists already spend nearly 50% of their time engaged in assessment (Castillo, Curtis, & Gelley, 2010a, 2010b; Fagan & Wise, 2007; Sotelo-Dynega & Dixon, 2014)? The response to this question of course depends on the practitioners themselves, their professional goals, and the available funding. To actualize this shift in practice, many school psychologists will have to request that additional tests be purchased and will have to seek additional training in the administration and interpretation of any new measures; both of these require additional financial resources.

To help facilitate this transition for practicing school psychologists, the remainder of this chapter describes a user-friendly framework that can be used with students who present with specific reading issues.

FRAMEWORK FOR IMPROVING THE IDENTIFICATION OF READING DISORDERS

Background Information

When a student is referred for an evaluation to rule out a reading disorder, the first step is typically to confirm that the reported reading problem exists (Flanagan, Alfonso, & Mascolo, 2010). Data obtained from the student's cumulative records, teacher and parent reports, and response to intervention (RTI) are critical pieces of information for the school psychologist to review in the identification process and can help to inform test selection and diagnostic decision making. With these data, the school psychologist can generate hypotheses regarding which cognitive or neuropsychological constructs may be related to the reported academic weaknesses, and can begin to build an individualized assessment battery. For example, if the student is struggling with decoding, deficits in phonological processing may be suspected, and therefore phonological and auditory processing should be assessed.

Unfortunately, some schools may not have formal pre-referral procedures in place. Therefore, the exact academic weaknesses may be unknown at the time of referral and may require a deeper investigation of the student's background and academic history information. Regardless of the background data available at the time of the referral, the practitioner is encouraged to complete a thorough background history with the student's parents. The Behavior Assessment System for Children, Third Edition (Reynolds & Kamphaus, 2015), includes a Structured Developmental History; this is an excellent tool that comprehensively covers an abundance of relevant domains. Information from a thorough background interview can assist in generating hypotheses in the absence of concrete academic data.

Another useful tool for hypothesis generation is Miller's (2012) Neuropsychological Processing Concerns Checklist for School-Aged Children and Youth, Third Edition (NPCC-3). The NPCC-3 is a multipage checklist that is completed by the student's parents and teachers. Each respondent is asked to rate the severity of the student's functioning in several neuropsychological and academic domains: sensory–motor, visual–spatial, and auditory processes; learning and memory, executive functions, attention, and working memory; speed, fluency, and efficiency of cognitive processing; language, reading, and writing; and mathematics. Furthermore, the NPCC-3 provides the respondent with the opportunity to describe specific concerns in each of these domains. The information that can be obtained from this checklist can provide the practitioner with highly specific, qualitative information regarding the student's strengths and weaknesses that can guide test selection, hypothesis development, and approaches to intervention.

This instrument is not only invaluable for practitioners looking to incorporate neuropsychological testing into their assessment practices, but also for those who have received limited pre-referral data regarding the students that they will be evaluating.

Depending on the data gathered during this first step of the assessment, the use of additional rating scales may be warranted. For example, if the student is exhibiting symptomatology consistent with a diagnosis of attention-deficit/hyperactivity disorder (ADHD), the practitioner should most likely incorporate data from the administration of one or several relevant behavior rating scales. Whenever possible, it is best to obtain information about a student's behavior from several informants (e.g., parents, classroom teacher, reading specialist) representing different environments (e.g., home, classroom, resource room). Generally, the practitioner wants to assess whether or not the behavior is consistent across each setting. If the behavior is affecting the student's learning experience, a functional behavioral assessment may be warranted.

Assessment Planning

Although the suggestions listed in the previous step are relatively similar to those utilized during the traditional psychoeducational assessment process, assessment planning will most likely differ significantly. An interpretive approach developed by Flanagan and colleagues (2013) can be used to guide this phase of the evaluation process. The approach depicted in Figure 34.1 incorporates the "Cattell–Horn–Carroll (CHC) theory of human cognitive abilities, neuropsychological, and Lurian perspectives" (p. 129) to guide practitioners in the development of a comprehensive assessment battery for students presenting with a variety of issues that affect learning. Although a detailed description of this approach is beyond the scope of this chapter (the reader is encouraged to refer to the Flanagan et al. book), it important to note that all of its components are essential in comprehensively assessing students, particularly those with reading difficulties. CHC theory is a "taxonomy of cognitive abilities . . . [and] a set of theoretical explanations of how and why people differ in [these] abilities" (Schneider & McGrew, 2012, p. 99), and it has been described as "the best validated model of human cognitive abilities" (Ackerman & Lohman, 2006, p. 140). Furthermore, the inclusion of neuropsychological perspectives arranged according to Luria's (1970) theory is important, considering the "wealth of research on the neurobiological bases of childhood learning disorders . . . [and] increased emphasis on the identification of processing disorders among children diagnosed with a SLD" (Miller, 2013, p. 1), as well as the "empirical research that strongly supports Luria's clinical documentation of the three functional units" (Kaufman, Lichtenberger, Fletcher-Janzen, & Kaufman, 2005, p. 6).

For the purposes of this chapter, each facet of Flanagan and colleagues' (2013) framework is briefly described, in order to provide an empirical rationale for assessing each of these domains. The primary aim is to highlight the most salient research currently available in each domain regarding the relationships between CHC and neuropsychological constructs and reading issues among school-age children. Practitioners must be careful not to "over-test" the students they are working with. Therefore, they are advised to gather sufficient background information (using the tools described in the previous section) to develop specific hypotheses to guide test selection. Once an initial set of tests is scored, a practitioner may have to reframe the hypotheses according to the findings and administer additional tests.

Lurian Block 1

According to Luria (1973), "human mental processes are complex functional systems . . . that take place through the participation of groups [blocks] of concertedly working brain structures, each of which makes its own particular contribution" (p. 43). The first block, as described by Luria, includes the functions of the brainstem. Some of the main tasks of the brainstem are to "regulate the individual's ability to maintain arousal and attention" (Kaufman et al., 2005, p. 6). The neuropsychological domains included in this block are attention, sensory–motor functions, and speed/efficiency; adequate functioning in these domains is essential for learning, as described in detail below.

Attention

Without attention, learning cannot take place. Students have to be alert, aware, attentive, and available to learn. Although multiple behavioral, emotional, and wellness-related factors can affect an individual's attentional capabilities and should be investigated and ruled out, brain-based attentional issues must also be considered. In a review of

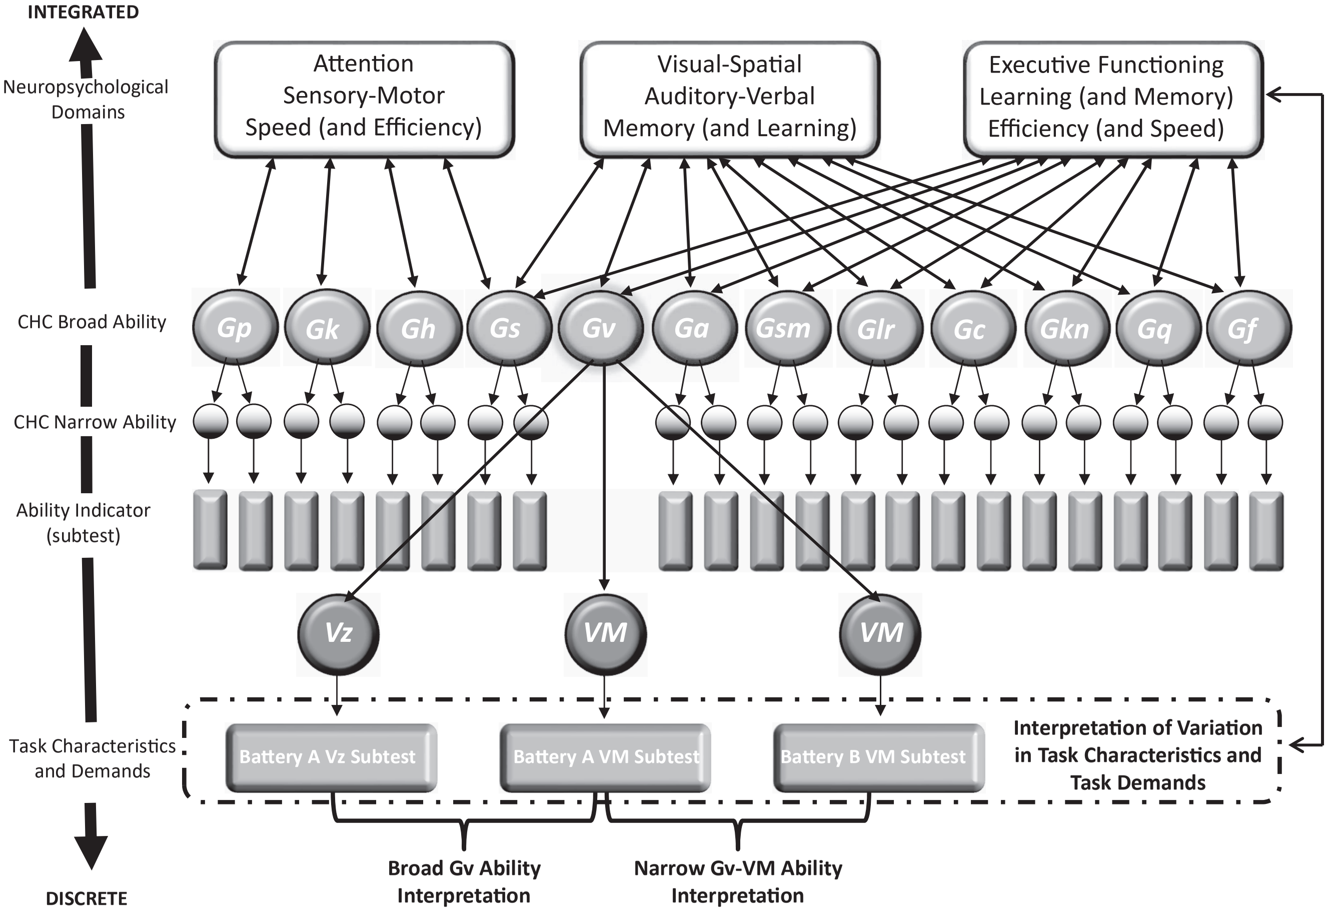

FIGURE 34.1. Integration of psychometric, neuropsychological, and Lurian perspectives for interpretation. From Flanagan, Ortiz, and Alfonso (2013, p. 129). Copyright © John Wiley & Sons, Inc. Reprinted by permission.

the literature on the neurobiology of reading and dyslexia, Shaywitz and Shaywitz (2008) conclude that "attentional mechanisms play a critical role in reading and that disruption of these attentional mechanisms play[s] a causal role in reading difficulties" (p. 1343). These mechanisms can affect every facet of the reading process, including the development of phonological and orthographic reading skills, fluency, and comprehension. Therefore, whenever attentional issues seem to exist for a student, a school psychologist should investigate whether such issues are a potential cause for the student's reading problem. The practitioner can gather this information via the procedures listed earlier in the discussion of background information, as well as via direct behavioral observation of the student's behavior. If necessary, the practitioner can then confirm or rule out attentional issues via standardized measures of attention.

Sensory–Motor Functions and Speed/Efficiency

The next domains to assess include the sensory and motor functions of the brain, as well as the individual's ability to process simple information quickly. Sensory and motor functions "serve as a baseline for all of the higher-order processes (e.g., visual–spatial processing, language skills, memory and learning)" (Miller, 2013, p. 261). For example, if a student has difficulties with visual acuity, or has a fine motor weakness, then all other tasks that involve those abilities will most likely be affected. Although practitioners are encouraged to assess sensory and motor functions, the results should be either confirmed or ruled out by specialists in each of these domains (e.g., ophthalmologists, audiologists, occupational or physical therapists).

According to Miller (2013), tests that measure "speed, fluency, and efficiency of processing [are] classified as a type of facilitator/inhibitor . . . almost all cognitive and behavioral tasks require some aspects of processing speed to increase the automaticity of responses. However, fast processing speed is not always a desired outcome as evidenced by the child who rushes through an assignment to get it done, but makes multiple errors in completing the task" (p. 399). Therefore, when assessing a student's processing speed, a practitioner should qualitatively evaluate how the student achieved the score: Were the responses quick and accurate, quick and inaccurate, slow and accurate, or slow and inaccurate? Considering that processing speed tasks (particularly measures of perceptual speed) have been found to be related to slower reading speed, by qualitatively analyzing how a student earns scores on these tasks, the school psychologist can generate hypotheses as to how the student approaches similar speeded tasks in the academic environment.

Tables 34.1, 34.2, and 34.3 have been developed to provide the reader with a concise, (although not exhaustive) summary of the literature regarding the relations between specific narrow cognitive/neuropsychological domains and reading-related issues. The purpose of these tables is to allow the reader to gauge the importance of including these constructs as part of a comprehensive school-based assessment when evaluating students with reading issues. Although the majority of narrow domains listed in these tables and their relationships to reading issues are supported by at least one study, I have also included some logical but not empirically supported hypotheses as to how low scores on measures of these narrow abilities might affect the reading process. These hypotheses are listed without citations.

Table 34.1 highlights the broad and narrow domains that are associated with Luria's Block 1 and the related domain-specific reading issues that can be manifested when weaknesses are present in those domains. Flanagan and colleagues (2013), Feifer (2010), and Miller (2013) provide various test suggestions for many of these constructs. The reader is urged to select measures that are current and psychometrically sound. Furthermore, if weaknesses are identified, best practices suggest that low scores be confirmed as representing true weaknesses by administering follow-up tests measuring the same abilities (Flanagan et al., 2013). If a suspected weakness is confirmed, the practitioner should also explain how this weakness has been manifested, or can potentially be manifested, in the academic setting (Miller, 2013).

Lurian Block 2

Luria's second block is responsible for "receiving, analyzing and storing information" (Luria, 1973, p. 67) that is projected onto the occipital, temporal and parietal lobes. Cognitive and neuropsychological abilities and processes that help determine the effectiveness and efficiency of this block include visual processing, auditory processing, short-term memory, and learning ability.

Visual Processing

According to Schneider and McGrew (2012), "visual processing can be defined as the ability to make use of simulated mental imagery (often

TABLE 34.1. Lurian Block 1 Domains and Possible Domain-Specific Reading Issues When Weaknesses Are Present

Broad domain	Narrow domain	Possible domain-specific reading issues when weaknesses are present
Attention	Selective/focused attention	• Difficulty remaining focused on reading tasks • Slower reading rate (Casco, Tressoldi, & Dellantonio, 1998) • Letter sequence errors and confusions (Yap & van der Leij, 1993) • Irregular-word reading difficulties (Valdois, Bosse, & Tainturier, 2004)
	Sustained attention	• Difficulty sustaining attention to task when reading lengthier passages • Weaknesses in reading comprehension (Stern & Shalev, 2013) • Decoding weaknesses (Arrington, Kulesz, Francis, Fletcher, & Barnes, 2014)
	Attentional capacity	• Difficulties with reading comprehension (Engle, Carullo, & Collins, 1991; Leather & Henry, 1994; Seigneuric & Ehrlich, 2005)
Sensory functions	Auditory acuity	• Possible hearing and/or auditory processing issues • Phonologically based reading issues (e.g., reading decoding)
	Visual acuity	• Possible visual and/or visual processing issues • Visually/orthographically based reading issues (e.g. irregular word reading)
	Tactile sensation/ perception	• Difficulties with fine motor activities, and/or hyper- or hyposensitivity to certain sensations that could affect the student's attention and availability to learn (Miller, 2013)
Motor functions	Fine motor functions	• Limited vocabulary and reading speed (Viholainen et al., 2006)
	Visual–motor functions	• Impaired general reading performance (Kavale, 1982; Keogh & Smith, 1967; Mazzola Sortor & Taylor Kulp, 2003; Taylor Kulp, 1999)
	Visual scanning/ tracking	• Difficulty reading words printed on a line (Miller, 2013) • Text-reading issues (De Luca, Di Pace, Judica, Spinelli, & Zoccolotti, 1999; Diller, 1974)
Speed/ efficiency	Perceptual speed	• Slow reading speed (Flanagan, Ortiz, & Alfonso, 2013; Flanagan, Ortiz, Alfonso, & Mascolo, 2006) • Weaknesses in basic reading skills (Johnson, Humphrey, Mellard, Woods, & Swanson, 2010; McGrew & Wendling, 2010; Pennington, 2009) • Weaknesses in reading comprehension (McGrew & Wendling, 2010; Tiu, Thompson, & Lewis, 2003)
	Rate of test taking	• Weaknesses in reading comprehension (McGrew & Wendling, 2010)

in conjunction with currently perceived images) to solve problems" (p. 129). To date, there is no evidence to support the idea that visual processing constructs are related to the process of reading. The absence of evidence supporting a relationship between reading and visual processing may very well be the result of how we define the constructs subsumed by visual processing and how we measure them. According to Feifer (2010), "while reading may begin as a visual process, it ends as a linguistic one" (p. 492). Therefore, constructs such as orthographic processing may be more useful in the assessment of reading disorders. Orthographic processing is described as a broad term given to a group of constructs that enable (or inhibit) the acquisition of orthographic knowledge (Apel, 2011). Orthographic knowledge "represents information that is stored in memory that tells us how to represent spoken language in written form" (Apel, 2011, p. 592). Orthographic processing skills are critical in the acquisition of sight word vocabulary and reading fluency. Unfortunately, little is currently known about the cognitive/neuropsychological processes underlying the acquisition of these skills, which play such a large role in the reading process.

Auditory Processing

Auditory processing involves the "ability to detect and process meaningful nonverbal information in sound" (Flanagan et al., 2013, p. 404). This ability allows us to develop associations between letter sounds (phonemes) and their respective graphemes, which then leads to the process of decoding, or sounding out the words that we read. As presented in Table 34.2, extensive research has demonstrated that multiple constructs subsumed by auditory processing (not all listed in the table), particularly phonemic awareness, are highly related to the development of reading. As previously mentioned, considering that the majority of referrals school psychologists will receive are related to reading issues, it would be a disservice to any referred student to omit assessment of this construct during an evaluation. Unfortunately, the majority of cognitive measures available today

TABLE 34.2. Lurian Block 2 Domains and Possible Domain-Specific Reading Issues When Weaknesses Are Present

Broad domain	Narrow domain	Possible domain-specific reading issues when weaknesses are present
Visual–spatial processing	Visual–spatial perception	No literature available
	Visual–spatial reasoning	No literature available
Auditory processing	Sound discrimination	Weaknesses in basic reading skills (McGrew & Wendling, 2010)
	Auditory processing	• Weaknesses in general reading (Flanagan, Ortiz, Alfonso, & Mascolo, 2006) • Weaknesses in basic reading skills (McGrew & Wendling, 2010) • Weaknesses in reading comprehension (McGrew & Wendling, 2010) • Weaknesses in word reading (Compton, Olson, DeFries, & Pennington, 2002; Olson, Forsberg, Wise, & Rack, 1994; Hulslander et al., 2004; Kamhi & Pollock, 2005; National Reading Panel, 2000; Wagner & Torgesen, 1987)
Memory (and learning)	Verbal immediate memory	• Weaknesses in basic reading skills (Baddeley, 2006; De Jong, 2006; Hutton & Towse, 2001). • Weaknesses in reading comprehension (Just & Carpenter, 1992; Turner & Engle, 1989)
	Visual immediate memory	• Weaknesses in reading comprehension (McGrew & Wendling, 2010)
	Verbal long-term memory	No literature available
	Visual long-term memory	No literature available
	Verbal–visual associative memory	No literature available
	Working memory	• Difficulties with decoding (Palmer, 2000) • Weaknesses in reading comprehension (Cain, Oakhill, & Bryant, 2004; Daneman & Carpenter, 1980; Daneman & Merikle, 1996; De Beni, Borella, & Carretti, 2007; De Jong, 2006; Goff, Pratt, & Ong, 2005; Hulme & Mackenzie, 1992; Just & Carpenter, 1992; Linderholm & Van Den Broek, 2002; Seigneuric & Ehrlich, 2005; Seigneuric. Ehrlich, Oakhill, & Yuill, 2000; Swanson, 2010; Swanson, Howard, & Saez, 2006)

do not include measures of this ability (Flanagan et al., 2013). Therefore, practitioners are encouraged to use a battery that includes this construct, to supplement their preferred assessment battery with measures of this construct, or to consult with a speech–language pathologist to ensure that they have assessed a student's functioning in this domain.

Memory and Learning

According to Miller and Blasik (2010), "memory and learning are very similar and can be easily confused . . . Memory is the ability to recall past events and information. Learning is a process of linking memories with new experience; therefore, memory is essential to learning and memory is dependent on learning" (p. 641). Dehn (2010) adds that "there is no learning without memory, and there is no memory without learning" (p. 4). Therefore, to thoroughly assess a student's functioning in this domain, the three main aspects of memory and learning must be evaluated: encoding, consolidation, and retrieval of information.

Encoding involves the pairing of new information obtained via short-term and working memory with already learned information that has been stored in long-term memory. Foundational abilities that include short-term and working memory must therefore be evaluated to determine whether or not the means by which information enters the brain are functioning as expected. As presented in Table 34.2, abilities such as verbal and visual immediate memory, as well as working memory, have been shown to be related to the development of basic reading skills and comprehension. Consolidation occurs when the new memories are stored in the brain, and retrieval involves efficient access to the memories that have been consolidated (Dehn, 2010). An individual's consolidation skills can be assessed via both immediate and delayed measures of verbal and visual associative memory. Typically, these types of tasks require the examinee to pair at least two nonrelated stimuli and to recall them immediately and after some time has elapsed, respectively. Unfortunately, empirical data to support the relationship of consolidation skills with the process of reading are lacking. Finally, the retrieval of information (discussed in more detail in the section on Lurian Block 3) involves the efficiency with which an individual is able to access the information that has been consolidated or stored in long-term memory. A lack of efficiency in any aspect of this process—encoding, consolidation, or retrieval—can significantly disrupt the learning process, which in turn can directly affect the different aspects of the reading process.

Lurian Block 3

According to Luria (1973), Block 3 involves the functions of the frontal lobes that include "programming, regulation and verification of activity" (p. 79). Some of the primary functions of this block are referred to as a group of skills known as *executive functions*. In addition to executive functions, other abilities/processes that are measured for this block include learning and memory, and crystallized knowledge.

Executive Functions

According to McCloskey and Perkins (2013), "executive functions can be viewed as an overarching developmental cognitive neuropsychological construct that is used to represent a set of neural mechanisms that are responsible for cueing, directing, and coordinating multiple aspects of perception, emotion, cognition, and action (Gioia, Isquith, Guy, & Kenworthy, 1996; McCloskey, Perkins, & Van Divner, 2009; Stuss & Alexander, 2000)" (p. 8). As presented in Table 34.3, various executive functions have been found to be related to different aspects of the reading process, but they primarily have to do with the more complicated aspects of reading that require higher-order thinking (e.g., reading comprehension). For example, measures of fluid reasoning typically involve assessing an individual's ability to solve problems with verbal or visual information. If this ability is not intact, the student may demonstrate considerable difficulties when asked to respond to questions about written text, especially if the questions are inferential in nature and cannot be immediately identified in the text.

Learning and Memory

As previously mentioned, learning and memory work simultaneously. When the abilities subsumed under this domain are classified, those related to memory processes are more in line with the brain functions associated with Lurian Block 2, whereas those related to the assessment of the retrieval of previously learned information are better classified in Lurian Block 3. Specifically, measures of abilities such as retrieval fluency and naming fa-

TABLE 34.3. Lurian Block 3 Domains and Possible Domain-Specific Reading Issues When Weaknesses Are Present

Broad domain	Narrow domain	Possible domain-specific reading issues when weaknesses are present
Executive functioning	Cognitive flexibility	• Problems related to language processing (Deák, 2000, 2003; Jacques & Zelazo, 2005) • Weaknesses in general reading ability (Arlin, 1981; Briggs & Elkind, 1973; Canter, 1975; Cohen, Hyman, & Battistini, 1983; Elkind, Larson, & Van Doorninck, 1965; Reiter, Tucha, & Lange, 2005) • Weaknesses in reading comprehension (Cartwright, 2002, 2006, 2007; Cartwright, Marshall, Dandy, & Isaac, 2010)
	Concept formation	No literature available
	Planning	• Weaknesses in reading comprehension (Keeler, 1995; Palincsar & Brown, 1984; Pearson & Fielding, 1991; Pressley, 2000; Reiter et al., 2005; Sesma, Mahone, Levine, Eason, & Cutting, 2009; Tierney & Cunningham, 1984). • Weaknesses in single-word reading (Sesma et al., 2009)
	Fluid reasoning	• Weaknesses in reading comprehension (Flanagan, Ortiz, Alfonso, & Mascolo, 2006; McGrew, 1993; McGrew & Wendling, 2010).
	Response inhibition	• General reading weaknesses (Altemeier, Abbott, & Berninger, 2008; Palmer, 2000) • Weaknesses with reading comprehension (De Beni & Palladino, 2000; Savage, Cornish, Manly, & Hollis 2006; Savage, Lavers, & Pillay, 2007)
Learning and memory	Retrieval fluency	No literature available
	Naming facility	• Weaknesses in word reading (Ackerman & Dykman, 1993; Blachman, 1984; Bowers, 1995; Bowers & Swanson, 1991; Compton, 2000; Manis, Doi, & Bhadha, 2000; Manis, Seidenberg, & Doi, 1999; McBride-Chang & Manis, 1996; Meyer, Wood, Hart, & Felton, 1998; Scarborough, 1998; Schatschneider, Francis, Fletcher, & Foorman, 2002; Vellutino et al., 1996; Wagner, Torgesen, & Rashotte, 1994; Wolf, Bally, & Morris, 1986)
Crystallized knowledge	Language development	• Difficulties with reading comprehension (Catts, Fey, Zhang, & Tomblin, 2001; Dehn, 2008; Leach, Scarborough, & Rescorla, 2003; Nation, Marshall, & Snowling, 2001; Nation & Snowling, 1998, 1999; Was & Woltz, 2006)
	General verbal information	• Difficulties with basic reading skills (McGrew & Wendling, 2010) • Difficulties with reading comprehension (McGrew & Wendling, 2010)

cility (also known as rapid automatized naming) assess how efficiently the individual is able to retrieve information that has already been encoded and consolidated in long-term memory. Although there is no literature available to support the relation between ideational fluency and reading, a great deal of work has shown that those individuals with deficits and weaknesses in naming facility struggle with word reading. Typically, tasks that assess naming facility require the examinee to rapidly identify the names of letters, numbers, colors, or common objects. When asked to identify the name of a stimulus, students with reading impairments are often able to do so, but at a much slower pace than nonimpaired readers (Wolf, Grieg Bowers, & Biddle, 2000). This difficulty mimics the difficulties that poor readers experience when trying to automatically recognize a printed word. In this case, it is not necessarily true that the individuals have difficulties with the foundational aspects of word reading; rather, they struggle to automatically retrieve the names of words that have already been encoded and consolidated in their long-term memory.

Crystallized Knowledge

Crystallized knowledge is defined as "the depth and breadth of knowledge and skills that are valued by one's culture" (Schneider & McGrew, 2012, p. 122). The assessment of crystallized knowledge typically involves the measurement of language development and general verbal information. Language development entails a "general understanding of spoken language at the level of words, idioms, and sentences" (Flanagan et al., 2013, p. 389), and general verbal information is defined as "the breadth and depth of knowledge that one's culture deems essential, practical, or otherwise worthwhile for everyone to know" (Flanagan et al., 2013, p. 389). As presented in Table 34.3, individuals with weaknesses in these areas tend to struggle with tasks that require reading comprehension. Logically, to comprehend what is being read, a reader must first have an adequate understanding of language, and must also be able to draw from personal experiences to make sense of the content and respond to questions about it. Fortunately, all of the major cognitive tests available today include measures of crystallized knowledge (Flanagan et al., 2013); therefore, it will not be a challenge for school psychologists to incorporate this construct into their assessment batteries.

Administration, Scoring, and Interpretation of Tests

Administration

Considering that the majority of constructs included in Flanagan and colleagues' (2013) framework derive from CHC theory, school psychologists can easily assess many of these factors through the complete administration of one of the newly released cognitive batteries and their accompanying achievement tests. Practitioners must be cognizant of what the tests are actually measuring, however. For example, if a broad construct (e.g., visual processing, auditory processing) is to be adequately assessed, it is necessary for that construct to consist of at least two qualitatively different narrow indicators (Flanagan et al., 2013). In the event that a construct is not adequately assessed as part of a test battery, the practitioner is advised to supplement this battery with measures from another test. The reader is encouraged to refer to Flanagan and colleagues (2013) for detailed guidelines regarding how to organize a comprehensive battery that is consistent with CHC theory and how to interpret scores on clusters that are derived from different test batteries.

Once the practitioner has comprehensively evaluated the student's academic achievement and CHC-based cognitive abilities, additional tests may be necessary. For example, if the student has been referred for reading comprehension difficulties, measures of attention, memory and learning, and executive functioning may be warranted, according to the research summarized in Tables 34.1, 34.2, and 34.3. Typically, neuropsychological assessment involves the inclusion of tests representing all of the neuropsychological domains. The assessment strategy presented herein may actually be more practical for use by school psychologists because it will enhance the amount of information available to these practitioners without having to engage in cumbersome, unnecessary testing.

Scoring and Interpretation

Scoring procedures should not differ from the recommendations provided by test authors for each of the measures used in the assessment. Although test authors typically provide guidelines for score interpretation, it is my own preference to utilize an interpretive framework that takes into consideration whether a student's performances are within normal limits, or normatively strong or weak. Such information provides the practitioner with the ability to differentiate weaknesses from deficits. Table 34.4 displays a suggested guide to score interpretation that can be applied to all tests. All scores that are normatively weak (i.e., standard scores below 85) should be considered as deficits, and scores that are below average but within normal limits (i.e., standard scores of 85–89) should be considered to be weaknesses. This differentiation is important when practitioners are interpreting results because weaknesses warrant attention even when they do not constitute a disorder per se. Therefore, "because research demonstrates that the relationship between the cognitive dysfunction and the manifest learning problems are causal in nature . . . , data analysis at this level should seek to ensure that identified weaknesses or deficits on cognitive and neuropsychological tests bear an empirical relationship to those weaknesses or deficits on achievement tests identified previously" (Flanagan et al., 2013, p. 252). Therefore, when interpreting test results, the examiner must connect the results obtained from cognitive and neuropsychological tests to the achievement test results and to the data obtained from the real-world learning environment. Furthermore, suggestions for interventions, accommodations, and program

TABLE 34.4. Suggested Guide to Score Interpretation

Standard score/*scaled score*	Description of performance	Normative range
131 or above/*17 and above*	Upper extreme	Normative strength
116–130/*14–16*	Above average	Normative strength
85–115/*7–13*	Average	Within normal limits
70–84/*4–6*	Below average	Normative weakness
69 or below/*3 or below*	Lower extreme	Normative weakness

modifications should be made accordingly for all identified deficits and weaknesses.

Linking Results to Recommendations

Among the most important aspects of a comprehensive assessment are the recommendations made by the school psychologist. Regardless of the outcomes of the evaluation, the fact that the student was referred for an evaluation suggests that one or more issues have been occurring in the academic or home environment that warrant comprehensive assessment. Therefore, it is the school psychologist's responsibility to make suggestions aimed at improving the reason for the student's referral issue(s). Mascolo, Alfonso, and Flanagan (2014) present a very practical method for tailoring interventions, which they call a "systematic method of analyzing assessment results for tailoring interventions" (SMAARTI). The SMAARTI "involves the organization, analysis, and synthesis of assessment data to aid in understanding the cognitive basis of students' learning difficulties. Based on multiple data sources, the steps of the SMAARTI assist in identifying various methods of tailoring intervention" (pp. 4 and 6). Mascolo and colleagues provide the reader with guidelines regarding when (and how) to make suggestions for modifications, accommodations, remediation, and compensation.

CONCLUSIONS

Although a great deal of currently available research supports the relationships between specific cognitive and neuropsychological constructs and reading skills, significantly more research is necessary to elucidate relationships between the numerous abilities measured by tests commonly available to practitioners. School psychologists are in a unique position to make a difference for children with reading difficulties in the manner in which they assess, identify, and intervene in these difficulties. The literature summarized in this chapter reveals the need for school psychologists to go beyond traditional psychoeducational assessment practices by including additional measures of less commonly measured cognitive and neuropsychological constructs. By following the simple framework described herein, practitioners will be able to comprehensively assess students that are referred to them for reading-related issues in a way that is consistent with the research literature and limits the amount of testing conducted. School psychologists who engage in these practices will be better able to determine *why* these students are struggling with reading, which will lead to more individualized suggestions for intervention.

CHAPTER 35

Incorporating Recent Advances in Understanding Word-Reading Skills into Specific Learning Disability Diagnoses

The Case of Orthographic Mapping

David A. Kilpatrick

BACKGROUND

In the spring of 1988, I took a graduate course in neuropsychology from Larry Lewandowski at Syracuse University. After describing the inadequate nature of the neuropsychological tests available at the time, he stated that the best tool we had for conducting a neuropsychological evaluation was between our ears. He indicated that the more we knew about the functioning of the brain, the better equipped we would be to select and interpret cognitive and neuropsychological tests and subtests to address the questions we would want to answer. This chapter is written in the spirit of Lewandowski's comment. It may differ from other chapters in this volume, in that only a portion of it is devoted to some critical "nuts-and-bolts" issues of diagnosing specific learning disabilities (SLD) in reading. However, it provides important background information for understanding the very nature and causes of word-level reading difficulties. Such a knowledge base will help practitioners conduct more informed evaluations and make more valid decisions regarding SLD in word-level reading.

Why a Special Chapter on Word-Level Reading?

The reason for this rather in-depth chapter on the nature of word-level reading problems is quite simple: Approximately 80–85% of students diagnosed with SLD have reading disabilities, and the vast majority of these students have word-level reading issues (Fletcher, Lyon, Fuchs, & Barnes, 2018; Lerner & Johns, 2012). The term *word-level reading disabilities* refers to SLD in basic reading and/or reading fluency. Far and away the most common type of SLD, word-level reading disabilities can occur alone or may be comorbid with SLD in reading comprehension, writing, or math. Given the sheer magnitude of SLD in reading, and the vast empirical research that has been conducted to investigate such problems, it seems judicious to examine word-reading difficulties in a fair degree of depth.

The Psychology of Reading

The late Robert Crowder was a cognitive psychologist at Yale University. In his book *The Psychology of Reading* (1981), he mentions an interesting insight regarding the relationship between the field of psychology and research on reading. He said that the cognitive revolution from the 1950s to 1970s involved studying perception, input, storage, and retrieval. Various stimuli were used to examine these phenomena, including letters of the alphabet, written words, sentences, and paragraphs. By the 1970s, it became recognized that the field of cognitive psychology had unwittingly amassed hundreds of studies on reading. The goal had been to understand complex cognitive processes; the reading-related stimuli were only the raw materials for studying those cognitive processes (Crowder, 1981).

An examination of the departmental affiliations in the empirical research reports on reading acquisition and reading disabilities indicates that the lion's share of scientifically oriented research articles come from departments of psychology around the globe. Reading research is, however, a highly interdisciplinary pursuit: It is shared by such fields as speech pathology, linguistics, special education, general education, literacy, neurology, and pediatrics. Nonetheless, the field of psychology has arguably made the largest volume of contributions to the hundreds of scientifically oriented reports on reading acquisition and reading disorders that appear every year (Kilpatrick, 2015).

Reading Research versus Classroom Practice

Most unfortunately, this large and heavily grant-funded body of research has not made inroads into the teaching of reading in our nation's K–12 schools. It has been pointed out by numerous sources that "a chasm exists between classroom instructional practices and the research knowledgebase on literacy development" (American Federation of Teachers, 1999, p. 7; see also Joshi, Binks, Graham, et al., 2009; Joshi, Binks, Hougen, et al., 2009; Kilpatrick, 2015; Moats, 1994, 2009; Seidenberg, 2017). One attempt to close this gap between research and practice was the implementation of *response to intervention (RTI)*. RTI was prompted by federal grant initiatives on reading that yielded highly encouraging findings in terms of preventing and correcting reading problems (Foorman, Francis, Fletcher, Schatschneider, & Mehta, 1998; National Reading Panel, 2000; Torgesen et al., 2001; Vellutino et al., 1996). The original intent of RTI was to scale up that research, so that all at-risk and struggling readers in the United States would benefit from these highly effective approaches. Most unfortunately, however, the implementation of RTI focused on the processes, frameworks, universal screenings, and progress monitoring for RTI, while the actual instructional and intervention practices that were so highly successful in those seminal studies were never adequately communicated (Kilpatrick, 2015; Seidenberg, 2017). Teachers have been charged with using "research-based" or "evidence-based" instructional practices, without knowing what those practices were (Seidenberg, 2017). As a result, a recent federal report indicated that RTI is having little or no impact on the students it is designed to serve (Balu et al., 2015).

It appears that school psychologists, like teachers, are not likely to be incorporating the findings from the reading research into their professional practice. A study published in *School Psychology Review* indicated that school psychologists, by and large, are not familiar with some of the most important findings from empirical studies of reading acquisition and reading difficulties/disabilities (Nelson & Machek, 2007). The present chapter is intended to provide information about some important recent advances related to word-level reading difficulties that practitioners should consider when evaluating and diagnosing students who display such difficulties.

READING WORDS VERSUS LEARNING WORDS

One of the most plausible reasons for the limited effects of RTI appears to be that educators continue to teach reading the way they have always taught it, but now they do so within an RTI framework (Kilpatrick, 2015; Seidenberg, 2017). There is no evidence that the highly effective general and remedial instructional techniques used in the federal grant initiatives that prompted RTI have been widely incorporated into our schools, while there is evidence that they are not (e.g., Joshi et al., 2009). This would account for the null results found in the recent federal report (Balu et al., 2015). An important problem related to this is that neither of the two dominant reading approaches used in schools over the last 40 years properly distinguishes between *reading* words and *learning* words. They focus on the former without adequately addressing the latter. This is problematic because the most highly successful outcomes in the reading research literature appear to have facilitated the ability to learn and remember words, not just to read and identify them (Kilpatrick, 2015).

The most common approach to teaching reading in the United States in recent decades has been the three-cueing-systems approach. This approach was made popular by the whole language movement in the 1980s and 1990s and now forms the foundation of balanced instruction, Reading Recovery, and the Leveled Literacy Intervention (commonly known as LLI). The three-cueing-systems model teaches students to read words and sentences by using three types of cues: (1) the *context* of the sentence or passage; (2) the *linguistic* features of the words (grammar and syntax), and (3) the *grapho-phonic* features (i.e., letters and sounds) of the word (Goodman, 1996). The second most common approach to reading instruction has been phonics. The phonics approach encourages students to use knowledge of letter–sound relationships to "sound out" unfamiliar words. The phonics approach has been shown to yield superior results to the three-cueing-systems approach, particularly for weak readers (Bond & Dykstra, 1967; Brady, 2011; Ehri, Nunes, Stahl, & Willows, 2001; National Reading Panel, 2000; Moats, in press; Share, 1995).

The problem with both of these approaches is that they focus on developing students' abilities to *identify* words. This is not the same as *learning* those words. A word can be read or identified without actually being learned or remembered. When this happens, a word that has been correctly identified via phonic decoding or contextual guessing may not be remembered when encountered in the next paragraph, and most likely not remembered when encountered the next day. By contrast, skilled readers are very adept at remembering the words they read. From second grade on, skilled readers learn newly encountered words after only one to four exposures (Cunningham, 2006; Reitsma, 1983; Share, 2004b; see more below). From then on, those newly learned words are recognized as familiar when they are encountered, and that recognition is instantaneous and effortless (Ehri, 2005). There is no need to sound out such words, nor is any guessing involved. Currently, there does not appear to be an instructional methodology used in schools that takes account of the empirical research that has occurred on printed-word learning (but see Kilpatrick, 2016). Yet, as mentioned, it appears that the studies that displayed highly successful intervention results all helped students develop the ability to learn words rather than simply read words.

It must be pointed out here that most children will learn to read, "no matter how unhelpful the instruction" (Liberman & Liberman, 1990, p. 54). For approximately two-thirds of students, this distinction between reading/identifying words and learning/remembering words is of very little consequence. These students acquire the ability to learn words as a result of being exposed to literacy activities. The situation is quite different for struggling readers. For them, the distinction between reading words and learning words is of great significance. A large portion of the bottom third of readers are not able to learn words efficiently, regardless of which of the two dominant teaching approaches they receive.

ASSESSMENT CONCERNS REGARDING WORD-LEVEL READING

In the same way that conventional approaches to reading instruction do not adequately distinguish between reading words and learning words, neither do most standardized tests that involve isolated-word reading. Nationally normed, word-level reading assessments evaluate students' ability to read words. They do not directly evaluate their ability to learn words. Additionally, such assessments confound two different aspects of word reading: identification and recognition (Kilpatrick, 2015). *Word identification* refers to the ability to correctly read a given word, regardless of its prior familiarity. *Word recognition* presumes that a word is already familiar (Aaron et al., 1999; Harn, Stoolmiller, & Chard, 2008; Kilpatrick, 2015). Yet the terms *word identification* and *word recognition* are typically used interchangeably. Some subtests that assess isolated-word reading in reading and achievement batteries are called word identification subtests (e.g., in the Woodcock–Johnson Tests of Achievement), while others are called word recognition subtests (in the Kaufman Test of Educational Achievement). This is despite the fact that these subtests use identical or nearly identical formats. The synonymous use of these terms appears to compromise precision in understanding and addressing two different reading-related skills or processes.

Some of the words on standardized word identification subtests are already familiar to any given student. The pool of words that a student already knows has been referred to as an *orthographic lexicon* or a *sight word vocabulary* (Ehri, 2014; Van den Broeck & Geudens, 2012). Such words are instantly recognized on those subtests; no sounding out or guessing is needed. The size of a given student's orthographic lexicon/sight word vocabulary appears to result from the interaction between the student's ability to remember words and the student's reading experience. The latter factor (reading experience) allows him or her to be exposed to more and more words to be learned.

In addition to tapping into a student's orthographic lexicon, standard word identification subtests evaluate another skill. This second skill involves a student's ability to figure out a word, on the spot, that he or she did not previously know. Students can correctly determine unfamiliar words in isolation by using one or more strategies. One strategy involves guessing based on the first letter and the length of the word. For example, a student may say "lunch" when presented with *laugh,* or "expect" when presented with *expert.* Such guessing will often yield a correct response. A correct response does not mean that the student knows the word. It means that the student made a good guess. A second strategy that can be used to determine a previously unfamiliar word involves reading by analogy (Ehri, 2005). If a student is familiar with the word *since,* he or she can use knowledge of that word when encountering a word like *prince.* A third strategy is what researchers call *phonological recoding* (Share, 1995), which educators call *phonic decoding.*

A fourth strategy for determining an unfamiliar word without the aid of context is called *set for variability* (Kearns, Rogers, Koriakin, & Al Ghanem, 2016; Tunmer & Chapman, 1998, 2012). Essentially, set for variability refers to one's ability to correctly determine a mispronounced word. This applies to reading when a student correctly determines a word despite having mispronounced it, either because it is an irregular word or because it was simply misread. Students with stronger oral vocabularies make better use of set for variability than students with more limited oral vocabularies (Tunmer & Chapman, 2012).

Thus, on standard, context-free word identification subtests from normative achievement batteries, students can read unfamiliar words via four different strategies. This means that on our most popular word-reading subtests, two different aspects related to word-level reading are inherently confounded: the size of the sight vocabulary and the ability to figure out unfamiliar words without the aid of context. While subtests of nonsense-word reading may help us understand a student's ability to sound out an unfamiliar word, we have more difficulty assessing the sight vocabulary. Yet the size and growth of the sight vocabulary are what may give us some clues about a student's efficiency in learning/remembering words.

Language Skills May Confound Word-Reading Assessment and SLD Diagnosis

The advantage that vocabulary skills provide in making use of set for variability implies that the scores on word-reading subtests for those with higher vocabulary skills might tend toward an overestimation of their raw word-level reading capabilities. This has no bearing on the classical IQ–achievement discrepancy; indeed, the scoring pattern is in the wrong direction (i.e., it minimizes any discrepancy between IQ and achievement). However, this phenomenon appears to have implications for identifying readers who are poor at learning words and who may benefit from additional general educational remedial reading help, or even in some cases students who may qualify as SLD. Such students have been called *compensators* (Kilpatrick, 2014, 2015, 2016). A study of compensators indicates that they often dislike and avoid reading, despite average word identification subtest scores on normed tests (Kilpatrick, 2014). It seems that their strong verbal skills combined with even rudimentary phonic decoding skills allow them to correctly identify previously unfamiliar words on word-reading tests via set for variability.

Consider the possible impact of set for variability on interpreting the word identification subtest scores of two third-grade boys. The first student has a verbal IQ (VIQ) of 90, and the other has a VIQ of 113. They both have equal phonic decoding skills, as reflected by a standard score of 83 on a test of nonsense-word reading. Let us say they happen to have prior familiarity with the same number of words on the word identification subtest. They also both received a scaled score of 11 on the Blending Words subtest of the Comprehensive Test of Phonological Processing—Second Edition (CTOPP-2; Wagner, Torgesen, Rashotte, & Pearson, 2013), but a 7 on the Elision subtest.

On the word identification subtest, these two students each instantly recognize the same words that are familiar to both of them. The student with the 90 VIQ goes on to correctly identify three unfamiliar words, using his weak phonic decoding skills and subpar set for variability. His word identification score is 83, or 13th percentile. This score is well within the range of weak reading, according to the National Assessment of Educational Progress (2015), which indicates that about 30% of fourth graders read below a basic level. By contrast, using the same rudimentary phonic skills but applying his strong vocabulary skills to yield better set for variability, the student with the 113 VIQ goes on to correctly identify several additional words, yielding a standard score of 92. The former student may receive Tier 2 remedial instruction for his reading skills. Also, depending on the rest of his profile and his school's criteria/cutoffs for SLD, he may even be considered for an SLD designation. By contrast, the second student has an average word identification score. That student would not be considered as having SLD and likely would not even be considered for Tier 2 remedial services. Yet both students have the same raw word-level reading abilities, although the latter student can mask his inadequacies due to strong vocabulary skills. While the classic IQ–achievement discrepancy unfairly favored those with higher IQs, the issue of compensation has the opposite effect.

This illustration is not intended to suggest that the second student should be designated as having SLD. However, it should be acknowledged that such a student is likely to be a struggling reader who, at minimum, should receive Tier 2 remedial instruction. Yet what if one of the school's criteria is that a student must have a standard score of 85 or lower for an SLD diagnosis, and this student received an 87 on word identification? The first student's 83 makes the cut and the second student's does not, although they have a similar-sized orthographic lexicon and the same level of phonic decoding and phonemic awareness. The student with the VIQ of 113 disqualifies himself because he is better at figuring out words, due to his high vocabulary and correspondingly stronger set for variability. But the trajectory for this student is that he will spend more time having to figure out words, while his skilled fellow students will remember the words they read and will not have to keep applying strategies to the same words. Thus, when diagnosing SLD in word-level reading (basic reading and/or reading fluency), we must acknowledge the nature of the inherent problems with the word identification assessments we routinely use to make such diagnoses.

Word-Reading Strategies and the Orthographic Lexicon May Be Confounded

Reading familiar words involves no strategies. Known words are instantly and automatically accessible (Ehri, 2005; Rayner, Pollatsek, Ashby, & Clifton, 2011), even precognitive, so that they are already available before any conscious strategy could be applied. Word-reading strategies, such as the four strategies referred to earlier—to which we could add the use of contextual guessing—are only necessary when encountering unfamiliar words. The confounding phenomenon of evaluating both the recognition of familiar words and the identification of unfamiliar words on the same subtest means that there is no way to know which of the correctly read words were familiar and which were not. Clinical observation may be somewhat useful here by noting whether the student responded to a given word instantly or not. However, such observations cannot be followed up with normative comparisons to determine what constitutes typical performance. This confounding is not without consequence. Known words are read more quickly than unknown words, and the number of known words appears to be the driving force behind reading fluency. That is, reading fluency appears to be primarily a function of the size of a student's orthographic lexicon or sight vocabulary (Ehri, 2005; Jenkins, Fuchs, van den Broek, Espin, & Deno, 2003; Kilpatrick, 2015; Torgesen, 2004b; Torgesen, Rashotte, Alexander, Alexander, & MacPhee, 2003). Students who know all or most all of the words in a given passage read more fluently than students who know fewer of the words in the passage. A student may have 100% accuracy on a passage, but may have poor fluency because he or she had to phonologically recode or guess at a substantial number of the words. While the student correctly *read* those previously unfamiliar words, their unfamiliarity means that these were not words that had been previously learned.

LEARNING WORDS

Having a pool of known words presumes a previous learning history on each and every one of those familiar words. Like other cognitive and linguistic skills, it also presumes that given equal instruction, opportunity, and effort, there will be individual differences in the ease with which students learn and remember written words (Ehri & Saltmarsh, 1995; Share, 2011; Share & Shalev, 2004). But how do students learn words rather than just identify them? At what point does a given word go from being unfamiliar to familiar, and thus instantly and effortlessly accessible? What cognitive, linguistic, and academic skills and processes contribute to our memory for the words we read? Also, why are there such large individual differences in this skill? For example, in a classic study, Ehri and Saltmarsh (1995) discovered that the word-*learning* skills of typically developing first graders were stronger than those of a comparison group of fourth graders with reading disabilities. Share and Shalev (2004) also showed that children with reading disabilities required more exposures to words before they learned them.

The Nature of Dyslexia

In the reading research literature, significant word-level reading difficulties/disabilities are referred to as *dyslexia* (Fletcher et al., 2018; Hulme & Snowling, 2009; Vellutino, Fletcher, Snowling, & Scanlon, 2004). Although popular understandings of the term *dyslexia* are fraught with 100-year-old misconceptions, from the standpoint of researchers dyslexia simply refers to poor word-level reading despite adequate effort and opportunity, and it cannot be accounted for by blindness, deafness, or severe intellectual impairment (Fletcher et al., 2018; Hulme & Snowling, 2009; Vellutino et al., 2004). For the last three decades, many researchers have conceptualized dyslexia as being the result of a nonword-reading deficit (Rack, Snowling, & Olson, 1992; Share, 1995). In this understanding, word-level reading disabilities are based primarily on poor phonological skills, which make acquiring the alphabetic code of written English very challenging. As a result, sounding out new words is very difficult for those with dyslexia. However, more recently, on empirical, statistical, and design grounds, Van den Broeck and colleagues (Van den Broeck & Geudens, 2012; Van den Broeck, Geudens, & van den Bos, 2010) have shown that poor nonsense-word reading among dyslexic readers appears to be only half the story. Students with word-level reading difficulties also have a weakness in remembering the words they read (Ehri & Saltmarsh, 1995; Share & Shalev, 2004; Van den Broeck & Geudens, 2012; Van den Broeck et al., 2010). In addition to supplementing and extending the notion of dyslexia as a nonword-reading deficit, these findings challenge the older notion that dyslexia can be reliably divided into *phonological* and *surface* subtypes (see more on this below).

Word-Learning Theories

There are several theories designed to explain how words are learned. For simplicity, a distinction is made here between *computational* theories and *cognitive* theories. Computational theories of word learning involve computer programs that simulate both reading words and learning words (Coltheart, 2012; Seidenberg, 2002, 2017). These computational models have yielded rich insights about reading, but they are based only indirectly on behavioral evidence from studies of actual human reading. These models are not considered further in this chapter because the number of trials required for word learning in these models is discrepant with actual data from human readers (surprisingly, typical human readers learn words far more quickly).

Cognitive Theories of Word Learning

The two theories of word learning that have generated the most empirical support are Linnea Ehri's (1992, 2005, 2014; Miles & Ehri, in press) *orthographic mapping theory* and David Share's (1995, 1999, 2011) *self-teaching hypothesis*. Torgesen referred to Ehri's theory of word learning as "the most complete current theory of how children form sight word representations" (Torgesen, 2004a, p. 36). Van den Broeck and Geudens (2012) speak as highly of Share's theory when they say that the "self-teaching model is the most dominant account of the developmental process toward fully specified orthographic representations" (p. 416). This latter quote is not inconsistent with the quote by Torgesen because of the tremendous overlap between these two theories. Indeed, one researcher explicitly says that Share's self-teaching hypothesis "is essentially the same as Ehri's [orthographic mapping] hypothesis" (Apel, 2009, p. 43). While this statement is not technically accurate, it testifies to the large overlap between these models of learning to read.

Both orthographic mapping and the self-teaching model posit a central role for letter–sound knowledge and for phonemic awareness in building the orthographic lexicon. Visual memory plays no role (see below). An important difference between Ehri's and Share's theories is that Ehri's theory provides a specific cognitive mechanism for the process of forming connections between pronunciations and their orthographic representations. Share's theory provides the scenario under which this connection-forming process occurs, without providing specific details about how words are encoded into the orthographic lexicon. Ehri, on the other hand, says little about this learning scenario that Share describes. Rather, her theory presents a more abstract representation of the connection-forming process.

Before this process of orthographic learning is described in detail, a more dominant theory of word learning, even if informal and intuitive, must first be addressed. This is the common view that word learning is based on some form of visual memory process via paired-associate learning. This intuitive theory assumes that learning to read words is a process similar to learning to name familiar objects or people (i.e., visual input, verbal output).

Do We Remember Words Based on Visual Memory?

When we look at a chair and say "chair," or when we see the printed word *chair* and say "chair," the naming activity intuitively appears to be similar, if not identical. In both cases, visual input is used to access a phonological code, which is our memory of the pronunciation of the spoken word *chair*. There are, however, multiple, independent lines of evidence demonstrating that word reading is not based on a visual memory process similar to naming objects in our environment. These various lines of evidence have been presented in detail elsewhere (Kilpatrick, 2015), which are summarized below and in Table 35.1.

First, in 1886, James Cattell tested naming speed for objects versus printed words. He did so using a newly developed millisecond-level timing device. Adults read words like *chair* and *tree,* and Cattell compared their reaction times, measured to 1/1,000th of a second, to visual presentations of a chair or a tree. To his surprise, Cattell found that the reaction times to the printed words were consistently faster than to the actual objects. Thus, by the late 1800s, there already existed evidence challenging our intuitive notion that visual memory and orthographic memory (i.e., printed-word recognition) represent the same process.

Second, in the preface to his 1979 book *Dyslexia,* researcher Frank Vellutino says he began the decade of the 1970s assuming the common view that word reading is based on some sort of visual memory process. By the time he wrote his book, however, he had abandoned that view, based on studies he and others conducted in the 1970s that failed to find the expected visual memory deficiencies in dyslexic readers (Vellutino, 1979).

TABLE 35.1. Summary of Reasons Why We Know Words Are Not Remembered via Visual Memory

1. Reaction times to printed words (e.g., *chair* or *tree*) are faster than reaction times to objects (e.g., a picture of a chair or tree), suggesting that visual memory and orthographic memory are different processes.
2. Persons with poor word-level reading tend to have average visual memories.
3. Despite the finding that their visual memory is equivalent to that of hearing individuals, those who are deaf struggle with remembering the words they read.
4. There is a moderate to strong correlation between word reading and phonological skills, but a very weak correlation between word reading and visual memory.
5. Words are instantly recognized despite their visual presentation (uppercase, lowercase, differing fonts, handwriting styles, etc.), as long as the letters are legible.
6. Neuroimaging studies indicate that there is limited overlap in the areas of the brain responsible for visual memory versus memory for written words.
7. We routinely have "visual memory" failures in forgetting the names of familiar people or even objects, but we have no such failures with remembering familiar words.

Third, if reading were based on visual memory, it becomes very difficult to explain why students who are deaf tend to graduate from high school at about a third-grade reading level (Lederberg, Schick, & Spencer, 2013; Leybaert, 2000). Individuals who are deaf have visual memory skills comparable to those of hearing individuals, so if visual memory were the basis for printed word memory, students who are deaf would learn to read at a rate comparable to that of their hearing peers.

Fourth, the correlation between visual skills and word reading tends to be very low, while the correlation between word reading and phonological processes is substantially higher (Vellutino, 1979; Vellutino et al., 1996; Wagner & Torgesen, 1987). It is difficult to understand why this would be the case if visual skills play a substantial role in word learning.

Fifth, studies done to disrupt readers' visual memories of words have been inconsistent with the visual memory hypothesis. As long as readers are acclimated to unusual forms of print (e.g., strange or ornate fonts or a specific individual's handwriting), readers have instant access to words written in those differing ways, despite having no prior exposure to that unusual visual presentation for any given word (Adams, 1990). One example of this involved disrupting a visual presentation of words using mixed type (e.g., wOrDs WrItTeN LiKe tHiS), which virtually guarantees that the reader has no prior exposure to or visual memory of words printed that way (Adams, 1990). Adams (1990) described studies in which words were presented on a computer screen for 1/20th of a second, in either uppercase, lowercase, or mixed case, followed by a mask (e.g., #####). During debriefing after the study, some research participants indicated that they were unaware of these different presentations, and others even insisted that they had all been presented in lowercase letters only.

A likely reason for this finding can be found in studies that show that readers have an abstract representation of each of the letters of the alphabet in the memory system, irrespective of case and font (Bowers, 2000; Frost, 1998; Van den Broeck & Geudens, 2012). Within the first 1/10th of a second after a word is seen, it appears that the particular letters perceived are translated into their respective abstract representations. Apparently, the memory system then seeks to determine whether that *specific sequence of letters*—regardless of its visual characteristics—is stored in the orthographic lexicon. Thus orthographic memory appears to be based on familiar sequences of letters,[1] not familiar visual input at the letter or word level. If the memory system detects a familiar letter sequence, the left fusiform gyrus (in the left ventral occipito-temporal area) activates and the word is recognized. If it does not, the activation then moves higher in the temporo-occipital area associated with the letter–sound conversion process (Dehaene & Cohen, 2011; Glezer, Kim, Rule, Jiang, & Riesenhuber, 2015; Simos et al., 2002). This helps understand why case and font appear to make little or no difference in recognizing words, as long as the letters are legible to the reader.

Sixth, neuroimaging studies have indicated that the areas of the brain that are activated during visual memory tasks show limited overlap with the areas activated during the reading of familiar words (Dehaene & Cohen, 2011; Simos et al., 2002). This helps explain Cattell's results from over 125 years ago.

Finally, in addition to these various lines of research evidence, there is another phenomenon readers experience that is inconsistent with the visual memory hypothesis of word reading. It is not uncommon for us to have an apparent "visual memory failure"—that is, a failure to retrieve the phonological code associated with some visual input. For example, this occurs when we encounter a familiar person and yet fail to retrieve his or her name. It also happens when we fail to retrieve the name of an object in our line of sight ("Hand me that thingy over there").[2] By contrast, it appears that this same retrieval failure never occurs with orthographically familiar words. Familiar words are consistently retrieved. Only unfamiliar words or words printed illegibly represent challenges to accurate retrieval. This disparity in retrieval failures of people's names and objects' names, but not written words, is difficult to explain with the intuitive theory that memory for written words is based on visual processes similar to those used in object recognition. Input and storage are not the same thing. We input words visually, but store them orthographically, phonologically, and semantically.

In sum, several independent lines of empirical evidence appear to falsify our highly intuitive notion that printed words are stored and retrieved from long-term memory via some form of visual memory process. But if visual memory is not the mechanism by which we remember words, what is?

ORTHOGRAPHIC LEARNING AND MEMORY

In contrast to visual memory, the notion of remembering words via *orthographic memory* has received substantial empirical support (Ehri, 1992, 2005; Rack, Hulme, Snowling, & Wightman, 1994; Share, 1995, 2011). *Orthography* refers to the proper way to represent written words in a given writing system. In alphabet-based writing systems, orthographic memory refers to a memory for the precise letter order that comprises a written word or word part (Ehri, 2005; Van den Broeck & Geudens, 2012). Because orthographic memory involves a specific letter sequence, there is no particular relevance to the visual features of the printed words, such as size, case, font, or whether a word is in print or handwriting. The necessary feature is that the letters in the sequence are legible. The question arises as to how such a highly efficient and largely automatic memory for specific letter sequences occurs within the cognitive system. Recent clues have come from neuroimaging studies (Dehaene & Cohen, 2011; Glezer et al., 2015; Simos et al., 2002). As mentioned previously, when familiar words are viewed, the left fusiform gyrus is activated. However, when unfamiliar words and nonsense words are viewed, areas in the left superior and medial temporal and occipital areas are activated. One recent study even tracked this shift in areas of activation as words became familiar (Glezer et al., 2015). In this chapter, however, the focus is on a cognitive description of the orthographic learning process. The neuroimaging and other neurophysiological data serve largely to confirm or disconfirm cognitive explanations of reading (Anderson & Reid, 2009). Currently, neuroimaging and other neurophysiological data appear to provide important evidence that confirms the cognitive explanation of written-word learning described below.

The Nature of Orthographic Knowledge

Orthographic knowledge is understood on multiple levels. On one level, it refers to a familiarity with what would be considered permissible and nonpermissible letter sequences in a given written language. For example, in English, words do not begin with *ck* or *mb,* but they may end with those letters (e.g., *back, thumb*). On another level, orthographic skills refer to the pronunciation of common subword sequences or orthographic patterns that do not yield to simple letter-by-letter, grapheme–phoneme conversion regularities (e.g., *-ight, -alk, -tion, -ould*). Finally, orthography can refer to the correct spelling of any given word (e.g., *brain,* not *brane*).

Orthography as an Independent Reading-Related Subskill

One issue in this area has been whether orthographic skills represent a separate reading-related subskill in the same way that letter–sound knowledge, nonsense-word reading, phonemic awareness, and rapid automatized naming are considered to be reading-related subskills. Orthographic skills have been commonly assessed in research studies via the word likeness task, the homophone or pseudohomophone task, and exception-word reading (e.g., Olson, Forsberg, Wise, & Rack, 1994).

A word likeness task asks children which of two nonwords is most like a word. For example, given *lmk* and *pif,* the latter is more like a word because it has a common consonant–vowel–consonant (CVC) pattern, while the first item has no vowel. A homophone or pseudohomophone task requires students to identify the correct spelling pattern for a given word, such as which of the following is a flower: *rows, rose,* or *roze*. An exception-word task simply involves having students read words that do not yield correct pronunciations via phonic decoding (e.g., *iron, yacht, rendezvous*).

Before the middle of the last decade, many researchers argued that orthographic skills contribute to word reading above and beyond letter–sound skills and phonemic awareness (e.g., Cunningham, Perry, Stanovich, & Share, 2002; Holmes, 1996). In contrast, other researchers claimed that these orthographic skills are by-products of letter–sound knowledge, phonological skills, and reading experience, and thus are not causal elements in word-reading development (Vellutino, Scanlon, & Tanzman, 1994). This latter view was supported by research in the 1990s showing that orthographic sequences become "unitized" as part of reading development and experience. For example, typical fourth-grade readers and strong second-grade readers read a nonsense word like *nalk* to rhyme with *walk* and *talk,* while weaker-reading second graders read it to rhyme with *talc,* following a more strict application of letter–sound regularities (e.g., Bowey & Underwood, 1996). Presumably, with reading experience, orthographic patterns become familiar to readers.

More recently, there appears to have been a shift in understanding the relationship between orthographic skills and reading development. This shift followed a comprehensive review of the empirical literature by Jennifer Burt (2006). Her review indicated that there were no theoretical or empirical grounds for considering orthographic skills to be a reading-related skill that contributes to the development of reading skills apart from letter–sound skills, phonemic awareness, and reading experience. Rather, orthographic skills appear to represent a point in letter–sound knowledge development that occurs as a result of reading experience and noting patterns that are consistently pronounced (e.g., *-ight, -tion*), even if they are inconsistent with a simple letter-by-letter phonic decoding approach. This view has received further support from longitudinal research. Deacon, Benere, and Castles (2012) found that first-grade reading skills predicted third-grade performance on orthographic skills tasks, while orthographic skills tasks assessed in first grade did not predict third-grade reading skills. Despite this trend in the research, it appears that some authors (e.g., Feifer, 2011, 2014; Mather & Wendling, 2012), while describing subtypes of dyslexia, continue to maintain that orthographic skills independently contribute to reading (for more detail, see below).

HOW ORTHOGRAPHIC LEARNING OCCURS: SELF-TEACHING AND ORTHOGRAPHIC MAPPING

The Self-Teaching Hypothesis

The evidence in support of David Share's self-teaching model of orthographic learning is large and growing (e.g., Bowey & Muller, 2005; Cunningham, 2006; Cunningham et al., 2002; Share, 1999, 2004b, 2011), as is the empirical support for Ehri's orthographic mapping model (e.g., Dixon, Stuart, & Masterson, 2002; Ehri & Saltmarsh, 1995; Laing & Hulme, 1999; Rack et al., 1994). I examine each in turn.

The self-teaching hypothesis begins with a simple and self-evident observation. A skilled adult reader has tens of thousands of written words in his or her orthographic lexicon/sight word vocabulary, yet it is likely that only a few hundred of those words were directly taught by teachers or parents. The essence of the self-teaching model is that children teach themselves most of the words they know, once they have in place adequate or better phonic decoding skills (i.e., phonological recoding; Share, 1995). As students with phonological recoding skills encounter new words, they perform the letter–sound conversion process and phonological blending to identify those words (Share, 1995, 2011). Context and set for variability may assist in the identification of an unfamiliar word, especially irregular or exception words. Regardless, the self-teaching model proposes that the process of tracking through the letter sequence and sounds that constitute a printed word helps establish that letter sequence in long-term memory (Share, 1995).

Numerous studies have shown that from second grade on, an average reader requires only one to four exposures to a new word in order for that word to become established in the orthographic lexicon/sight word vocabulary (Cunningham, 2006; Reitsma, 1983; Share, 1999, 2004b; Share & Shalev, 2004). At first this may seem a bit surprising. However, a moment's reflection on the growth trajectories of early readers independently supports these findings (Adams, 1990; Ehri, 2005; Snow, Burns, & Griffin, 1998). Most children enter first grade knowing dozens of words, yet 2 years later they enter third grade knowing thousands of words. This steep growth trajectory within this limited time frame does not allow the opportunity for students to have dozens of exposures to each of those thousands of words, except for high-frequency words.

A common research paradigm involves having students silently read a narrative—for example, about a fictional city called *Yait*. Some students see the target word only once at the beginning of the passage, after which "this city" or "that city" is used. Other students receive two, four, six, or eight exposures to the target pseudoword in the passage. The frequency of exposure varies both within and across studies. Some studies test students on the newly encountered "word" the following day, or a week later, or even a month later. These tests may include a spelling test; an orthographic choice task using phonologically plausible foils (e.g., "Was the name of the city *Yate, Yait, Yat, Yaet,* or *Yaite?*"); or measuring reaction time (RT) to the words flashed on a computer screen (and comparing that to the RT to the homophonic foil). Performance accuracy is quite high for all types of queries, with spelling accuracy being the weakest. Many words are learned after a single exposure, yet there is an increase in accuracy if the words are encountered two to four times. Beyond four exposures, there is a very limited benefit in terms of performance on the various types of posttests. This learning paradigm mimics the self-teaching situation, in which the silent reading of passages involves encountering new words that need to be phonically decoded. The storage in long-term memory appears to be phonological and orthographic, not visual. One way this has been determined has been through efforts to allow only visual exposure to these new words and suppress phonological recoding (e.g., by having students continuously repeat a nonsense word while reading); such efforts result in very limited accuracy in the posttests (Share, 1999). It therefore appears that processing the letter sequence at a phonological level is the key to establishing an orthographic sequence in long-term memory.

Despite the success of the self-teaching model in accounting for a great deal of empirical findings, it leaves open an important question: Precisely what is it about phonological processing during phonic decoding that allows for the establishment of a very secure orthographic sequence in long-term memory? Ehri's theory of orthographic learning directly addresses that question.

Orthographic Mapping

Ehri has been refining her theory of word learning, recently dubbed *orthographic mapping* (Ehri, 2014), for four decades (Ehri, 1978, 1992, 1998, 2005, 2014; Ehri & Wilce, 1985; Miles & Ehri, in press). Her theory provides an empirically supported explanation of how we remember the words we read. Efficient orthographic learning requires two skills: letter–sound knowledge and phoneme segmentation (Ehri, 1998, 2005). Spoken words are already stored in long-term phonological memory, and the object of orthographic learning is to have a sequence of letters attach to, or bond to, the pronunciation of that spoken word. This is not to be confused with a letter-by-letter phonic decoding of the word. Rather, once it is familiar, the particular sequence of letters becomes *unitized* (Treiman, Sotak, & Bowman, 2001); that is, the whole string of letters as a unit is familiar and instantly activates the word's pronunciation, with no need for letter-by-letter phonic decoding.

Conventional phonic decoding involves a flow of information from letters to sounds, and those sounds are blended together to arrive at a pronunciation. Orthographic mapping benefits from this flow of information, but also proposes an additional flow of information that goes in the other direction—from (1) the oral word's pronunciation, to (2) a segmented representation of the oral word, to (3) the alphabetic characters that align with that segmented pronunciation. This process of associating a known and well-established phonological representation (the word's pronunciation) with a newly encountered stimulus (a letter sequence/printed word) allows for that newly encountered stimulus (the letter sequence) to become bonded in memory with that known phonological representation (the oral pronunciation). In a sense, it represents a flow of information that goes in the opposite direction from phonic decoding. It could be said that phonic decoding goes "from text to brain," while orthographic mapping goes "from brain to text." This is an oversimplification, however, because orthographic mapping involves "reciprocal bidirectional connections" (McKague, Davis, Pratt, & Johnston, 2008, p. 69). Nonetheless, this flow of information from pronunciation to letter sequence—a flow in the opposite direction from that found in phonic decoding—does not appear to be commonly understood outside the niche area of reading research that directly studies orthographic learning. Yet this flow of information is central to Ehri's theory (Ehri, 2005; Kilpatrick, 2015; Miles & Ehri, in press).

The result of this mapping process is a sequence of letters that is instantly familiar, stable, and highly unlikely to be confused with other words that look similar (e.g., *black, block, blank, blink, blind*). The fully specified representation is like a precise URL or "web address" within the memory system that activates the word's pronunciation and meaning the instant it is perceived (Ehri, 2005, 2014). Familiar written words are fully specified letter sequences that gain their familiarity by being bonded to the word's pronunciation at the phoneme/letter level, or in some cases the level of a group of letters (e.g., *-ight*; see more below on irregular words).

Phoneme segmentation and letter–sound knowledge work together to produce this orthographic mapping effect. For example, consider a first-grade girl who encounters the word *red* for the first time. If she is capable of segmenting the spoken word into its individual phonemes, /r/ /e/ /d/ (the letters between the slash marks represent the *sounds* associated with those letters and not the letters themselves), she then has three anchoring points in her long-term memory with which to attach that written letter sequence. She is attaching the new information (the letters in that word) to existing, well-specified information in her phonological long-term memory—namely, the segmented pronunciation of the word *red*. Again, notice that this represents the opposite direction of information flow from that required for phonic decoding. The net effect is that this particular letter sequence quickly becomes familiar because of the student's ability to associate the segmented phonemes in the spoken word's pronunciation to the written sequence designed to represent that spoken pronunciation.

By contrast, consider a first-grade boy who lacks proficient phoneme segmentation skills. When he sees the word *red*, how is he to remember it? If that student cannot pull apart the spoken pronunciation, then he cannot attach the spoken word *red* to that particular letter sequence. Most dyslexic students are able to create a connection between the first sound in the pronunciation and the first letter of the word. But beyond that, there is little opportunity to create a familiar sequence out of the rest of those letters because there is nothing in the child's long-term memory to which that letter string can be reliably anchored. Thus the student must sound it out or guess over and over upon seeing the word. With time and many, many exposures (not the one to four exposures found in typical readers), struggling readers map high-frequency words and other words (Ehri & Saltmarsh, 1995; Share & Shalev, 2004). The net effect for these weak readers, however, is that this orthographic mapping process is so inefficient that their sight word vocabularies grow very slowly relative to those of their peers, and they almost never catch up.

The Problem of Irregular Words

A question that arises is how orthographic mapping works with irregular words. English is the most inconsistent of all the major alphabet-based written languages (Seymour, Aro, & Erskine, 2003). Interestingly, however, the inconsistencies of English spellings create much less of a problem for orthographic mapping than they do for phonic decoding.

Orthographic mapping requires creating connections between pronunciations and print. Students cannot map a word unless they know what the word is—either because they sounded it out, they guessed it correctly, or someone told them what the word is. Orthographic mapping thus works from a starting point in which something is already known and already stored in phonological long-term memory (i.e., the word's pronunciation). By contrast, phonic decoding presumes that the word is not known, and thus does not start with any known anchoring point in long-term memory. Phonic decoding requires sufficient accuracy with the letter–sound sequence and blending to identify the spoken word correctly. Orthographic mapping does not require the same level of consistency as phonic decoding. Consider the irregular word *put*. Once a student knows that the written word he or she is looking at is *put*, it is a simple matter of noticing the association between the sounds in the spoken word and the letters. Two of the sounds in the spoken word *put* attach normally to their respective letters (*p, t*), and only one has an irregular connecting point (*u*). It is as if the student were to say "Oh, *that's* how we spell *put*!"

This type of adjustment to the mapping process for an irregular word is equally true for words that are phonically regular. For example, the word *make* is phonically regular, but requires an adjustment when it is being mapped into orthographic memory because *make* has three sounds but four letters. Knowing the silent-*e* rule presumably helps facilitate the adjusted mapping required for remembering such a word, but it requires an adjustment nonetheless. The same kind of adjustment needs to occur with phonically regular vowel and consonant digraphs (*ch, th, oa, ee*) because multiple letters represent a single sound. Also, such adjustments are routinely required in many multisyllabic words when an unstressed syllable has a vowel reduction, such as in *holiday* or *market*. The adjustments needed to map words to orthographic memory are routine for both regular and irregular words. These common adjustments are not problematic for students skilled in both letter–sound knowledge and phoneme segmentation. Yet they represent a major difficulty for those with the phonological-core deficit of dyslexia, due to their weaknesses in letter–sound skills and/or phonemic awareness.

Integrating Orthographic Mapping and the Self-Teaching Hypothesis

Elsewhere (Kilpatrick, 2015), I have made what may be the first formalized attempt to integrate the self-teaching and orthographic mapping models. On one level, this integration is straightforward. As proposed by the self-teaching model, students read and encounter new words. They perform phonological recoding, which activates the sounds of the letters in working memory. Ehri's theory then explains how the segmentation of that newly identified spoken word allows the reader to bond the segmented phonemes in the word's pronunciation to the printed letter sequence.

On another level, the integration of these two models requires a bit more thought. Throughout their elementary school years, readers add thousands of new words to their orthographic lexicons. However, this process appears to happen in the background, without conscious attention. It is doubtful that readers say with each new encounter of an unfamiliar word (let's say *clap*), "Hey, look how the /k/ sound maps onto the letter *c*, and how the /l/ sound I'm hearing next fits so well with that letter *l*," and so forth. Neither Ehri's nor Share's theory tries to account for how orthographic memory occurs without conscious effort or awareness. The fact that this process occurs is well supported by numerous lines of research. But this research does not explain why we do not seem to remember mapping the thousands of words we know. The *phonemic proficiency hypothesis* (Kilpatrick, 2015; Kilpatrick & Song, 2018) appears to have resolved this question. The phonemic proficiency hypothesis allows for a virtually seamless integration of Ehri's orthographic mapping theory with Share's self-teaching hypothesis, while accounting for the fact that the mapping process is largely outside the conscious awareness of the reader.

The Phonemic Proficiency Hypothesis

A colleague and I have proposed (Kilpatrick, 2015; Kilpatrick & Song, 2018) that phonemic proficiency, which is related to but not identical with phonemic awareness, is a critical aspect of efficient orthographic learning when Ehri's (2004, 2014) orthographic mapping hypothesis is integrated with Share's (1995) self-teaching hypothesis. At the same time, the phonemic proficiency hypothesis incorporates the research on the phonological-core deficit of dyslexia (Fletcher et al., 2018; Hulme & Snowling, 2009; Vellutino et al., 2004) with the orthographic learning theories of Ehri and Share. As mentioned, Ehri (2005) proposes that a phoneme analysis mechanism (i.e., segmenting words into phonemes) is required for orthographic memory. However, for that to occur within the very time-limited context of Share's self-teaching opportunities (correctly sounding out a word takes very little time), phonemic segmentation/analysis must be highly proficient and largely unconscious. The phonemic proficiency hypothesis (Kilpatrick, 2015) suggests that proficient letter–sound skills and proficient phonemic skills both involve automatic processes that are precognitive and do not require conscious awareness.

Letter–Sound Proficiency

Studies have shown that by late first grade, typically developing readers can *instantly* respond to CVC nonsense words, such as *mot, tam,* or *gub* (e.g., Harn et al., 2008). Anyone who has administered the Phonological Decoding subtest from the Test of Word Reading Efficiency—Second Edition (TOWRE-2; Torgesen, Wagner, & Rashotte, 2012) to an average student at the end of first grade has directly experienced this. Consider what is involved for first graders to respond instantly to a CVC word, such as *mip*. In less than a second, they retrieve the sounds for the letters *m, i,* and *p,* and then blend those three sounds together. It is argued that those children do not use a conscious search process to retrieve those letter sounds, but that they are automatically available. This instant responding illustrates letter–sound proficiency: It involves automatic, unconscious access to the most common sounds of the letters, plus proficient phonological blending that allows those letter sounds to be accurately pronounced as a single, spoken unit (Harn et al., 2008). Due to its greater complexity, those first graders may not be able to respond instantly to the nonsense word *splenk*. But by the end of second grade, average students can do so, given their additional year of development of their letter–sound skills. Those second graders have instant access to letter sounds even when they encounter a complex string of letters. No conscious effort is involved in retrieving those letter sounds.

Phonemic Proficiency

Phonemic proficiency can be viewed as an advanced form of phonemic awareness. *Phonemic awareness* has been generally conceptualized as the ability to be aware of and/or manipulate phonemes within words. It is a latent construct that has been assessed in many ways with a variety of tasks, including segmentation, isolation, categorization, deletion, and substitution (Kilpatrick, 2012a, 2012b). Only recently has any effort been made to examine whether some phonemic awareness tasks are better suited than others for assessing the phonemic substrates of reading (Kilpatrick, 2012a, 2015). It turns out that phoneme manipulation tasks, the most common being phoneme deletion and substitution, correlate more strongly with reading than phoneme segmentation and blending tasks do (Catts, Fey, Zhang, & Tomblin, 2001; Kilpatrick 2012a, 2012b, 2015; Swank & Catts, 1994; Wagner, Torgesen, & Rashotte, 1999). Phoneme manipulation "ranks highly among phonological awareness tasks in predicting reading achievement" (Catts et al., 2001, p. 40).

Interestingly, very little attention has been paid to the speed of phonemic awareness task responses. We (Kilpatrick & Song, 2018) reviewed the very limited pool of studies on this. The findings from these studies indicate that using timed manipulation tasks, researchers discovered that phonemic awareness continues to develop well into third and fourth grade and appears to display continued influence on reading development well beyond first grade (e.g., Vaessen & Blomert, 2010). This contrasts with the common assumption that phonemic awareness plays no substantive role in reading development after early first grade (e.g., O'Connor, 2011). Evidence for a causal role in reading development for these more "advanced" phonemic skills comes from a recent review of the word reading intervention literature (Kilpatrick, 2015; Kilpatrick & Van den Broeck, 2016). Studies that rigorously trained students by using manipulation tasks (phoneme deletion and substitution) produced gains in real-word reading that ranged from 12 to 25 standard score points. By contrast, studies that trained phonemic awareness skills by using the more "basic" phonological awareness skills of phoneme segmentation and/or blending yielded increases in standard scores ranging from 6 to 9 points. Studies that incorporated no phoneme awareness training yielded increases of 0–6 standard score points in word-level reading (Kilpatrick, 2015; Kilpatrick & Van den Broeck, 2016). Noteworthy is the fact that socioeconomic status, age of the students, group size, severity of the problem, and total length of the intervention were evenly distributed across these three groups of studies with varying results. This indicates that these factors cannot explain the disparity in outcomes (cf. Flynn, Zheng, & Swanson, 2012; Torgesen, 2004b; Torgesen et al., 2003).

Phonemic proficiency goes beyond the conventional conceptualization of phonemic awareness and can account for the findings from the intervention research just mentioned. Phonemic proficiency, parallel to letter–sound proficiency, is conceptualized as the automatic, unconscious access to the phonemes in spoken words. This is more appropriately assessed via a manipulation task than a segmentation task. For example, in a segmentation subtest, all of a student's focus is on that task, so it is difficult to determine how automatic are the cognitive processes behind the task responses. However, manipulation tasks are more complex. A second grader with phoneme proficiency can respond in 1 second or less to a request to delete the /l/ from the spoken word *clap*. To do this, the student has to perform four classic phonemic awareness tasks in less than 1 second. First, he or she has to *segment* the word *clap*. Then the student has to perform *phoneme isolation*, which involves locating where the target sound appears on the word ("Is the /l/ in the beginning, middle, end . . ."). Next, he or she has to delete (*manipulate*) the sound. Finally, the student has to *blend* the remaining sounds to produce the correct response. Thus, four traditional phonemic tasks—segmentation, isolation, manipulation, and blending—all occur in 1 second or less. I have contended (Kilpatrick, 2015) that for the student to perform those four operations that quickly, it is likely that access to the phonemes via segmentation does not require conscious effort, but is automatic. This is the essence of phonemic proficiency.

We (Kilpatrick & Song, 2018) have provided some evidence for phonemic proficiency and its role in word learning. In one study, 136 first graders were administered a phoneme manipulation task (a mix of deleting and substituting sounds). Correct responses were coded differently, depending on whether those responses occurred in less than or more than 2 seconds. These students were also administered the *Sight Word Efficiency* subtest from the TOWRE-2 (Torgesen et al., 2012). This subtest consists of a graded word list, and students have 45 seconds to read as many words as possible. The inference is that students with larger sight vocabularies will get higher scores than those with smaller sight vocabularies because it takes longer to sound out a word than to recognize a known word. We found that the correlation between this reading task and phonemic awareness items responded to instantly (i.e., in 2 seconds or less) was $r = +.58$. Yet the correlation between the reading task and the non-instant phonemic awareness responses was $r = +.004$. This suggests that instant access to the sounds in words tells us something about word-reading development that is not captured by correctly responding to a phoneme task without evidence of phonemic proficiency.

We (Kilpatrick & Song, 2018) also examined this phenomenon with 58 typical fifth-grade readers. To evaluate the impact of phonemic awareness on sight vocabulary, we used a reading test that only contained irregular words (from Adams & Huggins, 1985), like *iron, tongue, suede,* and *yacht*. The assumption is that sounding out these words is likely to yield an incorrect response, so the test assesses prior familiarity with those words. The inference is that those with higher scores are likely to know more words in general (i.e., to have a larger sight word vocabulary). The same phonemic task was used as with the first graders. Coincidentally, the correlation between the instant responding on the phonemic awareness task and the reading measure was, again, $r = +.58$. But the correlation with the non-instant responding was $r = –.25$, suggesting that even among a population of typical fifth-grade readers, those with presumably larger sight vocabularies had greater phonemic proficiency than those with presumably smaller (though average) sight vocabularies. Thus, even in a population of typical fifth-grade readers, the degree of phoneme proficiency correlated with the likelihood of identifying phonically irregular words, which is a fairly direct assessment of the orthographic lexicon.

Phonemic Proficiency and Orthographic Learning

Students routinely encounter new and unfamiliar words while reading silently. They use their letter–sound skills and phonological blending to determine the word. This is Share's self-teaching scenario. Once the word is correctly determined, the pronunciation of the word is activated. Students with automatic, unconscious access to the sounds within that word's pronunciation can implicitly map those sounds within the pronunciation to the letter sequence representing that pronunciation, as orthographic mapping theory suggests. Phonemic proficiency allows the mapping process to be unconscious, given that the two subprocesses involved in mapping are unconscious and automatic (i.e., letter–sound proficiency and phonemic proficiency). This explains why most of us would have no recall of consciously making connections between pronunciations and letter patterns while we were learning the tens of thousands of words we know.

The Development of Word-Learning Skills

I have proposed a description of the interaction between the developmental of reading-related phonological skills and word-level reading (Kilpatrick, 2015). This developmental paradigm is presented in Table 35.2. The left side of the table portrays three levels of phonological development, while the right side depicts three levels of word-reading development. It is proposed that the phonological skills directly to the left of the given reading skills represent causal factors for that level of reading. Additionally, each level of reading development has a causal relationship with the next level of phonological development. This reciprocal, causal relationship was first established empirically by Perfetti, Beck, Bell, and Hughes (1987).

Early phonological skill development appears to have a causal relationship with the speed and efficiency with which children develop knowledge of letter names and sounds. The "softer" evidence for a causal relationship is found in studies that examined phonological skills before children learned letter names and sounds. Those with stronger early phonological skills learned letter names and sounds more quickly than those with weaker phonological skills (Cardoso-Martins, Mesquita, & Ehri, 2011; Share, 2004a). Harder causal evidence comes from experimental studies in which children provided with early phonological awareness training outperformed untrained children in the acquisition of letter names and letter sounds (Cardoso-Martins et al., 2011; Williams, 1980).

TABLE 35.2. Developmental Levels of Phonological Awareness and Word Reading

Level of phonological awareness	Level of word-reading skill
1. *Early phonological awareness* Rhyming, alliteration, first sounds, and syllable segmentation	1. *Letters and sounds* Requires simple phonology to learn letter names and letter sounds
2. *Basic phonemic awareness* Blending and segmentation	2. *Phonic decoding* Requires letter sounds and blending
3. *Advanced phonemic awareness* Phonemic proficiency	3. *Orthographic mapping* Requires letter–sound skills and advanced phonemic awareness/proficiency

Learning letter sounds is causally related to the development of basic phoneme-level awareness. We know this from studies of adults who, due to lack of opportunity, never learned to read. These individuals do not naturally develop phoneme-level awareness (Morais, 1991). There then appears to be a causal relationship between the development of phoneme-level awareness and blending, and that of phonic decoding and basic spelling. These basic phoneme-level skills are typically developed by the end of first grade. It is often at that point that phonemic awareness assessments (e.g., Dynamic Indicators of Basic Early Literacy Skills, Aimsweb, easyCBM) and training programs (e.g., Blachman, Ball, Black, & Tangel, 2000) discontinue phonological/phonemic awareness training. This appears to assume that any further phonemic awareness development that occurs after first grade is of no consequence for reading. Yet this is not the case (Ashby, Dix, Bontrager, Dey, & Archer, 2013; Kilpatrick, 2015; Torgesen et al., 2001; Truch, 1994; Vaessen & Blomert, 2010). Indeed, practicing phonic decoding/letter–sound skills and spelling throughout first and second grades appears to make these segmenting and blending skills more automatic and efficient. This suggests a causal factor in the development of more "advanced" phonemic awareness skills. It is these advanced skills, as demonstrated by instant responses to phoneme manipulation tasks, that provide the phonemic proficiency to drive orthographic mapping skills and thus rapidly expand the sight word vocabulary.

Impaired Development in Dyslexia

Students with the phonological-core deficit, which is the basis of dyslexia (Ahmed, Wagner, & Kantor, 2012; Vellutino et al., 2004), do not move smoothly through the levels of phonological development or reading development depicted in Table 35.2. They typically have poor early phonological skills, which is why they lag behind their peers in developing letter–name and letter–sound knowledge. When their letter–sound skills do develop, their phonological systems are not efficient enough for the learning of those letter sounds to prompt the next level of phonological skills, that is, phoneme segmentation and blending. However, even many children with dyslexia will develop these "basic" phonological skills by late second or third grade (recall that typically developing readers have these skills in place by late first grade). With proper instruction, children with dyslexia who have basic segmentation and blending skills can benefit from phonics instruction. However, when these children learn phonics and spelling skills, these skills do not naturally prompt the more "advanced" phonemic skills needed for orthographic mapping. Thus children with the phonological-core deficit only develop the phonological skills to the level they are directly taught. They do not develop those skills via reading instruction, like their typically developing peers.

IS THERE A NEED TO DIAGNOSE SUBTYPES OF DYSLEXIA?

There are three very well-established subtypes of reading disabilities (Fletcher et al., 2018; Gough & Tunmer, 1986; Hulme & Snowling, 2009)—namely, *dyslexia*, *hyperlexia*, and a combined type (traditionally called *garden-variety poor readers*; Gough & Tunmer, 1986). Dyslexia refers to poor word reading despite adequate language skills. Hyperlexia refers to skilled word reading but weak reading comprehension, typically due to oral language comprehension difficulties. The combined type refers to problems in word reading and oral language comprehension. Distinguishing among these three types of reading problems is essential for designing a given student's remedial instruction. Students with dyslexia and hyperlexia do not make good small-group partners. Their strengths and weaknesses in reading have no functional overlap.

Subtypes Based on Rapid Automatized Naming

Although there are three empirically derived subtypes of reading disabilities, with dyslexia being one of them, efforts to subdivide dyslexia into valid subtypes have been problematic on many levels. The most popular subtyping approach in the empirical reading research distinguishes among dyslexic students based on the presence or absence of poor phonemic awareness and poor rapid automatized naming, or RAN (Wolf et al., 2002). The subtypes involve the presence of one or the other or both, the latter being referred to as the *double deficit*. The presumption has been that students with problems in both have more severe word-reading difficulties. However, that may not be the case, as students with a severe single deficit in phonemic awareness can have greater difficulties than students with more moderate problems in both phonemic awareness and RAN (Vukovic & Siegel, 2006). The status of subtypes based on these characteristics is still under investigation. Moreover, there is no clear, empirically based protocol for distinguishing among these subtypes when it comes to planning instruction.

Despite these uncertainties, it is still recommended that practitioners invest the 2–4 minutes of total administration time involved in tests of RAN when evaluating struggling readers. Table 35.3 lists six reasons for including assessments of RAN and working memory (WM) in any evaluation of struggling readers. One of these relates to the fact that the double deficit tends to suggest poorer outcomes from milder interventions (i.e., Tier 2). Research has shown that for some students, skipping Tier 2 of RTI and going directly to Tier 3 provides better outcomes for such students than requiring students to demonstrate poor progress at Tier 2 before trying a more intensive Tier 3 remediation (Al Otaiba et al., 2014).

TABLE 35.3. Rationale for Including Rapid Automatized Naming (RAN) and Working Memory (WM) in Reading Evaluations or Universal Screenings

1. They are good predictors of later reading skills.
2. They are good predictors of how well students will respond to reading interventions.
3. They help evaluators and teachers understand *why* students struggle in reading. This is particularly true when students appear to have adequate phonemic awareness and phonic decoding skills, but still struggle with word identification and fluency.
4. They affect how one interprets a student's larger profile. If either RAN or WM is weak, one can anticipate the need to build stronger phonemic awareness skills in struggling readers. For example, a phonemic awareness scaled score of 9 (37th percentile) on the Elision subtest from the CTOPP-2 may be adequate for students with RAN and WM scores of 10 or higher, but inadequate for students with either a RAN or WM score of 7 or lower. The latter students should receive phonemic awareness instruction to compensate for the negative impact that weak RAN or WM is likely having on reading. Several studies that showed large improvements in phonemic awareness and word reading also showed substantial improvements in RAN and WM performance (Kilpatrick, 2015). This was the case even though RAN and WM were not directly addressed in the intervention.
5. Knowing that a student has a WM weakness in particular can affect the choice of remedial strategies. The classic special educational strategies of multiple repetitions and multisensory tasks are based upon decades of clinical experience with struggling students, a large proportion of whom have WM difficulties. Such strategies are not quite so necessary for students who struggle academically but have average or better WM. Knowing a student's WM skill level can thus influence the selection of intervention techniques.
6. The presence of poor RAN and WM increases the validity of an SLD diagnosis in students with reading problems, given the capacity of weaknesses in these skills to predict future struggles in reading and weaker RTI response.

These six possible advantages can justify the brief assessment time involved in administering RAN and WM subtests in reading evaluations and including them in universal screenings.

Subtypes Based on the Dual-Route Model of Reading

In recent years there has been increased discussion of subtypes of dyslexia based on the dual-route model of reading (Feifer, 2011, 2014; Mather & Wendling, 2012), and even a new reading test battery that, in fair measure, is designed to distinguish among these subtypes (Feifer & Nader, 2015). Before the validity of this popular subtyping model is considered, two broader categories of dyslexia must be distinguished: *acquired dyslexia* and *developmental dyslexia*.

Acquired Dyslexia

Acquired dyslexia refers to a situation in which a skilled reader (typically an adult) loses all or some of his or her reading ability as a result of a stroke, head injury, or other neurological condition. Acquired dyslexia was first described in clinical cases in the early 1970s (Marshall & Newcombe, 1973). Although persons with acquired dyslexia showed a variety of reading related difficulties, some displayed one of three subtypes: *surface dyslexia* (Patterson, Marshall, & Coltheart, 1985), *phonological dyslexia* (Coltheart, 1996), or *deep dyslexia* (Coltheart, Patterson, & Marshall, 1980).

Individuals with surface dyslexia struggle to instantly recognize words that were previously familiar to them, but they can sound out phonically regular words and nonsense words. By contrast, those with phonological dyslexia remember the words they previously learned before the neurological incident, but can no longer read nonsense words or sound out new words. Individuals with deep dyslexia are similar in some respects to those with phonological dyslexia but have more varied symptomatology, including a tendency to make semantic errors, such as reading "truck" for *bus*. These acquired dyslexia subtypes are well-established clinical syndromes, even though most individuals with acquired dyslexia do not fall into these distinct subtypes.

This distinction among these types of dyslexia was instrumental in developing the *dual-route model of reading*. The dual-route model acknowledges that some words are not familiar to the reader and must be read by phonological recoding. This is called reading by the *phonological route*. Other words are familiar to the reader, and these words are read instantly, without conscious effort. This is called reading by the *direct route*. These two routes parallel the deficits found among some of those with acquired dyslexia. Individuals with phonological dyslexia still have access to the direct route but struggle immensely with the phonological route, while those with surface dyslexia display the opposite pattern.

It must be pointed out that the dual-route model describes two different ways of *reading* words, not two different ways of *learning* words. These two routes do not translate into two reading strategies. Familiar words are instantly and effortlessly recognized, so no strategy is involved. By contrast, the phonological route uses the strategy of phonic decoding. But the result is that the word is read/identified, but not necessarily learned. The dual-route model makes no presumptions about how unfamiliar words become familiar. Nor does this model tell us how one becomes skilled with the phonological route. It must be emphasized that the dual-route model long predates the more recent advances in our understanding of orthographic learning, described earlier in this chapter.

The dual-route model is not a useful instructional framework. To be useful instructionally, we need a framework that allows us to understand the development of the skills needed for children to become good orthographic mappers. These skills will allow students to efficiently remember more and more words, and thus read more words via the direct route. We also need to know the best way for struggling readers to develop the skill of accurately sounding out unfamiliar words and thus read via the phonological route when encountering new words. The dual route model provides no answers here. As a result, a healthy skepticism must be applied when one seeks to superimpose the subtypes of acquired dyslexia onto developmental dyslexia.

Developmental Dyslexia

Developmental dyslexia, by contrast, refers to a situation in which an individual has never developed typical reading skills, despite adequate opportunity and effort. Unlike those with acquired dyslexia, individuals with developmental dyslexia have not mastered phonological recoding or orthographic mapping. Is there evidence to suggest that some children can develop orthographic mapping without developing phonological recoding (phonological dyslexia) while other children develop the opposite pattern (surface dyslexia)? Can the subtype distinction found in clinical populations of adults with acquired dyslexia be validly superimposed onto cases of developmental dyslexia in children?

This question has been investigated in the research literature for decades. The consensus among reading researchers is that distinguishing between phonological and surface dyslexia as subtypes of developmental dyslexia is not well supported empirically. Multiple teams of reading researchers have reviewed the studies that attempt to make such a distinction and do not find convincing evidence that such a distinction can or should be made (Ahmed et al., 2012; Fletcher et al., 2018; Hulme & Snowling, 2009; Van den Broeck & Guedens, 2012; Vellutino et al., 2004).

There is no attempt here to provide a review of the vast subtyping literature. However, listed below are some of the major problems with the understanding that the surface and phonological patterns represent valid subtypes of developmental dyslexia.

First, as mentioned, this subtyping scenario superimposes an adult, neuropathology-based model onto children who do not display similar neurological conditions. The dual-route model describes the two “routes” of word identification among *skilled* readers. It does not inform us about how those routes develop, which is precisely what needs to be addressed if we are to properly understand developmental dyslexia. The phonological versus surface subtyping model treats the dual-route theory as a word-learning theory when it is actually a “finished-product” theory; that is, it describes the finished product of skilled reading. As a result, using the dual-route model for understanding developmental dyslexia appears to be inherently problematic.

Second, the evidence in favor of the phonological versus surface dyslexia subtypes has been mixed at best, and those results have often depended on the specific type of research methodology used (for more detail, see below). At worst, after adjustments for the methodology, the distinction between those subtypes virtually disappears (Van den Broeck & Guedens, 2012; Van den Broeck et al., 2010). However, despite the fact that the empirical reading research field remains rather skeptical of a distinction between phonological and surface subtypes of dyslexia, some authors in the areas of school psychology and neuropsychology seem to present this subtyping scenario as if it were a well-established phenomenon, and little or no mention is made of the controversy surrounding its existence (e.g., Feifer, 2011, 2014; Mather & Wendling, 2012).

Third, initial and subsequent attempts to find developmental surface and phonological dyslexia have used chronological-age (CA) controls (Castles & Coltheart, 1993; Heim et al., 2008). Such research designs yield results suggesting that a portion of students fit the phonological and surface subtypes, while most exhibit the mixed type. But critics have pointed out major confounds in using CA control groups (e.g., Stanovich, Siegel, Gottardo, Chiappe, & Sidhu, 1997; Van den Broeck & Guedens, 2012). As a result, there has been a shift to including reading-age (RA) controls—for example, matching fifth graders who are reading at a second-grade level with average second grade readers. For two decades, the reading research field considered this a more valid comparison because it removed some of the confounds associated with the CA matched design. When RA controls are used, fewer students fit the phonological dyslexia subtype, more fit the mixed profile, and the surface dyslexia subtype virtually disappears (Stanovich et al., 1997; Van den Broeck & Guedens, 2012).

More recently, Van den Broeck and colleagues (Van den Broeck & Guedens, 2012; Van den Broeck et al., 2010) have demonstrated that, like the CA control design, the RA control design has significant confounds, and the design itself may *produce* the phonological dyslexia subtype rather than *reflect* an actual subtype. They have pointed out that in subtyping studies, it is most common for dyslexic children in fourth through sixth grades to be compared with RA control second graders on word identification tests. In such matches, it is common to find a substantial portion of dyslexic children to have lower rates of nonsense-word reading than the second-grade typical readers used in the comparison. This is taken as evidence for the phonological dyslexia subtype.

The problem with this design is that it fails to account for the fact that the older dyslexic children have had 2–4 more years of instructional experience and exposure to reading. Such experience allows them to eventually learn many common second-grade-level words and thus receive a score comparable to typical second graders on a word identification test. But their actual phonological skills that underlie reading remain weak, as reflected in their poor nonsense-word reading. In addition, based on the fact that these older students have a larger vocabulary than their younger controls, they have better use of set for variability, discussed above, to respond correctly to words on word identification subtests. As a result, matching a fifth-grade dyslexic reader and a second-grade typical reader with the same word identification raw score confounds age, experience, and set for variability. Such confounds create the pattern of phonological dyslexia because the older children sound out words more poorly than their normative word-reading scores would suggest. The apparent cases of phonological dyslexia in these studies thus seem to be an artifact of the confounded research design.

To address the issue of the CA control and RA control designs, Van den Broeck and colleagues have developed two ingenious and sophisticated designs that avoid these confounds without creating new confounds. With these non confounded designs, the phenomena of phonological dyslexia and surface dyslexia virtually disappear. Rather, these authors argue for a developmental explanation in which different continuous skill levels in phonemic awareness, reading experience, and compensating factors all interact differently at different ages to produce the variability we see among children with dyslexia. It is this variability that has been traditionally interpreted as phonological versus surface subtypes of dyslexia (Van den Broeck & Guedens, 2012; Van den Broeck et al., 2010). It is worth pointing out that the findings of Van den Broeck and colleagues are consistent with the orthographic learning theories of Ehri and Share, described above (Van den Broeck & Guedens, 2012; Van den Broeck et al., 2010). By contrast, the conventional phonological versus surface dyslexia subtyping is not consistent with the orthographic learning literature.

A fourth problem is related to the previous point. The variations in nonsense-word and irregular-word reading performance found among individuals with dyslexia that have formed the basis of the proposed dyslexia subtypes can be better explained via an updated model of word-reading development, such as the one described earlier in this chapter. Students who might be considered to have phonological dyslexia are typically older students who can instantly identify an array of common words that have been mapped via orthographic mapping, albeit after many, many more exposures than would be needed by typically developing readers (Ehri & Saltmarsh, 1995; Share & Shalev, 2004). In studies of dyslexia, these students' pools of mapped words are not at grade level. Yet these students struggle with nonsense-word reading because they have not adequately developed the phonological skills listed on the left side of Table 35.2. Students who are considered to have surface dyslexia can be better understood by recognizing that they have typically received phonic-based instruction and they have only developed to the second level of phonemic awareness development and reading development in Table 35.2. Such students can sound out words, but are not efficient at orthographic mapping, since they have not developed the more advanced phonemic awareness skills needed for efficient orthographic mapping. Consistent with this interpretation is the finding that subtyping studies have found that children with both phonological and surface dyslexia display below-average phonemic awareness skills, indicating that poor phonemic awareness skills are found in those alleged to have surface dyslexia as well as those alleged to have the phonological subtype, but typically to a milder degree (Hulme & Snowling, 2009). This is consistent with Table 35.2 and with the developmental explanation provided by Van den Broeck and colleagues.

Fifth, the dual-route subtyping issue does not seem to reflect more recent work on the nature of the orthographic tasks that gave rise to the notion that orthographic skills should be considered separate reading-related subskills. As described above, more recent research has suggested that orthographic task performance is a by-product of phonological skills, letter–sound skills, and reading experience. It does not appear to be an independent reading-related subskill or to have a causal relationship with early reading development. Yet presentations regarding the phonological and surface dyslexia subtypes appear to assume this older understanding of the nature of orthographic skills.

Sixth, related to the previous point, is that the division of dyslexia into phonological and surface subtypes appears to assume that some form of visual memory plays a significant role in word-level reading. For example, one author describes a child with surface dyslexia as a student who has "an under-reliance upon the orthographical or spatial properties of the visual word form" (Feifer, 2014, p. 157). It is unclear precisely how the term "orthographical" is being used in this statement, but we have no evidence that any spatial or visual word "form" properties are involved in the way skilled readers learn words as unitized wholes. This issue has been addressed extensively above.

More problematic in this regard is the instructional advice that would result from such a notion. After making a major contribution to our knowledge of the neuropsychological substrates of learning new words, Glezer and colleagues (2015) lapse into speculation when they say, "These findings have interesting implications for reading remediation in individuals with phonologic processing impairments because they suggest the possibility that these individuals might benefit from visual word learning strategies to circumvent the phonologic difficulties and directly train holistic visual word representations in the VWFA [visual word form area]" (p. 4971).[3] It is no coincidence that they did not cite a study to support this instructional suggestion because it appears likely that no such study exists. Their suggestion is entirely intuitive and without an empirical basis. By contrast, Truch (1994) reports that out of 281 individuals with phonological-core dyslexia ages 5–55, only one did not make progress in phonological awareness training, and 70% reached an average or above-average level of phonological awareness skills. Truch noted that for those students whose phonics skills were not moving forward, training in advanced phonemic awareness resulted in dramatic gains in both phonic decoding and sight word learning. So Truch provides rather extensive and direct evidence (as do others—e.g., Torgesen et al, 2001; Vellutino et al., 1996) that "phonologic processing impairments," as Glezer and colleagues call them, can be successfully overcome in more than 99.5% of those with such "impairments" (i.e., 1 out of Truch's 281 equals less than 0.5% failure rate among those with phonological-core dyslexia). Thus there is no need to suggest speculative ideas about "visual word learning strategies" that have no demonstrated efficacy and run counter to our current empirical understanding of both normal word-learning skills and effective word-reading intervention.

Conclusions Regarding Dyslexia Subtypes

From the previous considerations, it would seem that the proposed phonological and surface subtypes of dyslexia do not have a well-established empirical foundation. This conventional subtyping model does not reflect research advances in the last 20 years regarding word-reading development, orthographic skills, and the role (or lack thereof) of visual skills in reading; nor does it take account of the research literature on word-reading intervention effectiveness. Despite its recent popularity in the field of school psychology, practitioners should not feel the need to attempt to establish dyslexia subtypes when evaluating students who struggle in word-level reading.

IMPLICATIONS OF RECENT ADVANCES FOR DIAGNOSING READING DISABILITIES

This chapter has presented numerous concepts and research related to understanding the nature of word-level reading difficulties. Several implications that can be drawn from these concepts and research may inform decisions about the presence or absence of a reading difficulty, and whether such a difficulty (if present) rises to the level of being considered an SLD.

One of the key themes of the chapter is that we must not just look at isolated word reading and phonic decoding, but must work from a broader understanding of word-reading development—from letter–sound knowledge, to phonic decoding and spelling, to the size of a student's orthographic lexicon. A student can arrive at a given profile of test scores via multiple routes, and the hope is that the material in this chapter will allow practitioners (1) to examine multiple possibilities to determine the nature of a student's reading struggles and (2) to take a proper perspective on interpreting a profile of test scores.

It will be important to consider the relationship between a student's language skills and his or her word identification subtest performance. It is important to acknowledge that students with stronger vocabulary skills can create the impression that their word reading is stronger than it really is, due to their ability to use set for variability in responding to conventional word-reading subtests. It will be important to put more weight on nonsense-word reading subtests for such students.

Timed tests of real words and nonsense words arguably provide a better indication of a student's sight vocabulary and his or her letter–sound proficiency, two hallmarks of skilled reading. It is much harder to compensate under timed conditions than on untimed reading subtests. Tests like the TOWRE-2, the Test of Silent Word Reading Efficiency—Second Edition, or the timed real- and nonsense-word subtests from the Kaufman Test of Educational Achievement—Third Edition (KTEA-3) can be very valuable in this regard. Personal experience with these tests suggests that the real-word versions of these tests are very useful at the elementary level, but less so at the secondary level. This is because the word difficulty is not challenging enough on the TOWRE-2 Sight Word Efficiency subtest, and the timing is not long enough to get to the more difficult words on the KTEA-3 timed word-reading subtest. At the elementary level, however, this type of subtest may provide the most valid assessment of the size of a student's sight vocabulary (i.e., below-average performance means a limited orthographic lexicon whereas an average or better score suggests an average or larger orthographic lexicon).

The 3-second timing on the word identification subtest from the Wechsler Individual Achievement Test—Third Edition is too long to assess automaticity. Also, the timed sentence-reading tasks found in the Woodcock–Johnson IV Tests of Achievement, the Woodcock Reading Mastery Test—Third Edition, and the KTEA-3 use common words that older students eventually map to memory, so it does not adequately address their fluency or automatic word recognition with grade-level reading material. *Such subtests should not be used to "rule out" a reading difficulty with students beyond about fourth grade.* However, if an older student has a low score on such a subtest, that indicates a very limited sight vocabulary.

RAN and WM should also be considered as part of any evaluation of students who struggle with word-level reading. As described in Table 35.3, such tests are quickly administered and have multiple advantages in understanding a student's reading challenges.

Two skills needed for orthographic mapping are letter–sound proficiency and phonemic proficiency. The former can be assessed with the TOWRE-2 Phonetic Decoding subtest (valuable at all age levels) and the timed nonsense-word subtest from the KTEA-3. However, at this writing, there are no commercially available tests for phonemic proficiency. The CTOPP-2 is highly recommended for assessing phonological awareness, RAN, and phonological WM. It is highly recommended and should be a central component in any assessment of a student with word-level reading difficulties. However, the phonological awareness subtest (Elision) is untimed. Universal screeners have timed phonological awareness tasks, but they do not go beyond the first-grade level of skill and thus do not address phonemic proficiency. The *Phonological Awareness Screening Test (PAST)*[4] is free and is designed to assess phonemic proficiency. It is available from *www.thepasttest.com* or from *kilpatrickd@cortland.edu*.

The practitioner's greatest assessment tool is a strong knowledge base regarding the nature of typical word-reading development and the sources of reading difficulties. With such a knowledge base, evaluators can more appropriately select and interpret tests of word-level reading and related skills (i.e., phonemic awareness, RAN, WM, spelling, and vocabulary). Such evaluations should yield more accurate representations of a student's skills, which should lead to better decisions regarding the next step in addressing the student's reading difficulties. The next step may involve general educational intervention within an RTI/multi-tiered system of support framework, or it may involve a designation of SLD. Regardless of which route is taken, it will be important to incorporate the highly effective reading intervention approaches that prompted the development of RTI in the first place (Kilpatrick, 2015). These approaches allowed a large portion of struggling readers to "catch up" with their typically developing peers. And for most of those who did not catch up, they developed better reading skills than they would have if traditional remedial approaches had been used.

NOTES

1. This must not be misinterpreted to mean that general visual sequencing skills underlie our memory for written words. Only letter sequences based on phonology appear to be involved. Skill at recalling sequences of shapes or even nonpronounceable letter sequences (e.g., *ZNWRT*) do not appear to relate to reading like phonologically based, pronounceable letter sequences.

2. Actually, these examples do not truly represent visual memory failures, which is why the term *visual memory failure* is given in quotation marks. Rather, they represent failures in phonological retrieval. A true visual memory failure would involve failure to recognize something as visually familiar. In other words, rather than just failing to come up with the name of an acquaintance, it would involve not even recognizing the person visually as someone we had ever seen before.

3. It is an unfortunate quirk of reading research history that with the discovery that the left fusiform gyrus area is activated when familiar words are seen, this area was improperly named the *visual word form area*. We have no evidence to suggest that the visual form of the word plays any role in the initial storage or subsequent activation of known words. There is ample evidence to show it is *the precise letter order* that is instantly recognized in known words, as a holistic letter sequence. Thus *bear, BEAR,* bear, BEAR, ***bear, BEAR***, and even *bEaR* all provide the same activation—as a holistic, familiar letter sequence—because they all represent the same letter order, despite their dramatically different visual word forms. Interestingly, Glezer and colleagues (2015) showed in their study that the now familiar sequences were all processed first phonologically before they became unitized, orthographically familiar wholes. There was nothing in their study to suggest that phonology can be bypassed in this learning process, nor is there anything in the broader reading research literature to suggest this.

4. This is not to be confused with another phonological awareness test using the same acronym, PAST, that turns up on Internet searches. This other test, called the Phonological Awareness *Skills* Test. It takes a different approach to phonological awareness assessment and does not assess phonemic proficiency.

CHAPTER 36

The Role of Cognitive and Intelligence Tests in the Assessment of Executive Functions

Denise E. Maricle
Erin K. Avirett

The study of executive functions is a popular area of research within the fields of cognition and neuroscience. Over the last 15–20 years, there has been a proliferation of articles, books, and research about executive functions. Psychologists and other professionals have referred to "executive functions" or "executive functioning" as if it is a well-known, singular cognitive construct that is understood and easily measured. In fact, despite the wealth of available information, very little is known about executive functions.

The purpose of this chapter is to provide a review of how the major measures of intellectual functioning can be used in the assessment of executive functions. However, assessment of executive functioning involves more than the choice of tools. In order to evaluate executive functions effectively, an understanding of how such functions are defined and conceptualized, knowledge about the neuroanatomical correlates and developmental trajectories of executive functioning, and familiarity with how executive functions are operationalized and measured are mandatory. Therefore, a brief discussion of definitional issues, theoretical conceptualizations, and neuropsychological underpinnings is provided to assist the reader in understanding the complexity of the topic. Each of the major assessment instruments for broad cognitive functioning is reviewed with regard to its utility in the evaluation of executive functions. Within this chapter, the terms *executive functions*, *executive function*, and *executive functioning* are used interchangeably.

DEFINITIONAL ISSUES

The terminology for executive functions is frequently used inconsistently and interchangeably, with little understanding of, or even mutual agreement as to, what the terms actually imply. The complex reciprocal nature of executive functions makes developing a cohesive definition challenging (Maricle, Johnson, & Avirett, 2010). Researchers cannot agree as to whether executive functions are a single process, or a descriptive term for a collection of cognitive processes. In the fields of school psychology, neuropsychology, school neuropsychology, and cognitive psychology, the prevailing perspective is that executive functions consist of separate but related cognitive processes. Despite this consensus, researchers have not agreed upon the components of executive functioning, although several domains are generally accepted. These domains include self-monitoring and regulation of cognition, emotion, and behavior; initiating, planning, and completing complex tasks; working memory; attentional control (inhibition, sustained attention, shifting attention); and cognitive flexibility (Alvarez & Emory, 2006; Anderson, Levine, & Jacobs, 2002; Baron, 2004; Chan, Shum, Toulopoulou, & Chen, 2008; Cheung, Mitsis, & Halperin, 2004; Goldstein, Naglieri, Princiotta, & Otero, 2014; Hughes & Graham, 2002; Hunter & Sparrow, 2012; Jurado & Rosselli, 2007; Lezak, Howieson, & Loring, 2004; Stuss & Alexander, 2000). Overall, the concept of executive functioning includes the processes of mental flexibility, the ability to filter out interference or distractions, the ability to engage in goal-directed behavior, and the ability to anticipate the consequences of one's actions (Ardila, 2008; Ardila & Surlof, 2007; Hunter & Sparrow, 2012; Knight & Stuss, 2002).

This definitional debate is not an esoteric one. How executive functions are defined is critical to the assessment process because how test authors define the construct determines how it is operationalized and thus measured in a particular instrument. It is also necessary for the examiner to define what elements or components of executive function they are interested in measuring, since executive functioning in and of itself has not been proven conclusively to exist. In addition, no single measure or instrument is able to evaluate all of the proposed executive functions. Thus examiners need to know what aspects of executive functions should be measured and how the instruments or tools they have chosen actually measure these specific aspects. Finally, understanding the limitations posed by definitional differences is important when researchers and clinicians alike are reading and filtering through the wealth of literature published on this challenging topic.

THEORETICAL MODELS

The variety of current models and theories reflects diverse and disparate perspectives on the nature, structure, and role of the executive functions; however, the literature is cluttered with competing claims and datasets that are inadequate for leveraging support for any one theory or model over another. Although the structure and role of executive functions have been debated and conceptualized in a multitude of ways by numerous researchers, no clear consensus has emerged regarding a specific theory or model of executive functioning. Executive function models can be categorized according to the way they conceptualize various functions (Zelazo, Muller, Frye, & Marcovitch, 2003). Two primary perspectives dominate the literature at this time. Executive functions are considered to be either a unitary and hierarchical system with control and monitoring processes, or a set of distinct but interlocking cognitive processes.

In the hierarchical perspective, executive functions are considered a unitary construct. In this view, executive functioning is regarded as metacognitive and is frequently seen as analogous to overall intelligence (Anderson, 2008; Blair, 2006; Friedman et al., 2006; Grafman, 2006; Kane & Engle, 2002). This view depicts executive functioning as the supervisor of other subordinate and narrower cognitive processes. For a recent example of this perspective, one could examine McCloskey's holarchical model of executive functions (McCloskey & Perkins, 2013). Accordingly, executive functioning is more difficult to operationalize, define, and assess in most hierarchical models, due to the complexity of identifying and measuring the managerial metacognitive aspect in conjunction with the varied associated cognitive processes. Within this viewpoint, executive functions constitute a nebulous, overarching entity similar to *g*: We all know it when we see it, but no one can really "define" it. Examples of this perspective can be seen in Luria's theory of cognitive functioning (the theory that underlies the NEPSY-II, the Cognitive Assessment System—Second Edition [CAS2], and one interpretive framework for the Kaufman Assessment Battery for Children—Second Edition [KABC-II]) and in Cattell–Horn–Carroll (CHC) theory (the primary theory underlying the Woodcock–Johnson IV Tests of Cognitive Abilities [WJ IV COG], the Stanford–Binet Intelligence Scales, Fifth Edition [SB5], the Differential Ability Scales—Second Edition [DAS-II], the other interpretive framework for the KABC-II, and other modern measures of cognitive functioning).

Luria described human cognitive processes within the framework of three functional units. In Luria's theory, the first functional unit (block 1) is arousal and attention; the second unit (block 2) codes information using simultaneous and successive processes; and the third functional unit (block 3) is involved in the regulation of executive functioning (planning, strategizing, regulating performance, and solving problems). Luria identified the prefrontal lobes of the brain as primarily responsible for the third functional unit. However, rather than a strict localization perspective, Luria took a more dynamic or systems-based approach. He posited that complex brain functions (such as executive functions) are mediated by a coordinated set of brain structures or physiological processes, and that no specific brain area completely controls a specific function/process. As a result, a variety of disruptions may be seen if a particular brain region is damaged, and compromised functioning may or may not be subsumed or ameliorated by other brain regions (Lewandowski & Lovett, 2008). Luria's work served as one impetus for the study of executive functions and has been used as a blueprint for defining components of human intellectual competence.

CHC theory describes human cognitive processes within the framework of three strata: a general overarching factor, broad cognitive factors, and multiple narrow abilities. CHC theory does not describe a specific and separate element of executive functioning; rather, components of executive functions are integrated primarily into the Gf (fluid reasoning) broad-ability factor (Kane & Engle, 2002) and the narrow-ability factors of induction, general sequential reasoning, and attention and concentration. Drawing from more recent research, Flanagan, Alfonso, Ortiz, and Dynda (2010) and Flanagan, Ortiz, and Alfonso (2013) present an integrated interpretive framework based on psychometric, neuropsychological, and Lurian perspectives, and provide a neurocognitive demand task analysis of the major test batteries using this framework. Defining executive functioning as a global neuropsychological domain represented by metacognition, planning, learning, memory, and cognitive efficiency, Flanagan and colleagues (2010, 2013) posit that the neuropsychological domain of executive functions corresponds well with eight broad CHC abilities: fluid reasoning (Gf), comprehension–knowledge (Gc), processing speed (Gs), short-term memory (Gsm), long-term storage and retrieval (Glr), quantitative knowledge (Gq), reading and writing ability (Grw), and general knowledge ability (Gkn).

Proponents of unitary conceptualizations of executive functions argue that their perspective is the most parsimonious view of executive functions, and that nonunitary models or perspectives are reductionistic and not helpful, given their fractionation of executive functions (Sugarman, 2002). In contrast, researchers from the second major viewpoint see executive functions as a label for a collection of distinct, yet associated, cognitively complex higher-order processes (Anderson, 2001; Ardila et al., 2000; Baron, 2004; Elliott, 2003; McCabe, Roediger, McDaniel, Balota, & Hambrick, 2010). Proponents of this perspective would argue that the factorial evidence clearly supports distinct cognitive processes that correlate moderately with each other. However, as previously stated, researchers cannot reach a consensus as to what cognitive processes constitute these executive functions. Salthouse (2005) has suggested that reasoning and perceptual speed represent the underlying features of executive functions, whereas others have proposed working memory (Baddeley, 1996, 2000), verbal working memory (Sugarman, 2002), or inhibition (Barkley, 2000) as the clear foundation of executive functioning. Miyake, Friedman, Emerson, Witzki, and Howerter (2000) propose an intermediate position. They see executive functions as separate but moderately correlated constructs, and suggest that the executive system is composed of both unitary and nonunitary components. Other researchers have elaborated on this idea and proposed two types of executive functions: metacognitive and behavioral (Fuster, 2001, 2002; Happaney, Zelazo, & Stuss, 2004). According to this perspective, the metacognitive type consists of the usual executive functions and is mediated by the dorsolateral prefrontal cortex (PFC), whereas the behavioral type is responsible for the coordination of cognition and emotion, with inhibition as its primary expression, and is mediated by the ventromedial PFC.

Miller's (2007, 2013) integrated school neuropsychology/CHC conceptual model (integrated SNP/CHC model; see also Miller & Maricle, Chapter 33, this volume) provides an intermediate perspective on neuropsychological constructs such as executive functions; he views them as independent but moderately correlated constructs. Miller's model is unique in that he uses neuropsychological, neuroanatomical, and neuroassessment research to conceptualize the model's components. It is specifically intended to be applied to the neuropsychological development of children and adolescents, and it can be utilized in conjunction with interpretive approaches specific to children, such as Hale and Fiorello's (2004) cognitive hypothesis-testing model. In Miller's conceptual model, tasks are classified according to four broad classifications (basic sensorimotor functions; facilitators and inhibitors; basic cognitive processes; and acquired knowledge). These are then further subdivided into second-order and third-order classifications that respectively represent broad and narrow constructs being measured by the various tasks. Miller's model classifies executive functions as a second-order classification (broad construct) under the cognitive processes domain (Miller, McGill, & Bauman Johnson, 2016).

Miller categorizes executive functions as cognitive flexibility, concept generation, inhibition, behavioral/emotional regulation, and planning, reasoning, and problem solving. He views these executive functions as being strongly related to fluid reasoning abilities or tasks that require novel problem-solving skills. In contrast to other researchers, Miller views other common aspects of executive functioning, such as working memory and attention, as separate neurocognitive constructs and labels them as facilitators or inhibitors of cognitive processes. For example, attentional processes in Miller's model are comprehensively addressed as attentional control constructs involving selective or focused attention and sustained attention, and are considered separate and distinct from immediate memory capacity, working memory, or executive functions.

Understanding these different theoretical perspectives is important because they shape the research being conducted on executive functions and influence the interpretation of the obtained data. Some theories have exerted considerable influence on the field even when there is no supporting evidence. It is also important to note that the primary theoretical models of executive functioning were developed from an adult perspective and have been applied to children and adolescents on a post hoc basis. The problem with adult-based studies is that they examine executive functions from the perspective of the developed brain's responding to an acquired injury, resulting in an executive function deficit. Such studies do not take into account issues of development, such as how an acquired injury affects executive functions in a brain that is still developing or how neurodevelopmental disorders may affect the development of neurological functions such as executive functions (Hunter & Sparrow, 2012). Children often display differential performance, which does not fit many of the adult models currently available.

THE NEUROPSYCHOLOGY OF EXECUTIVE FUNCTIONS

Understanding the neuropsychological underpinnings of executive functioning is also critical to the assessment of executive functions. Despite amazing progress in neuroimaging, the neuroanatomy and neurophysiology of executive functions continue to be debated in the literature. Historically, executive functions have been associated with the PFC, and more specifically with the anterior (front) portions of the PFC. Exactly how the PFC supports executive functions is largely unknown and somewhat controversial (Alvarez & Emory, 2006; Hughes & Graham, 2008; Wood & Grafman, 2003). Attempts to localize executive functions to discrete areas in the PFC with neuroimaging techniques have been inconclusive (Roberts, Robbins, & Weiskrantz, 2002). A one-to-one correspondence between executive functions and the PFC has not yet been documented in the research, and many claims are speculative at best (Alvarez & Emory, 2006). Moreover, some neuroimaging results have implicated posterior, cortical, and subcortical regions in executive functioning, and it has been posited that executive functioning may be a more flexible distributed network than previously thought (Jacobs, Harvey, & Anderson, 2011; Roberts et al., 2002).

The PFC comprises approximately one-third of the brain; maintains intricate connections to the rest of the brain; and continues to mature through synaptogenesis, myelination, and pruning well into early adulthood. Three systems—the dorsolateral PFC, the anterior cingulate circuit, and the orbito-frontal cortex—are thought to be involved in executive functioning. The dorsolateral PFC is associated with most of the "typical" executive functions, including cognitive flexibility and behavioral spontaneity; maintaining and shifting cognitive attention; organization and planning; goal setting; performing dual-task activities; short-term memory; focusing and sustaining attention; inhibition; and fluency (Alvarez & Emory, 2006; Hale & Fiorello, 2004; Romine & Reynolds, 2005). Deficits within the dorsolateral PFC are often associated with attention problems, poor problem solving, and difficulties with self-monitoring and control. The anterior cingulate circuit appears to control the behavioral processes associated with initiation, inhibition, motivation, selective or divided attention, response monitoring, and error detection (van Vreen & Carter, 2002; Zilmer, Spiers, & Culbertson, 2008). Damage to the anterior cingulate circuit often results in difficulties with response inhibition (Miller, 2007, 2013), slow completion time or decision speed, lack of persistence, and difficulty with self-monitoring (Hale & Fiorello, 2004). The orbito-frontal cortex is involved with emotional and social behaviors such as tact, sensitivity, impulsivity, and emotional inhibition (Bradshaw, 2001; Knight & Stuss, 2002). Deficits in the orbito-frontal cortex are associated with emotional dysregulation, aggression, sexual promiscuity, disinhibition, impulsivity, and poor decision making. These three systems together create, support, and coordinate the complex cognitive functions involved in problem solving and decision making, which are the hallmarks of the construct being defined as *executive functions*.

Despite our neuroanatomical understanding of executive functioning, it is important to remember that our knowledge and understanding of how the brain functions when it is processing and performing executive function tasks is still very limited (P. Anderson, 2002). The PFC does not act in isolation; therefore, it is challenging to identify which brain regions contribute to which outcomes on specific measures of executive functions. In other words, a deficit in one area can lead to multiple behaviors or, conversely, one behavior may be the result of multiple underlying impairments. As result, Hunter and Sparrow (2012) have proposed that executive functions are best represented on a spectrum or continuum—given this underlying idea that with multiple executive functions in the equation, an individual may not display a significant deficit in any one skill, but the cumulative effects of mild executive dysfunction may result in severe executive function impairment. It is also important to remember that although a variety of neural correlates have been identified in adults for various components of executive functioning, no research to date has confirmed these findings with children.

DEVELOPMENTAL TRAJECTORIES OF EXECUTIVE FUNCTIONING IN CHILDREN

Until recently, executive functions were thought to emerge in adolescence and early adulthood. The belief was that they played little or no role in typical brain development during infancy and childhood. However, recent research has debunked this early perception and demonstrated the critical role executive functions play in typical brain development across the lifespan (V. Anderson, 2002; Reynolds, 2007). According to numerous researchers (Carlson, 2004; Hughes & Graham, 2008; Lidz, 2003), higher-order cognitive skills are present before they are observable, functional, or testable. In addition, research has demonstrated an interaction between developmental processes and the manifestation of executive functions (Blair, Zelazo, & Greenberg, 2005; Brocki & Bohlin, 2004; Hunter, Hinkle, & Edidin, 2012; Zelazo et al., 2003). Executive functions appear to emerge, develop rapidly, and reach adult levels of performance differentially; therefore, research would suggest that developmental profiles or trajectories will depend on the executive skill(s) being examined (Archibald & Kerns, 1999; Romine & Reynolds, 2005). As a result, it is important for psychologists working with children in any capacity to be aware of and understand the developmental trajectories of the executive functions they seek to measure.

ASSESSMENT OF EXECUTIVE FUNCTIONS

Operationalizing definitions of executive functions in order to assess them is even more difficult and fraught with challenges than is developing theoretical definitions. One of the challenges is obtaining valid, accurate, and reliable measures (Hughes & Graham, 2008), given the perspective that executive functions are not unitary but composed of multiple complex functions. Since there is no universal definition of what constitutes executive functions, or which domains are critical for successful executive functioning, there is no agreement as to what executive function domains should be measured or how these domains should be assessed. A second challenge is that by definition executive function tasks are complex, so task impurity becomes an issue, in that a task may require (and thus be influenced by) multiple cognitive processes. Thus it is difficult to distinguish executive function tasks from other tasks because the integrative simultaneous nature of frontal lobe functioning makes it difficult to parse out the specific cognitive functions being utilized in each type of task in order to create a pure measure of executive functioning (Hughes & Graham, 2002; Maricle et al., 2010; Romine & Reynolds, 2005).

Even when a task can be identified as a relatively valid, reliable, and somewhat pure measure of a particular executive function, the task or an individual's performance on the task is often misinterpreted. A common mistake is to equate deficient performance on an identified task of executive function with frontal lobe or neurological dysfunction. A second common mistake is to assume that each task taps an underlying cognitive process universal to all executive function tasks, or that all tasks of executive function are measuring the same aspects of the construct. Such presumptions lead to overly simplified, narrow, or inaccurate interpretations. Interpreting results from executive function tasks depends on precise specification of task demands; this specificity necessitates a systematic understanding of the components of executive function, as well as an understanding that most executive function tasks require several cognitive skills for successful performance (Flanagan et al., 2010; Hughes & Graham, 2008; Miller, 2007, 2013). Research demonstrates that successful performance on most complex cognitive tasks requires a combination of cognitive skills, such as working memory, attention, concept formation, inhibition, and/or cognitive flexibility. The breakdown in an individual's performance can occur at any stage of cognitive processing, from lower-level skills such as attention to the higher-order skills such as planning (Delis, Kaplan, & Kramer, 2001). Accurate interpretation then requires determining the neurocognitive constructs that contribute to successful or poor performance on a specific task, and then considering those results within the context of the assessment of a specific individual.

The broad range of skills implicated in executive functions has led to the use of many different assessment tools; however, no instrument has yet been developed to measure executive functioning in its entirety. Rather, there are tools available to measure specific components of executive functions. Assessment can be divided into broad overall measures of multiple cognitive constructs, or targeted measures of a specific cognitive construct. Executive functions can be more or less effectively evaluated by using both types of measures. Miller and Hale (2008) note that standardized intellectual measures are psychometrically some of the best tools available to practitioners, and that incorporating these tools into neuropsychological assessment is an essential practice. Thus a discussion of the major norm-referenced comprehensive batteries of intelligence and how they relate to the measurement of executive functions is warranted.

EVALUATION OF EXECUTIVE FUNCTIONS WITH THE MAJOR COGNITIVE BATTERIES

Woodcock–Johnson IV Tests of Cognitive Abilities

The WJ IV COG (Schrank, McGrew, & Mather, 2014) consists of a battery of tests designed to measure cognitive and intellectual abilities. The WJ IV COG was designed to work in concert with the Woodcock–Johnson IV Tests of Achievement (WJ IV ACH; Schrank, Mather, & McGrew, 2014a) and the Woodcock–Johnson IV Tests of Oral Language (WJ IV OL; Schrank, Mather, & McGrew, 2014b). The WJ IV COG was based on the iteration of the CHC theory of cognitive abilities described by Schneider and McGrew (2012), and McGrew, LaForte, and Schrank (2014). According to Ding and Alfonso (2016), the WJ IV COG was designed to focus on "important" broad and narrow CHC abilities critical for academic success, rather than simply measuring the broad abilities of CHC as did its predecessor, the WJ III. Additionally, some of the WJ IV tasks were designed to be cognitively complex, meaning that several skills are needed to complete these tasks successfully.

CHC theory regards cognitive abilities as multidimensional and dynamic rather than as static domains of function. The iteration of CHC as defined by Schneider and McGrew (2012) posits 16 broad abilities and over 80 narrow abilities. However, CHC theory, and by extension the WJ IV COG, does not view executive functioning as a specific independent cognitive domain; rather, executive functions are seen through the lens of cognitive processes such as fluid reasoning (Gf), working memory (Gwm), and processing speed (Gs) (Maricle & Johnson, 2016).

No research is yet available involving the WJ IV COG's relationship to executive functions. Research on the relationship to executive function constructs in the WJ III COG was also quite limited. The majority of this research focused on the broad CHC factors and the underlying narrow abilities. One exception was a study by Floyd and colleagues (2006) that examined the relationship of the WJ III COG clinical clusters with the Delis–Kaplan Executive Function System (D-KEFS; Delis et al., 2001). Their results suggested that the clinical clusters correlated moderately with the D-KEFS tasks, and that both measures appeared to be assessing a general construct—most likely general intellectual ability because of the strong correlation with the General Intellectual Ability score.

Thus, if using the WJ IV COG to screen for executive functioning or executive dysfunction, the examiner must extrapolate from the CHC factors and the WJ IV COG tasks. On the WJ IV COG, there are three Gf (fluid reasoning) tasks designed to measure problem solving and reasoning: Concept Generation, Analysis–Synthesis, and Number Series. One task on the WJ IV ACH, Number Matrices, could also be considered a Gf task. Ford, Keith, Floyd, Fields, and Schrank (2003) describe Concept Formation as a controlled learning task that measures fluid reasoning and requires rule formation, categorical reasoning, inductive thinking, and logical deduction. Schneider (2016) describes it as a measure of induction or the ability to use limited information to identify rule-based behavior and logical patterns. Analysis–Synthesis is thought to measure deduction, or the ability to work with a set of logical rules to deduce new information. Number Series is a measure of sequential/serial or quantitative reasoning. It is highly related to the Number Matrices task on the WJ IV ACH (Schneider, 2016). A study by Miller, McGill, and Maricle (2017) found that Number Series was the most predictive task for almost every academic skill measured by the WJ IV ACH.

The WJ IV COG delineates Object–Number Sequencing, Numbers Reversed, Verbal Attention, and Memory for Words as tasks that measure immediate short-term memory capacity and working memory (Gwm). Two WJ IV OL subtests, Sentence Repetition and Understanding Directions, are also classified as measuring Gwm skills. Previous research (Floyd, Shaver, & McGrew, 2003) and current speculation would suggest that Gwm tasks also measure aspects of cognitive attention, including attentional capacity/control (Numbers Reversed, Verbal Attention, Sentence Repetition), divided attention (Object–Number Sequencing, formerly Auditory Working Memory) and selective attention (Verbal Attention; Understanding Directions).

The WJ IV COG also provides measures of learning efficiency or long-term storage and retrieval (Glr) and processing speed (Gs). Measures of long-term storage and retrieval are often controlled learning tasks involving associative memory, such as Visual–Auditory Learning, or tests of meaningful memory, like Story Recall. However, Schneider (2016) suggests a classification of Visual–Auditory Learning as a meaningful memory task rather than an associative memory task. Two other measures of Glr, Retrieval Fluency and Rapid Picture Naming, are found on the WJ IV OL and appear to be measuring memory retrieval speed or speed of lexical access. The WJ IV COG measures processing speed (Gs) via the Number–Pattern Matching, Letter–Pattern Matching, and Pair Cancellation tasks. Number–Pattern Matching used to be Visual Matching, and Letter–Pattern Matching is an analogue. Both are designed to measure pure perceptual speed. Pair Cancellation is described as a complex measure that requires the examinee to identify a specific repeating pattern; successful performance requires attention, vigilance, speed of visual scanning, and interference control. Miller and colleagues (2016) suggest that Pair Cancellation also measures sustained, as well as selective or focused, attention.

Stanford–Binet Intelligence Scales, Fifth Edition

The SB5 (Roid, 2003b), the most recent revision of the popular Stanford–Binet series, was constructed on a five-factor hierarchical cognitive model consistent with CHC theory (Roid & Barram, 2004). Using nonverbal and verbal tasks, the SB5 evaluates Fluid Reasoning (Gf), Knowledge (Gc), Quantitative Reasoning (Gq), Visual–Spatial Processing (Gv), and Working Memory (Gsm). Each subtest in the Verbal domain has a counterpart in the Nonverbal domain. Roid (2003a) indicates that the Nonverbal domain measures the general ability to reason, to solve problems, to visualize, and to recall information presented in pictorial, figural and symbolic formats; the Verbal domain measures the general ability to reason, solve problems, visualize, and recall information using spoken or written words or sentences.

Studies reported in the technical manual support the presence of a general factor, two group factors, and five specific factors; however, research conducted by other investigators calls these results into question. Canivez (2008), DiStefano and Dombrowski (2006), Sattler, Dumont, Salerno, and Roberts-Pittman (2008) found either no support or limited support for the group (i.e., two-factor) model or for the specific (i.e., five-factor) model. Canivez also noted issues of subtest migration or cross-loading, wherein subtests theoretically associated with one factor were in fact associated with multiple dimensions/factors. For example, some of the SB5 Nonverbal subtests actually accounted for more variance on the Verbal factor than the Nonverbal factor. Another issue of concern with the SB5 is that the subtests in each domain change as the individual progresses through the levels. Each subtest has one to three unique activities or variations of the task. For example, Verbal Fluid Reasoning is composed of Early Reasoning, Verbal Absurdities, and Verbal Analogies, and each variation taps verbal fluid reasoning differentially and utilizes other cognitive skills to a greater or lesser degree. This convolution is problematic, in that it is difficult to determine whether the skill set or function being measured at one level is the same skill set or function being measured at another level within the same subtest. Given the massive task impurity issues, an examiner must have a good understanding of each task within each subtest, how and when the task changes form, what skills are being measured within each form of the task, and finally how the performance and score of the individual may be affected as a result.

No research is currently available that addresses the specific use of the SB5 for assessing executive functions. The current literature indicates that interpretation of the SB5 should be primarily at the level of *g* or overall general intelligence. However, task analyses do suggest how various tasks within the SB5 may be measuring different aspects of executive functioning. If executive functions are conceptualized from a cognitive construct perspective, then tasks within the SB5 could be parsed into likely measures of different aspects of executive functioning. For example, the Nonverbal Fluid Reasoning task (Object Series/Matrices) requires sequential reasoning and deductive thinking for successful completion of items at the early levels, and then incorporates a classic matrix or pattern reasoning task using inductive thinking at the more advanced levels. Matrix tasks have consistently been found to be good measures of Gf or fluid reasoning, which is considered by many to be one of the hypothesized executive function skills (Tranel, Manzel, & Anderson, 2008). In contrast, only the Verbal Analogies items of the Verbal Fluid Reasoning task constitutes true fluid reasoning or abstract thinking skills, and thus the Verbal Fluid Reasoning task should not be considered an adequate measure of verbal executive functioning. Roid (2003a) would take exception to this characterization, as he believes that the Verbal Fluid Reasoning task measures the ability to solve novel verbal problems, to identify cause-and-effect relationships, to classify according to form and function, and to use inductive reasoning with analogies. Another example can be found in the Nonverbal Working Memory subtest and its Verbal Working Memory counterpart. The Nonverbal Working Memory task measures visual short-term memory capacity and visual working memory capacity through a “shell game” at early levels and a block-tapping task at the more advanced levels. Its Verbal Working Memory counterpart uses memory for sentences and memory for a word in the presence of interference to assess verbal short-term memory and working memory capacity.

Differential Ability Scales—Second Edition

The DAS-II (Elliott, 2007) is a revision of the Differential Ability Scales (DAS; Elliott, 1990), which originated from the British Ability Scales (BAS; Elliott, 1983). According to Dumont, Willis, and Elliott (2009), the DAS-II was based on current knowledge of neuroscience and was designed to reflect cognitive processes that contribute to learning difficulties in children; it was not developed to reflect a unitary model of *g* or general intelligence. The selection of abilities to be assessed by the DAS-II was intended to be consistent with CHC theory.

The technical manual reports varying factor structures for the DAS-II at different age levels. At the earliest ages (2–3), a two-factor model (Verbal and Nonverbal) emerges; at ages 4–5, a five-factor model emerges (Verbal, Nonverbal Reasoning, Spatial, Visual–Verbal Memory, and Verbal Short-Term Memory); at ages 6–12, a seven-factor model emerges (Verbal, Nonverbal Reasoning, Spatial, Verbal Memory, Verbal–Visual Memory, Cognitive Speed, and Auditory Processing); and for ages 6–17, a six-factor model emerges (Verbal, Nonverbal Reasoning, Spatial, Verbal Short-Term Memory, Visual–Verbal Memory, and Cognitive Speed). Sattler, Dumont, Willis, and Salerno (2008) conducted a principal-components factor analysis, using data from the technical manual; they identified for the Early Years Lower Level battery a three-factor solution that they found difficult to define, but that did not support the factor solutions cited in the technical manual. Sattler and colleagues identified a seven-factor solution for the Early Years Upper Level battery and felt that five were clearly identifiable as Verbal, Nonverbal, Spatial, Working Memory, and Processing Speed. For the School-Age battery, a six-factor solution was determined with five identifiable factors (Verbal, Nonverbal, Reasoning/Spatial, Working Memory, Processing Speed, and Visual Memory). Examiners using the DAS-II need to be cognizant of these varying factor structures and what they purportedly measure at different age levels when interpreting results.

No research is available that directly addresses the DAS-II’s relationship to executive functions. According to Dumont and colleagues (2009), the DAS-II assesses seven broad abilities: verbal ability (Gc), spatial ability (Gv), nonverbal reasoning ability (Gf), retrieval (Glr), memory (Gsm), processing speed (Gs), and auditory processing (Ga). The Verbal and Spatial ability clusters are intended to reflect the major information-processing systems used to receive, perceive, remember, and process information through both auditory and visual modalities. Verbal ability as measured by the DAS-II essentially consists of language development and lexical knowledge. Spatial ability primarily consists of tasks requiring spatial relations and visualization, although one task, Recall of Designs, measures visual memory. The tasks of the Nonverbal Reasoning ability cluster (Matrices; Sequential and Quantitative Reasoning; and Picture Similarities) provide adequate to strong measures of inductive thinking and reasoning. The Matrices task assesses the ability to formulate and test hypotheses, inductive reasoning, verbal mediation, and visual perception. The Picture Similarities subtest evaluates the ability to formulate and test hypotheses about relationships and to solve nonverbal problems by attaching representation or conceptual meaning to a pictured object. The Sequential and Quantitative Reasoning task assesses the ability to perceive relationships, draw conclusions, reason inductively, formulate and test hypotheses, use analytic reasoning, and retrieve long-term information. The DAS-II also provides strong measures of another executive functioning construct, that of memory (free recall, span, and working memory), through the broad Retrieval and Memory clusters. The subtests Recall of Designs, Recall of Digits (Forward and Backward), Recall of Objects (Immediate and Delayed), Recall of Sequential Order, and Recognition of Pictures allow for a comprehensive assessment of visual and auditory short-term memory capacity, working memory capacity, and long-term retrieval.

Wechsler Intelligence Scale for Children—Fifth Edition

The Wechsler scales are believed to be the most widely used measures of intelligence throughout the world (Flanagan & Kaufman, 2009); however, there is insufficient evidence with neurological populations to ensure the tests' appropriate application for neuropsychological assessment (Loring & Bauer, 2010; McCrea & Robinson, 2011). The Wechsler Intelligence Scale for Children—Fifth Edition (WISC-V; Wechsler, 2014) embodies a fundamental shift from previous editions of the WISC, since it was redesigned to more adequately reflect the "latest research on intelligence, cognitive development, cognitive neuroscience, and neurodevelopment" (Wechsler, 2014, p. 1). Some researchers claim that the Wechsler tests lack a unified theoretical foundation (Coalson, Raiford, Saklofske, & Weiss, 2010; Kaufman, 2010; Raiford & Coalson, 2014), whereas others note that the evolution of the Wechsler tests is consistent with CHC theory (Canivez & Watkins, 2016; Miller & McGill, 2016).

The WISC-V consists of 21 subtests: 13 retained from the WISC-IV, and eight new subtests. The WISC-V organizes these subtests into three categories: primary, secondary, and complementary. The 10 primary subtests are considered to constitute the core WISC-V battery. The Full Scale Intelligence Quotient (FSIQ) is derived from seven of these primary subtests. There are six secondary and five complementary subtests, designed to be used in a supplemental or ancillary capacity. Beyond the FSIQ, a number of composite scores can be derived from various combinations of subtests (14 in total). There are five primary index scores, which represent the primary cognitive constructs being measured: the Verbal Comprehension Index (VCI), the Fluid Reasoning Index (FRI), the Visual Spatial Index (VSI), the Working Memory Index (WMI), and the Processing Speed Index (PSI). Additionally, there are five ancillary indexes and three complementary indexes.

Given its recent publication date, there is little research available regarding the WISC-V, but already there are criticisms of its identified factor structure (Canivez & Watkins, 2016; Canivez, Watkins, & Dombrowski, 2016; Miller & McGill, 2016). The harshest criticism comes from Canivez and various colleagues. They suggest that the WISC-V's reported factor structure is untenable and not supported by the normative data or statistical analyses found in the technical manual. Canivez and colleagues reanalyzed the WISC-V data and found no evidence to support a five-factor solution; rather, their analysis suggests either a one-factor *g* solution or a four-factor solution (the latter was favored). Canivez and colleagues' research on the WISC-V contrasts with research conducted on the WISC-IV (Flanagan & Kaufman, 2009; Keith, Fine, Taub, Reynolds, & Kranzler, 2006; Sattler & Dumont, 2008), which suggested that the WISC-IV four-factor solution was not appropriate and that a five-factor solution was the most parsimonious. Canivez and colleagues (2016) speculate that the shift in adequate factor solutions may be due to the addition/removal/restructuring of subtests in the WISC-V relative to the WISC-IV. Further research will be needed to identify the appropriate factor structure of the WISC-V.

Given the dissension regarding the factor structure of the WISC-V, a brief review of the indexes and their subtests is provided. The VCI is composed of tasks (Similarities, Vocabulary) that measure verbal abilities utilizing reasoning, comprehension, and conceptualization. The index involves tasks that require comprehension–knowledge, verbal fluid reasoning, and long-term memory (Weiss, Beal, Saklofske, Packiam-Alloway, & Prifitera, 2008). Within the CHC perspective, the VCI comprises a measure of Gc or comprehension–knowledge (Keith et al., 2006). Not included in the VCI but still considered measures of Gc are the subtests of Information and Comprehension. The FRI consists of tasks (Matrix Reasoning, Figure Weights) that measure fluid reasoning skills such as analogical reasoning, problem solving, and abstract categorical reasoning. In the Wechsler model, Picture Concepts and Arithmetic are also classified as Gf tasks. The VSI consists of Block Design and Visual Puzzles, and provides a measure of visual–spatial reasoning, problem solving, and constructional abilities (part–whole relationships and dimension).The WMI is defined as a measure of the ability to concentrate, sustain attention, and exert mental control. It consists of Digit Span (Forward, Backward, Sequencing) and Picture Span. Letter–Number Sequencing does not contribute to the WMI but is also a measure of Gwm. Flanagan and Kaufman (2009) classified the WMI as a narrow-band ability factor (the narrow ability of working memory within the broad Gsm/Gwm factor) in the CHC model. Weiss and colleagues (2008) take exception to this characterization and believe that the WMI tasks are strong measures of verbal short-term and working memory. Keith and colleagues (2006) determined that the WMI appears to be a mixture of Gsm and Gf. Finally, the PSI provides a measure of the speed of mental and graphomotor processing. Coding and Symbol Search comprise the PSI, with Cancellation serving in an ancillary role. Within CHC theory, the PSI tasks are seen as visual scanning and speed-of-processing tasks falling under the Gs factor. None of the subtests on the WISC-V are thought to measure executive functioning unequivocally, and no research is yet available that specifically assesses the contribution of executive functioning to WISC-V tasks.

Miller (2007, 2013; see also Miller et al., 2016, and Miller & Maricle, Chapter 33, this volume) conceptually groups the WISC-V and WISC-V Integrated subtests according to his integrated SNP/CHC model. Miller labels Similarities, Similarities Multiple Choice, Comprehension, Comprehension Multiple Choice, Matrix Reasoning, Picture Concepts, Figure Weights, and Figure Weights Recall as measures of executive functioning. Miller's model places measures of processing speed (Cancellation, Coding, Coding Copy, Symbol Search, Naming Speed—Literacy, Naming Speed—Quantity), and some measures of memory (Arithmetic, Arithmetic Process Approach, Spatial Span—Backward, Digit Span—Forward, Spatial Span—Forward) in the facilitator–inhibitor domain. Other measures of memory (Digit Span—Forward, Spatial Span—Forward, Coding Recall, Immediate Symbol Translation, Delayed Symbol Translation, and Recognition Symbol Translation) are classified as measures of cognitive processes under the domain of learning and memory.

Flanagan and colleagues' (2010, 2013) integrated interpretive framework incorporates additional subtests besides those discussed in Miller's model, including Cancellation, Coding, Digit Span, Letter–Number Sequencing, Spatial Span—Forward and Backward, Symbol Search, and Visual Digit Span. These subtests are primarily seen as measures of Gsm (short-term and working memory) and Gs (processing speed), but within the integrated interpretive framework they fall into the broader domain of executive functions.

Kaufman Assessment Battery for Children—Second Edition

Kaufman and Kaufman (2004) deliberately designed the KABC-II to incorporate two distinct theoretical models: the CHC and Lurian models. However, the authors recommend using the CHC model interpretively for most purposes. The KABC-II is composed of 18 subtests grouped into four or five scales, depending on the child's age and the interpretive model chosen. The Lurian model organizes the subtests into four scales: Sequential, Simultaneous, Learning, and Planning. The CHC model organizes the same subtests into short-term memory (Gsm), visual processing (Gv), long-term storage and retrieval (Glr), fluid reasoning (Gf), and crystallized ability (Gc). The KABC-II may be a promising tool for assessing intelligence and cognitive impairments, but research on its applicability within a neuropsychological framework for neuropsychological assessment is limited (Mays, Kamphaus, & Reynolds, 2009).

On the KABC-II, learning ability and planning ability from the Lurian perspective are the domains most applicable to executive functioning. Within the CHC perspective, these constructs equate to the cognitive factors of Glr (long-term storage and retrieval) and Gf (fluid reasoning), respectively. Kaufman, Kaufman, Kaufman-Singer, and Kaufman (2005) consider Planning/Gf to be the domain most closely associated with executive functioning. On the KABC-II, Planning/Gf tasks are designed to require a variety of mental operations to solve novel problems, including cognitive flexibility, inductive and deductive reasoning, hypothesis generation, and impulse control. Tasks that encompass the domain of Learning/Glr also require the integration of several executive functions. Kaufman and colleagues note that Learning/Glr on the KABC-II emphasizes efficiency of the storage and retrieval, not the specific information being stored. They further emphasize that effective paired-associate learning requires considerable attention and planning skills, as well as storage and retrieval skills.

Kaufman and colleagues (2005) delineate narrow cognitive abilities underlying the KABC-II subtests, identifying induction, general sequential reasoning, and associative learning/memory as the primary narrow abilities representative of executive functioning. Three KABC-II subtests are considered measures of induction: Conceptual Thinking, Pattern Reasoning, and Story Completion. The Conceptual Thinking task is only administered to children ages 3 years, 0 months to 6 years, 11 months (3:0–6:11), and involves determining conceptual relationships by identifying the concept that does not fit the relationship parameters. The Pattern Reasoning subtest requires an examinee to complete a logical linear pattern (i.e., the examinee must identify what part of the pattern is missing and complete the missing section with the appropriate choice from among a series of choices). The Story Completion task is similar, in that the examinee completes the missing elements of a pictured story by deducing from the remaining story line what aspects of the story are missing. Two subtests, Rover and Riddles, assess general sequential reasoning. Rover requires the examinee to determine the quickest and shortest path from one point to another by using rules, strategy selection, and visual–spatial thinking. The Riddles task involves solving a verbal puzzle/riddle by using characteristics of concrete or abstract verbal concepts. Associative memory is assessed by two subtests, Atlantis and Rebus, both of which are controlled learning tasks associating a word with a picture/symbol/concept.

Flanagan and colleagues' (2010, 2013) integrated interpretive framework suggests the addition of two subtests, Triangles and Word Order, to those discussed above. However, whereas the Gsm tasks on other instruments are also considered within this framework as being representative of executive functioning, these tasks on the KABC-II are not thus considered. Gsm tasks on the KABC-II are measures of short-term memory span or capacity only, and not of working memory.

The NEPSY-II

Conceptualized from Luria's perspective, the NEPSY-II (Korkman, Kirk, & Kemp, 2007) is an assessment instrument that focuses specifically on the neuropsychological development of children. The original NEPSY was traditionally under the purview of child clinical psychologists and pediatric neuropsychologists. However, the NEPSY-II has recently become popular with school psychologists, who tend to use it more as a measure of cognitive functioning in the tradition of intelligence tests than for its intended neuropsychological purpose, and thus it is included in this discussion. The Lurian tradition requires that assessments identify and distinguish between primary and secondary deficits of cognitive functions. From this perspective, examining simple and complex components of specific domains, and the additional use of qualitative information, provide a more thorough assessment of possible deficits.

The NEPSY-II is purported to measure six domains of cognitive functioning (Attention and Executive Functioning; Language; Sensorimotor; Visuospatial Processing; Memory and Learning; and Social Perception). Korkman and her colleagues (2007) acknowledge that not all cognitive functions constituting a specific domain are assessed. They believe that these cognitive functions do not develop in isolation, but work in concert together, and that broad conclusions based on individual subtests measuring only limited aspects of particular domains should not be drawn.

The Attention and Executive Functioning domain is the most germane to this discussion. Titley and D'Amato (2008) describe the tasks in this domain as a continuum of skills ranging from simple attention to complex self-monitoring. Animal Sorting, Auditory Attention and Response Set, Clocks, Statue, Design Fluency, and Inhibition compose the Attention and Executive Functioning domain of the NEPSY-II. Of these six subtests, four span the widest age range (7–16 years); one is limited to preschoolers (3–6 years); and one is limited to children ages 5–12 years.

Research on the NEPSY-II is currently quite limited; therefore, users must rely on information provided in the technical manual by the test authors. Animal Sorting is a classic card-sorting task similar to the Wisconsin Card Sorting Test (considered the "gold standard" for executive function measures). Card-sorting tasks demonstrate good construct validity as measures of concept generation, which is thought to be a fundamental executive function. Animal Sorting was designed to measure the ability to form basic concepts, categorize, and shift fluently from one concept to another. The Auditory Attention and Response Set subtest consists of two discrete tasks. Auditory Attention requires sustained and selective auditory attention, whereas Response Set adds the element of shifting attention and the ability to maintain set while inhibiting previously learned responses. The Clocks task uses analog clocks to assess planning, organization, visual-perceptual, and visual–spatial skills. Similar tasks have been frequently used for adults with brain injuries, who often exhibit impaired performance. Cohen, Riccio, Kibby, and Edmonds (2000) evaluated the use of a clocks task with children and found that performance improvements were associated with age. Children at age 6 can draw the basic elements of a clock, and by ages 10–12 most children can generate an accurate picture of a clock but may make positioning errors. Adult levels of performance are reached in early adolescence. However, no research appears to have looked at the validity of clocks tasks as measures of either executive function or attention. The Design Fluency task was designed to assess the ability to generate as many unique designs as possible by connecting dots presented in either a structured or random array. It provides a measure of the efficiency and speed of cognitive visual processing. The Inhibition task is a variation of the classic Stroop task (another "gold standard" measure of the executive functions of attentional control and set shifting); it was designed to assess the ability to inhibit an automatic response in favor of a novel response and to shift or switch response types. The task requires the individual to view a series of shapes or arrows and then to name either the shape, the direction, or an alternative response.

To date, there are no published independent research studies examining the Attention and Executive Functioning domain of the NEPSY-II; the available research focuses on the original NEPSY. Since the NEPSY-II replaced three of the original six subtests in this domain with new tasks, conclusions from previous research cannot be brought to bear on the validity of the current battery as a measure of attention, executive function, or a mixture of both. Kemp (2007) has stated that the subtests in the Attention and Executive Functioning domain measure the core components of executive functioning (including strategic planning, cognitive flexibility, and self-regulation), as well as subcomponents such as initiation, fluency, inhibition, and working memory. However, Kemp notes that the domain does not measure all aspects of executive functioning or attention. A major limitation of the Attention and Executive Functioning domain is the lack of empirical research on the validity of the domain. More specifically, the merging of the cognitive constructs of attention and executive function, and the validity of the tasks chosen to measure these cognitive constructs, have received limited attention in the literature.

TARGETED EVALUATION OF EXECUTIVE FUNCTIONS: A BRIEF DISCUSSION

Friedman and colleagues (2006) suggest that current measures of intelligence do not capture the breadth and depth of executive functioning and are best considered as screening tools for executive dysfunction. Evidence of executive function deficits therefore warrants a more targeted evaluation of identified areas of dysfunction. There are numerous instruments that target the assessment of executive functions and related neurocognitive constructs. A complete overview of such assessment instruments is beyond the purview and scope of this chapter; the reader is referred to Maricle and colleagues (2010) for a more comprehensive review.

Targeted assessment instruments measure neurocognitive constructs such as executive functioning, attention, or working memory more specifically and narrowly. As such, they often require more specialized knowledge and training for proper use. However, several targeted instruments of executive functions are commonly used by school psychologists and other child clinicians, including the D-KEFS; the Behavior Rating Inventory of Executive Function, Second Edition (BRIEF 2); and various versions of category, trail-making, tower, and Stroop-like tasks. In addition, numerous measures are used to evaluate related neurocognitive constructs such as memory (the Test of Memory and Learning—Second Edition; the Wide Range Assessment of Memory and Learning, Second Edition; the Children's Memory Scale) or attention (the Test of Everyday Attention for Children; the Conners Continuous Performance Test 3rd Edition). Two targeted assessment instruments thought to measure executive functions, The BRIEF 2 and the D-KEFS are briefly discussed here because they are the most commonly used in psychoeducational, psychological, and neuropsychological evaluations.

Behavior Rating Inventory of Executive Function, Second Edition

The BRIEF 2 (Gioia, Isquith, Guy, & Kenworthy, 2015) is the first revision of the Behavior Rating Inventory of Executive Function (BRIEF; Gioia, Isquith, Guy, & Kenworthy, 2000). The BRIEF has been frequently used by school psychologists and other professionals to measure executive functions in children and adolescents, and it is assumed that the BRIEF 2 will also be considered a popular measure. Unfortunately, a measure such as the BRIEF 2 is often the *only* measure used to assess executive functions. The BRIEF 2 defines executive functioning as "a multidimensional construct with distinct but interrelated domains of self-regulatory or management functions including the ability to initiate behavior, inhibit the effect of stimuli, select relevant tasks goals, plan and organize means to solve complex problems, monitor and evaluate the success of problem-solving strategies and shift problem-solving strategies flexibly when necessary" (Gioia et al., 2015, p. 3). Gioia and colleagues (2015) go on to say that executive functions are not restricted to cognitive constructs, and that control of emotional response and control of behavioral action also fall under the executive function canopy. The BRIEF 2 is standardized for children ages 5–18 years (parent and teacher report) and children 11–18 years (self-report). The questionnaire for teachers and/or parents utilizes a 3-point Likert scale ("never," "sometimes," "often") to determine how often a child performs a behavior that is thought to be a manifestation of executive dysfunction. The BRIEF 2 provides *T* scores (higher scores are indicative of dysfunction); it yields a global measure of executive functioning, the Global Executive Composite, and three indexes, Behavior Regulation, Emotion Regulation, and Cognitive Regulation. Two subtests (Inhibit and Self Monitor) constitute the Behavior Regulation Index; two subtests encompass the Emotion Regulation Index (Shift and Emotional Control); and five subtests make up the Cognitive Regulation Index (Initiate, Working Memory, Plan/Organize, Task Monitor, and Organization of Materials).

The BRIEF 2 is not a significant revision. In order to maintain the integrity of the scale and continuity with previous research, the authors chose not to add new items to the clinical scales or indexes. They did shorten the instrument slightly by eliminating items, and they revised other items for clarity and readability. A significant limitation of the original BRIEF was the adequacy and representativeness of its normative sample, which was obtained from one state (Maryland) and limited in size (1,419 parents and 720 teachers). The BRIEF 2 provides a larger, more diverse normative sample. The subsamples for the parent rating scale (n = 1,400), teacher rating scale (n = 1,400), and self-rating scale (n = 803) approximate the U.S. population on key demographic variables such as gender, race/ethnicity, parental education, and geographical region.

Internal consistency (the degree to which items within a single scale are measuring the same underlying construct) is adequate for the BRIEF 2. More problematic is its test–retest reliability (stability of the measure over time). Rather than address the rather mediocre findings (ranging from .61 to .92), the authors note that the results are within the acceptable standard (>.70) and that *T* scores do not change significantly over the test–retest period. A more significant concern is poor interrater reliability (<.50), in that parents have consistently been found to rate their children as having significantly greater difficulties than teacher raters do. If intrarater reliability (the same rater over time) were to be examined, which it has not been with the BRIEF 2, speculation is that it might be equally problematic.

With regard to the validity of the BRIEF 2, its authors claim that validity was established with the original version, and that since the BRIEF 2 is essentially the same measure, its validity is already established. The authors utilized confirmatory factor analysis to describe the latent factors of the model structure underlying the BRIEF 2. They noted that the analysis showed an acceptable fit for the data, but they seemed to minimize questionable fit statistics and the need to account for significant cross-loading or intercorrelation between factors.

Professionals who choose to use the BRIEF 2 need to realize that it is an indirect measure, and that what is being measured is an adult's perception (or a child/adolescent's own perception, in the case of the self-report version) of a young person's behavioral manifestations of executive dysfunction; the youth's cognitive executive functions are not assessed directly. In fact, the research with the original BRIEF suggests that it does not correlate with direct measures of executive functions (Anderson, Anderson, Northam, Jacobs, & Mikiewicz, 2002; Benjamin, 2004; Mangeot, Armstrong, Colvin, Yeates, & Taylor, 2002; Vriezen & Pigott, 2002). Given the BRIEF 2's similarity to its predecessor, it (like the BRIEF) should be considered a measure of attention or behavior, similar to measures such as the Behavior Assessment System for Children, Second Edition; the Achenbach System of Empirically Based Assessment; or the Conners Behavior Rating Comprehensive Scales. Based on research with the original BRIEF, the consensus of most researchers would be that the BRIEF 2 should never be used as the sole measure of executive functions.

Delis–Kaplan Executive Function System

An instrument that is gaining in popularity among school psychologists is the D-KEFS (Delis et al., 2001). The D-KEFS consists of an assortment of standardized individual measures of executive functioning, which Delis and colleagues combined into a comprehensive battery. There are nine tests, which may be administered in combination or separately: the Word Context Test, Sorting Test, Twenty Questions Test, Tower Test, Color–Word Interference Test, Verbal Fluency Test, Design Fluency Test, Trail Making Test, and Proverbs Test. The tests are thought to measure mental flexibility, inhibition, problem solving, planning, impulse control, concept formation, abstract thinking, and verbal or spatial creativity (Homack, Lee, & Riccio, 2005). The D-KEFS does not yield an overall composite score representing executive functioning; rather, each test is scored and interpreted individually. Each test yields an aggregate score (scaled score and percentile) and relevant process scores (response accuracy, error rate, and response latency).

A primary limitation of the D-KEFS is that its clinical usefulness with children and adolescents is largely unknown, since the majority of its tasks were developed and standardized on adults. Research using the D-KEFS is scarce, with the majority of research having occurred previously on the individual measures incorporated into the D-KEFS rather than on the battery as a whole. Research using the battery, or even the individual tests, with children is very limited. This limitation is a critical one, as the D-KEFS is subject to strong age effects: Children at the youngest ages generally exhibit the lowest scores, and performance on most of the measures is highly influenced by speed of processing until early adolescence (Strauss, Sherman, & Spreen, 2006). A second limitation of the D-KEFS is that it is a challenging instrument to learn to administer, score, and interpret. Clinicians wishing to use the battery should have appropriate training, practice, and supervision with the instrument, as well as an adequate background in neuropsychological assessment, in order to interpret the obtained results appropriately.

Currently, the research indicates that the most defensible way to evaluate executive functioning is to assess executive function components separately, using targeted measures specifically developed for this purpose. The dilemma facing the clinician is to determine which executive functions should be measured. As previously stated, researchers disagree about this, and there are various recommendations in the literature. The integrated SNP/CHC model (Miller, 2007, 2013) suggests the following: concept generation, inhibition, cognitive flexibility, planning, reasoning, and problem solving. Stuss (2009) would propose measuring initiation, planning, sequencing, inhibition, flexibility (shifting), and self-monitoring. Maricle and colleagues (2010) and Maricle and Johnson (2016) recommend evaluating the components of cognitive (mental) flexibility, attention, working memory, and problem solving/reasoning. The primary purposes for any assessment are to provide an understanding of an individual's functioning, as well as his or her specific strengths and weaknesses; to assist in differential diagnosis; and to inform intervention. Thus best practice indicates that the choice of which executive functions to assess should depend on the referral question, potential diagnostic conclusions, and subsequent assessment results.

MANIFESTATION OF EXECUTIVE DYSFUNCTION IN COMMON CHILDHOOD DISORDERS

Instead of asking what executive functions should be measured, astute clinicians might ask why it is important to measure executive functions and what executive functions have to do with an individual's ability to function in a home, school, or employment setting. Evans (2009) states that executive functions enable individuals to deal with problems that arise in everyday life and to cope with new situations; they are the cognitive skills required to identify and achieve personal goals and to modify actions when required. Interest in executive functions has resulted in greater study of executive functions in applied settings, and thus the importance of executive functioning to success in intellectual and social environments has been increasingly recognized (Han, Delis, & Holdnack, 2008). Good executive functioning in children or adolescents rarely warrants concern, but executive dysfunction often results in educational performance deficits that result in referrals for assessment. Executive dysfunction may be the fundamental underlying mechanism or symptom of many childhood disorders.

Delis and colleagues (2007) and Han and colleagues (2008) view executive functioning as a key concept that should be routinely assessed as part of any psychoeducational, psychological, or neuropsychological assessment. Including a component of executive functioning may be appropriate whenever the referral question relates to known or suspected attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorder (ASD), nonverbal learning disability (NVLD), specific learning disability (SLD), traumatic brain injury (TBI), or some other identifiable neurological disorder (e.g., epilepsy or Tourette syndrome) (Barkley, 2000; Brookshire, Levin, Song, & Zhang, 2004; Meltzer & Krishnan, 2007; Ozonoff & Schetter, 2007; Parrish et al., 2007; Shallice et al., 2002; Vaquero, Gomez, Quintero, Gonzalez-Rosa, & Marquez, 2008). To obtain the most informed differential diagnosis during an evaluation, it is necessary to understand how executive dysfunction may be manifested in each of these disorders, but it is also important to note that children with these clinical disorders often exhibit global executive functioning impairments that do not necessarily differentiate clinical groups (P. Anderson, 2002; Ozonoff & Schetter, 2007; Willcutt, Doyle, Nigg, Faraone, & Pennington, 2005).

Children and adolescents with ADHD most noticeably demonstrate difficulties with inhibition and attention (Barkley, 2000; Shallice et al., 2002). They often display difficulties with self-monitoring and vigilance, working memory, organizational skills, and planning (Roth & Saykin, 2004). These deficits may result in the obvious problems of behavioral regulation seen in ADHD, such as difficulties with inhibitory control (i.e., frequent impulsive or poorly thought-out behavior), problems with behavioral initiation (i.e., inability to independently initiate tasks like homework or chores), or difficulty in sustaining behavior (i.e., with resulting failures of task completion). Children and adolescents with ADHD fail to engage in planning or problem solving. They may carry out routine tasks, but if faced with novelty or lack of structure, they are at a loss as to what to do (Evans, 2009). They are seen as easily distracted and disorganized, in that they fail to pay attention to rules, complete work haphazardly, and rarely have the materials needed to complete a given task. Unfortunately, while the behavioral manifestations of ADHD appear consistent with impairments of executive function, tests of executive function do not always differentiate children with ADHD from children without ADHD or with other clinical disorders.

Children and adolescents with ASD may have problems with cognitive flexibility, planning, fluently shifting attention to new or novel tasks, appropriately responding to social cues and regulating social interactions, and recognizing or using nonverbal behaviors (Ozonoff & Schetter, 2007). These deficits are often manifested as difficulty in adapting to environmental changes, resulting in the rigidity and need for sameness seen in many children on the autism spectrum. Poor abstract reasoning skills often result in an inability to understand the subtleties of social interactions. Children with ASD often view things very concretely and may miss the figurative meaning of language involved in sarcasm or jokes. Although executive dysfunction is a significant component of ASD, manifestations of executive dysfunction do not define distinctions in ASD subtypes (Verte, Geurts, Roeyers, Oosterlaan, & Sergeant, 2006).

Executive dysfunction is also often associated with SLD, due to cognitive difficulties that interfere with academic learning; these include problems with self-regulation and monitoring, problem solving, retrieval fluency, cognitive flexibility, or organizing and prioritizing stimuli (Meltzer & Krishnan, 2007). Executive function deficits can have a significant impact on the essential academic skills involved in reading, writing, or mathematics. For example, reading decoding may be affected by difficulties with sustained attention and working memory, which are needed in order to attend to each phoneme, manipulate and apply phonemes according to reading rules, and fluently retrieve and remember each phoneme in order to sound out a word (McCloskey, Perkins, & Van Divner, 2009). Writing may be affected by poor graphomotor control, retrieval fluency deficits, or organizational difficulties, resulting in imprecise handwriting skills, strained writing with limited creativity, and disconnected or dysfluent ideas (McCloskey et al., 2009). In math, problems with working memory, inhibition, and retrieval fluency may affect the ability to recall rote math facts quickly and efficiently, to solve problems requiring mental manipulation, or to switch mental sets in order to solve problems using complex math facts (Bull & Scerif, 2001). Executive dysfunction has also been implicated in NVLD because of the problems with cognitive flexibility, set shifting, adapting to novel situations, working memory, self-regulation, and attentional control that are often seen in the population with NVLD (Stein & Krishnan, 2007).

Problems with executive functioning are also frequently seen in children and adolescents experiencing a variety of neurological conditions, such as TBI, tumors, or seizure disorders. With these disorders, impairment in executive function is often correlated with age of onset, as well as severity and location of injury, seizure activity, or tumor. Global impairments in executive functioning, and critical disruptions in attention and processing speed, are common in these children (Brookshire et al., 2004; Parrish et al., 2007; Vaquero et al., 2008). Han and colleagues (2008) note that executive function deficits are frequent sequelae of moderate and severe TBI, and that impairment on a variety of executive function measures commonly occurs, suggesting that comprehensive assessment and follow-up of these functions are warranted for these individuals.

Evaluation of executive functioning is critical to understanding why some children have difficulty with learning and behavior. Han and colleagues (2008) believe that the first step in designing appropriate interventions is to identify the core impairments in executive functioning and to understand how the deficits relate to behavior and learning problems. Various approaches to interventions for executive dysfunction have been developed; however, the evidence base for their effectiveness remains limited, though research in this area is growing. Evans (2009) claims that now is the time to develop and evaluate rehabilitation methods that are clearly set in a theoretical context and can be prescribed on the basis of assessment information.

CONCLUSION

Executive functions appear to be the foundation for human development and the cornerstone for cognition. The study of executive functions is a developing field that is still grappling to describe these functions and their relationship to cognition and behavior. This feat is made more difficult by a disconnection among theory, assessment, and intervention, as well as by limited research on the developmental nature of executive functions in children, the best ways to assess these functions, and effective ways to intervene if executive dysfunction is identified. Nevertheless, child clinicians including pediatric neuropsychologists and school psychologists are increasingly focusing on the assessment of executive functions in their assessments. Thus it is important for these clinicians to have appropriate training in administration, scoring, and interpretation of various measures of executive functions; adequate knowledge about what aspects of executive functions are being measured by various tasks in the different instruments; and an understanding of the neurological substrates and developmental trajectories of various executive functions. These issues, as well as the adequacy of measures of intelligence or targeted measures of neurocognitive constructs for measuring executive functioning, need to be discussed in assessment courses within training programs and within the broader field of child assessment in general.

CHAPTER 37

The Role of Cognitive and Intelligence Tests in DSM-5 Diagnosis of Specific Learning Disorder

Erin M. McDonough
Dawn P. Flanagan
Megan C. Sy
Vincent C. Alfonso

Controversies related to the definition of specific learning disability and the methods used to diagnose this condition have long been a foremost concern in assessment-related fields, such as school psychology and neuropsychology (e.g., Decker, Hale, & Flanagan, 2013; Reynolds & Shaywitz, 2009), as well as in the medical and legal fields (e.g., Colker, Shaywitz, Shaywitz, & Simon, 2013). The publication of new criteria for diagnosing a specific learning disorder in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; American Psychiatric Association [APA], 2013) has fueled such controversies (see, e.g., *www.landmarkoutreach.org/about/newsworthy/dyslexia-dropped-dsm-5*). This chapter begins with a brief history of learning disabilities, including the diagnostic criteria for learning disorders in the five editions of the DSM. Next, etiology, associated impairments and comorbidities, course and developmental changes, prognosis, outcomes, and treatment are highlighted. This chapter concludes with a brief discussion of the most salient vagaries inherent in the latest diagnostic criteria for specific learning disorder in the DSM-5, some of which will be debated for some time to come. Note that SLD is used from here on in this chapter to refer to *specific learning disorder* as defined in DSM-5, rather than *specific learning disability* as defined in the Individuals with Disabilities Education Improvement Act of 2004 (IDEA 2004).

A BRIEF HISTORY OF LEARNING DISABILITIES

Between the years 1800 and 1920, the field of learning disabilities began to emerge as the result of developments in the fields of neurology and reading disabilities. As Franz Joseph Gall explored relationships between head injury and movement and sensation, morality, and intellectual qualities during the early 1800s, the groundwork was laid for localization of brain function, and Broca's area was identified as responsible for speech production (Hallahan & Mercer, 2001). Toward the latter part of the 19th century, Sir William Broadbent identified the relationship between the loss of reading abilities and the loss of the ability to name after the onset of neurological symptoms. Kussmaul's work described what he termed *word-blindness*, which is possibly the first conceptualization of a specific learning disability as a disorder

---

This chapter has been reprinted from McDonough, Flanagan, Sy, and Alfonso (2017).

separate from other potential problems (Hallahan & Mercer, 2001). Similar case studies describing reading disabilities were reported by Hinshelwood and Morgan in the late 1800s and early 1900s. Hinshelwood (1902) also studied congenital and acquired reading disabilities and reported on six cases appearing within a family over two generations. Through these studies, he hypothesized that the primary deficit in these children was visual memory for words and letters, which might now be defined as an orthographic processing deficit (Hallahan & Mercer, 2001; see also Berninger, Abbott, Nagy, & Carlisle, 2010).

Interested in the earlier research of the aforementioned European scientists, several American researchers including Orton, Fernald, Monroe, and Kirk continued the study of learning disabilities, ranging from problems with language and reading to perceptual–motor and attentional disabilities. Orton (1925) determined that many students with reading disabilities had average to above-average scores on the Stanford–Binet IQ test, as Hinshelwood (1902) had also suspected. Orton's work significantly contributed to interventions for reading disabilities and emphasized a multisensory approach.

A former research associate for Orton, Marion Monroe, experimented with his methods for remediation as well as the methods of Fernald and Keller. Developing diagnostic tests and using results to inform instruction, she developed a synthetic phonetic approach and compared it to other methods (see Hallahan & Mercer, 2001). Monroe was the first to suggest that reading disabilities could be identified by examining the discrepancy between actual achievement and expected achievement, the latter of which was an average of the child's chronological age, mental age, and arithmetic grade (Monroe, 1932). Monroe also emphasized error analysis in order to guide instruction. Her work thus laid the foundation for the discrepancy approach and for the response-to-intervention approach to specific learning disability identification (Hallahan & Mercer, 2001; Hallahan & Mock, 2003).

The First Definition of Learning Disability

Working alongside Monroe as an instructor while earning his doctorate, Samuel Kirk studied interventions for reading disabilities and provided what is considered to be the first definition of the term *learning disability*. His definition linked brain dysfunction to behavioral manifestation of academic problems. According to Kirk (1962),

> A learning disability refers to a retardation, disorder, or delayed development in one or more of the processes of speech, language, reading, writing, arithmetic, or other school subject resulting from a psychological handicap caused by possible cerebral dysfunction and/or emotional or behavioral disturbances. It is not the result of mental retardation, sensory deprivation, or cultural and instructional factors. (p. 263)

During the 1970s, Kirk continued to develop assessment techniques to identify learning disabilities in children. His contribution to the field of learning disabilities, including the Illinois Test of Psycholinguistic Abilities (Kirk, McCarthy, & Kirk, 1967), and his definition of the disorder provided the foundation for later researchers to explicate the relationship between cognitive functions and academic problems. Integrating Monroe's discrepancy-based definition of learning disabilities and Kirk's brain-based definition, Barbara Bateman (1965) proposed an alternative definition:

> Children who have learning disorders are those who manifest an educationally significant discrepancy between their estimated potential and actual level of performance related to basic disorders in the learning process, which may or may not be accompanied by demonstrable central nervous system dysfunction, and which are not secondary to generalized mental retardation, educational or cultural deprivation, severe emotional disturbance, or sensory loss. (p. 220)

Since Bateman's reintroduction of the concept of discrepancy from cognitive potential, discrepancy has remained a central feature of most definitions, including the response-to-intervention approach, and has at times been a controversial feature of later definitions (see Flanagan & Alfonso, 2011, for a comprehensive review).

Contemporaneously, the federal government began its own efforts to provide a definition through the creation of two task forces; however, these task forces failed to provide a unified definition of learning disabilities. Task Force I provided a definition of *minimal brain dysfunction*, while Task Force II defined *learning disabilities*. The disparate definitions reflected the fact that Task Force I was made up primarily of medical professionals, while Task Force II consisted of educators.

Shortly thereafter, in the late 1960s, the U.S. Office of Education (USOE) formed the National Advisory Committee on Handicapped Children

(NACHC) to provide a definition that could serve as the basis for legislation and funding. Because Kirk chaired this committee, the resulting definition was highly similar to the definition he provided in 1962, and much of the language used in this definition is present in current definitions (e.g., that of IDEA 2004). The NACHC definition of 1968 emphasized a "disorder in one or more of the basic psychological processes" manifesting as disorders of "thinking, talking, reading, writing, spelling, or arithmetic" and excluded deficits related to visual, hearing, or motor handicaps, to mental retardation, emotional disturbance, or to "environmental disadvantage." In 1969, the Children with Specific Learning Disabilities Act was passed, which was included in the Education of the Handicapped Act of 1970 (Pub. L. 91-230), and provided for programs to serve children who were eligible (Hallahan & Mercer, 2001; Hallahan & Mock, 2003).

In 1975, McCarthy attempted to operationalize the definition of the NACHC by providing criteria. The first of these criteria included an IQ greater than 85, as well as sufficient opportunities for learning. The second of McCarthy's criteria included a "significant discrepancy" between academic aptitude and academic achievement, and the third criterion was that the discrepancy must be large enough to warrant specialized intervention (Tylenda, Hooper, & Barrett, 1987). McCarthy's inclusion of an IQ above 85 is closely aligned with some current research-based definitions of specific learning disabilities (e.g., Berninger, 2011; Flanagan, Ortiz, & Alfonso, 2013; Flanagan, Ortiz, Alfonso, & Mascolo, 2002; Hale & Fiorello, 2004; Kavale, Kauffman, Bachmeier, & LeFever, 2008; McDonough & Flanagan, 2016; Ortiz, Flanagan, & Alfonso, 2015).

Toward Consensus on the Definition and Identification of Learning Disability

From about 1975 to 1985, there was relative stability in the field as it moved toward consensus on the definition of learning disabilities, as well as methods of identifying the condition. Applied research was abundant at this time, much of which was funded by the USOE. This research led to empirically validated educational procedures for students with learning disabilities (Hallahan & Mercer, 2001).

Following the adoption of a federal definition of learning disabilities, organizations and researchers focused their efforts on developing and testing intervention programs for individuals with learning disabilities, and the definition of learning disabilities remained relatively stable (Hallahan & Mercer, 2001). Applied research funded by the USOE established a body of empirically validated methods to intervene with children with specific learning disabilities. The definition of *specific learning disability* was further consolidated by the passing of the Education for All Handicapped Children Act (Pub. L. 94-142), which essentially adopted the 1968 definition proposed by Samuel Kirk and the NACHC. This definition has survived conceptually in the federal legislation in its entirety, with only minor text revisions (Herr & Bateman, 2003; Sotelo-Dynega, Flanagan, & Alfonso, 2011).

Public Law 94-142 provided legitimacy—and, equally important, funding—for direct services for children with specific learning disabilities. In addition, the legislation set forth regulations as a way to deal with the absence of prescriptive guidance with regard to the methods used to identify learning disabilities (Sotelo-Dynega et al., 2011). These regulations continued to stipulate the presence of an ability–achievement discrepancy until the most recent reauthorization of this act: IDEA 2004 and its attendant regulations (U.S. Department of Education, 2006), the latter of which stated that ability–achievement discrepancy may be used as a method of identifying children with specific learning disabilities, but cannot be mandated. Shortly after Public Law 94-142 was enacted, DSM-III (APA, 1980) included discrepancy criteria for learning disorders.

Disorders of Learning in DSM

Even in the earliest versions of DSM, there was some recognition of learning difficulties as distinct problems facing some individuals. The first edition (APA, 1952) briefly referred to a "learning disturbance" under the category of "special symptom reactions," as well as to "specific learning defects," including alexia and agraphia. The definition included a reference to "word-blindness" as initially described by Kussmaul nearly 60 years earlier (Loriaux, 2010). Coding of the specific learning defects diagnosis was altered if known to be related to organic brain dysfunction. Despite the work of many contemporary American researchers in the field, the first edition of the DSM's definition of learning problems was limited in detail and scope.

DSM-II was published in 1968, several years following Samuel Kirk's initial definition of specific learning disabilities, and was again listed under a main category of "special symptoms" as a "specific learning disturbance." The definition or specification of symptom presentation in DSM-II was even more limited than that provided in the first edition, despite the proliferation of research and published work in the field of learning disabilities.

However, DSM-III (APA, 1980) devoted significantly more attention to the issue of defining learning disabilities. The DSM-III definition included six disorders within its new category of specific developmental disorders: developmental reading disorder; developmental arithmetic disorder; developmental language disorders, expressive and receptive types; developmental articulation disorder; and mixed specific developmental disorder. This definition also included a statement that while mutually exclusive of pervasive developmental disorders, a specific developmental disorder in reading or arithmetic could coexist with a diagnosis of mental retardation (APA, 1980, p. 94); this apparent contradiction served to confuse the issue of defining learning disabilities.

DSM-III provided definitions and criteria for developmental reading disorder and developmental arithmetic disorder. The essential feature of these disorders was a "significant impairment" in the academic skill, not accounted for by mental age, chronological age, or schooling. Diagnostic criteria for each of the disorders required a significant discrepancy between intellectual functioning as measured by an individually administered IQ test and performance on an academic achievement test measuring relevant domains. DSM-III also recommended a 1- or 2-year delay in measured reading skills for children ages 8–13 years. The discrepancy between a full scale IQ and academic achievement remained central to the definition and identification of these two disorders and was retained in DSM-III-R.

As compared with the diagnosis of developmental reading and arithmetic disorders in DSM-III, DSM-IV (APA, 1994) presented the category of learning disorders, and three specific diagnoses within this overarching category: reading disorder, mathematics disorder, and disorder of written expression. In addition, a diagnosis of learning disorder not otherwise specified was included in DSM-IV and encompassed academic problems that did not meet criteria for one of the aforementioned specific academic disorders; this diagnostic label was intended to be applied to individuals presenting problems across reading, math, and/or written expression, or who did not meet the threshold set forth by the term "substantially below" (i.e., achievement substantially below IQ), provided that the observed level of academic performance significantly interfered with academic achievement. DSM-IV also moved these disorders from Axis II to Axis I.

DSM-IV and its text revision, DSM-IV-TR (APA, 2000), sought to improve the definition of learning disabilities over the previous version. The definition again relied on a discrepancy approach, stating that "Learning Disorders are diagnosed when the individual's achievement on individually administered, standardized tests in reading, mathematics, or written expression is substantially below that expected for age, schooling, and level of intelligence" (APA, 2000, p. 49). DSM-IV-TR went on to define further "substantially below" as a difference of at least two standard deviations between achievement and measured intelligence. DSM-IV and DSM-IV-TR provided separate definitions for reading disorder, mathematics disorder, and disorder of written expression, and the second criterion for each disorder required that the "disturbance" identified in the first criterion (i.e., achievement as measured by individually administered standardized tests substantially below expected levels) must significantly interfere with academic achievement or with completing activities requiring that skill. And finally, the DSM-IV criteria required an impairment above and beyond a sensory deficit if one was present.

As DSM-III and DSM-III-R had done, DSM-IV and DSM-IV-TR stipulated that the academic deficits must be observed on "individually administered standardized tests," thereby assuring a formal evaluation of academic skills in addition to a measure of intelligence. These manuals also referenced the possibility of coexisting specific cognitive processing deficits in an area such as memory, visual–spatial processing, or the like, but did not require that one be present.

In terms of differential diagnosis, DSM-IV-TR required that learning disorders be differentiated from "normal variations in academic attainment," as well as "lack of opportunity, poor teaching, or cultural factors" (APA, 2000, p. 51), and should be beyond what one would expect to be associated with a sensory impairment (if present). In DSM-IV and DSM-IV-TR, as in DSM-III, a diagnosis of a learning disorder was also possible in addition to a diagnosis of mental retardation, provided that the academic achievement was significantly below estimated intellectual functioning. The publication of DSM-5 (APA, 2013), however, represents a significant departure in criteria for learning disorders as compared to previous editions.

DSM-5 DIAGNOSTIC CRITERIA

The introduction of the SLD diagnosis in DSM-5 resulted in considerable changes to the DSM-IV(-TR) diagnostic criteria for learning disorders. The most significant changes were that reading, mathematics, and writing disorders were combined into the one overarching diagnostic category of SLD. Tannock (2013) described the rationale behind this change as reflecting the work group's conceptualization of SLD as a single disorder that renders learning very difficult and effortful. Furthermore, whereas subtypes describe mutually exclusive disorders, specifiers allow for concurrent diagnoses of impairment in multiple academic domains. Therefore, the criteria were also altered to include symptoms of reading, writing, and mathematics impairment. Criterion A of the DSM-5 description of SLD calls for "difficulties learning and using academic skills, as indicated by the presence of at least one of the following symptoms that have persisted for at least 6 months, despite the provision of interventions that target those difficulties" (APA, 2013, p. 66). Symptoms include inaccurate or slow and effortful word reading, difficulty understanding the meaning of what is read, difficulties with spelling, difficulties with written expression, difficulties mastering number sense, number facts, or calculation, or difficulties with mathematical reasoning.

Criterion B (APA, 2013, p. 67) requires that academic skills must be "substantially and quantifiably below" what would be expected based on chronological age, and must cause significant interference with academic or occupational performance or with activities of daily living. Criterion B also requires that the determination regarding academic skills must be based on "individually administered standardized achievement measures and comprehensive clinical assessment." For individuals over age 17 years, a "documented history" of learning impairment may be substituted for the standardized assessment.

Criterion C states that "the learning difficulties begin during school-age years but may not become fully manifest until the demands for those affected academic skills exceed the individual's limited capacities" (APA, 2013, p. 67), thereby allowing for situations in which older individuals can be newly diagnosed with SLD. DSM-5 provides examples of situations of such demands, including timed tests, reading or writing long complicated reports for a tight deadline, and excessively heavy academic loads.

Finally, Criterion D remains similar to rule-out criteria in previous versions of DSM: It stipulates that the learning difficulties must not be better accounted for by "intellectual disabilities, uncorrected visual or auditory acuity, other mental or neurological disorders, psychosocial adversity, lack of proficiency in the language of academic instruction, or inadequate educational instruction" (APA, 2013, p. 67). Criterion D contains the only reference to cognitive ability in its provision that the academic deficits are not secondary to intellectual disability. A note below the four listed criteria states that they are to be met "based on a clinical synthesis of the individual's history" (APA, 2013, p. 67), including developmental, medical, family, and educational histories, as well as school reports and psychoeducational assessment.

The unification of three separate learning disorders into one diagnostic category has necessitated the addition of specifiers in order to identify the area(s) of academic weakness; a coding note indicates that when more than one domain is impaired, more than one specifier can and should be assigned. The coding note also directs the clinician to document the subskills that are impaired as part of the diagnosis. The specifier *with impairment in reading* is appended to the SLD diagnosis when the individual demonstrates significant impairment in one or more subskills, including word-reading accuracy, reading rate or fluency, and/or reading comprehension. *Dyslexia* may be used as an alternative term referring to problems with word-reading fluency or accuracy, decoding, and spelling, and if this term is used, impaired subskills should also be identified. An impairment in writing skills is assigned to the specifier *with impairment in written expression* and refers to impaired spelling accuracy, grammar and punctuation accuracy, and/or clarity or organization of written expression. The specifier *with impairment in mathematics* is used for individuals who demonstrate significantly below average skills in number sense, memorization of arithmetic facts, accurate or fluent calculation, and/or accurate math reasoning. The term *dyscalculia* can be used to refer to difficulties processing numerical information, learning arithmetic facts, and performing accurate or fluent calculations. Like the use of *dyslexia*, the use of the term *dyscalculia* also requires the identification of any additional impaired subskills.

In addition to specifying the domain of impairment, the degree of severity should also be indicated in the diagnosis. The range of severity includes the specifiers *mild, moderate,* and *severe*. The *mild* specifier is applied to an individual who has some difficulties in one or two academic domains but is able to function well when provided with appropriate accommodations or support services. The *moderate* specifier is used when there are marked difficulties in one or more academic domains and the individual is not likely "to become proficient without some intervals of intensive and specialized teaching during the school years" (APA, 2013, p. 68). Accommodations or supportive services may be needed in school, in the workplace, or at home in order for activities involving the academic skills to be completed accurately and efficiently. The *severe* specifier is used to describe impairments in individuals who are unlikely to learn those skills without "ongoing intensive individualized and specialized teaching for most of the school years" (APA, 2013, p. 68). Even with accommodations, an individual with severe SLD may not be able to perform academic tasks with efficiency.

Etiology

There is consensus among experts in the field that there is no known single cause, but rather numerous factors that contribute to the development of learning disabilities. According to DSM-5, SLD is a neurodevelopmental disorder with a biological basis resulting in cognitive abnormalities; academic skills deficits are considered the behavioral signs or manifestations of the disorder. Genetic, epigenetic, and environmental factors interact to impair the brain's ability to perceive or process information efficiently or accurately (APA, 2013). Table 37.1 provides a summary of the etiology of SLD, along with information on impairments that are associated with this condition and its cognitive correlates.

There is evidence to suggest the role of heredity as a significant contributory factor in the etiology of learning disabilities. Such evidence includes the fact that learning disabilities appear to run in families. Family and twin studies demonstrate moderate to high familiality and heritability of learning disabilities, specifically impairments in reading and spelling (Scerri & Schulte-Korne, 2010; Schulte-Korne, 2001). For example, heritability estimate values greater than .60 have been found for manifestations of learning abilities and disabilities (see Cortiella & Horowitz, 2014). Moreover, several genetic linkage studies implicate chromosomes 6 and 15 in the etiology of reading disorders, with chromosome 6 also suspected in the etiology of ADHD (Schulte-Korne, 2001; Willcutt et al., 2002; see Table 37.1 for more information on heritability).

In addition to the role of genetics, prenatal and perinatal factors are considered to be contributory factors in the etiology of learning disabilities. Prematurity, low birth weight, and *in utero* exposure to alcohol or cocaine are all associated with increased risk for learning problems. Loss of oxygen during birth may also result in altered brain development contributing to low academic achievement. Maternal metabolic conditions, including diabetes, hypertension, and obesity, likewise appear to contribute to the development of neurodevelopmental conditions such as autism and learning problems (Krakowiak et al., 2012).

In addition, research from the 1990s and early 2000s supported neurobiological factors in the etiology of learning disabilities. In numerous publications, Shaywitz and Shaywitz (e.g., 2004) describe overactivation of Broca's area with underactivation in the left parieto-temporal and occipito-temporal regions of the brain in children with reading disabilities. The left inferior prefrontal cortex, left angular gyrus, and inferior parietal lobes have been implicated in the development of math-related learning disabilities (Chochon, Cohen, van de Moortele, & Dehaene, 1999; Kesler, Sheau, Koovakkattu, & Reiss, 2011). In addition, the intraparietal sulcus appears to be a crucial region in the development of number sense (Dehaene, Molko, Cohen, & Wilson, 2004).

Furthermore, environmental characteristics are also considered to be etiological factors in the development of learning disabilities. Low socioeconomic status, low maternal education, male gender, and nonwhite race were all found to be related to increased risk for learning disabilities in a kindergarten sample (Resnick et al., 1999). Malnutrition may be another significant environment factor contributing to learning problems (Groce et al., 2014).

Symptom Presentation

One essential feature of SLD, as set forth in Criterion A, is persistent difficulty in learning vital academic skills that are first experienced during formal schooling. While skills like walking and talking typically develop naturally, academic

TABLE 37.1. Specific Learning Disorder (SLD): Etiology, Associated Impairments, and Cognitive Correlates

Subskill	Etiology	Associated impairments/cognitive correlates
Word-reading accuracy	SLD with impairment in reading Several cortical and subcortical structures are frequently implicated, including the planum temporale, temporal lobes, corpus callosum, and cerebellum (e.g., Eckert et al., 2003). More recent work appears to identify dysfunction in a left-hemispheric network that includes the occipito-temporal region, inferior frontal gyrus, and inferior parietal region (Fletcher et al., 2004; Richlan, 2012; Richlan et al., 2009; Shaywitz et al., 2000; Silani et al., 2005). Numerous imaging studies have also found that dysfunctional responses in the left inferior frontal and temporo-parietal cortices play a significant role with regard to phonological deficits (Skeide et al., 2015). Family and genetic factors have long been identified as crucial in dyslexia, with some researchers suggesting that a child with a parent with a reading disability is eight times more likely to have dyslexia compared to the general population (Pennington & Olson, 2005). Certainly, there is converging evidence from family and twin studies demonstrating the heritability and familiality of dyslexia (Grigorenko, 2001). Recently, genetic linkage studies have also identified several susceptibility genes for reading disabilities. These include sites on chromosomes 1, 2, 3, 4, 6, 11, 15, and 18, with one of the most commonly identified genetic locus being on chromosome 6 (Grigorenko, 2005; Paracchini et al., 2007; Scerri & Schulte-Korne, 2010; Scerri et al., 2011; Skeide et al., 2015). Shared environmental factors include language and literacy environment during childhood (Wadsworth et al., 2000), as well as quality of reading instruction.	**Phonological awareness:** The primary cognitive correlate—the metacognitive understanding that words have internal structures based on phonemes (Fletcher et al., 2007; Melby-Lervåg et al., 2012; Willcutt et al., 2013). When this awareness is impaired, word recognition is delayed, and fluency and comprehension skills are consequently affected. **Rapid naming:** Some researchers have found that phonological awareness and rapid letter naming both uniquely predict word recognition skills (Schatschneider et al., 2004; Wagner et al., 1994, 1997). However, a meta-analysis of studies examining the relationship between rapid naming and dyslexia found little evidence to support a central and persistent deficit in naming speed in individuals with the disorder (Vukovic & Siegel, 2006). On the other hand, there are findings to suggest that phonological awareness and rapid naming, although correlated, are distinct variables and contribute uniquely to word recognition (Petrill et al., 2006). **Phonological memory:** Working memory for verbal and sound-based information has also been found to be significantly related to word recognition, although it may not uniquely contribute when phonological processing is accounted for (Melby-Lervåg et al., 2012; Schatschneider et al., 2004; Wagner et al., 1997; Willcutt et al., 2013).
Reading comprehension	Several brain regions are often implicated in reading comprehension. These include the anterior temporal lobe, inferior temporal gyrus, inferior frontal gyrus, inferior frontal sulcus, and middle and superior frontal and temporal regions (Ferstl et al., 2008; Gernsbacher & Kaschak, 2003). More recent research has revealed a relationship between listening and reading comprehension and activation along the left superior temporal sulcus, which has referred to by some as the "comprehension cortex" (Berl et al., 2010). However, broader pathways are also activated in reading comprehension, reflecting increased cognitive demand compared to listening comprehension.	**Oral language:** Difficulties in reading comprehension are frequently associated with deficits oral language in general, including areas such as vocabulary, morphology, and syntax (Catts et al., 1999; Cutting & Scarborough, 2006; Share & Leikin, 2004; Torgesen, 2000; Willcutt et al., 2013). **Listening comprehension:** Several studies have demonstrated that a unique portion of the variance in reading comprehension can be explained by listening comprehension (Cutting & Scarborough, 2006; Kendeou et al., 2009). **Working memory:** Comprehension involves holding words and sentences in awareness,

(continued)

TABLE 37.1. *(continued)*

Subskill	Etiology	Associated impairments/cognitive correlates
Reading comprehension *(continued)*	Genetic factors are said to account for 41–76% of the variance in comprehension (e.g., Betjemann et al., 2008; Harlaar et al., 2007; Petrill et al., 2007). While genetic factors that influence decoding and listening comprehension account for nearly 40% of the variance in reading comprehension, there is little evidence for an independent source of genetic influence on comprehension alone (Harlaar et al., 2010; Keenan et al., 2006). However, estimating the genetic influences on reading comprehension may be particularly sensitive to the type of assessment test used (Betjemann et al., 2011).	while integrating prior knowledge with incoming information (Carretti et al., 2009). Poor comprehenders may have particular difficulty updating/revising information already in working memory (Pelegrina et al., 2014). **Executive functioning:** Several executive functions are involved in reading comprehension, including planning, organization, and self-monitoring (Cutting et al., 2009; Locascio et al., 2010; Sesma et al., 2008). Weaknesses in these executive functions result in difficulties with higher-order comprehension skills such as inferencing, integrating prior knowledge, monitoring comprehension, and adapting to text structure or genre (Fletcher et al., 2007).
Reading rate or fluency	Brain regions activated are similar to the network implicated in word reading, but additional activation is observed in areas involved in eye movement and attention (Jones et al., 2013). There is also evidence for increased activation in the left occipito-temporal region, in particular the occipito-temporal sulcus, which is important for rapid processing of letter patterns (Dehaene & Cohen, 2011; Shaywitz et al., 2004). Some studies have found increased activation in this region when normal reading automaticity is disrupted (Benjamin & Gaab, 2012). There is limited evidence of genetic influences specific to rapid naming and reading, suggesting that RAN may be etiologically distinct from phonological awareness (Byrne et al., 2005; Compton et al., 2001; Petrill et al., 2006). Genetic linkage studies have identified susceptibility genes for fluency, namely chromosome 2 (Raskind et al., 2005).	**Rapid automatized naming (RAN):** While the exact relationship between RAN and reading remains unclear, RAN is believed to be one of the best predictors of reading fluency (Georgiou et al., 2008; Tan et al., 2005). The automaticity required to complete RAN tasks is related to the ability to synthesize and automatize letter sequences/words when reading (Norton & Wolf, 2012). There are also various cognitive processes implicated in rapid naming. These include attention, executive functions (i.e., response inhibition, set shifting), lexical retrieval, and processing speed (Moll et al., 2015). **Orthographic processing:** Processing of orthographic information (i.e., the ability to process units of words based on visual long-term memory representations) is considered critical in automatic word recognition and consequently plays a crucial role in fluency (O'Brien et al., 2011). This ability is often impaired or underdeveloped in some reading-disabled individuals.
Number sense	SLD with impairment in mathematics Researchers differentiate between the basic processing of numerical information and processes involved in math calculation and problem solving, suggesting that these are both structurally and functionally distinct (Ansari, 2010). The intraparietal sulcus in both hemispheres is widely viewed as crucial in processing and representing numerical quantity, although there may be differences in activation as a function of age (Ansari & Dhital, 2006; Ansari et al., 2005; Dehaene et al., 2004; Kaufmann et al., 2006; Kucian et al.,	**Number representation:** Math disorders are associated with weaknesses in fundamental number representation and processing, which are manifested in difficulties with quantifying sets without counting, using nonverbal processes to complete simple numerical operations, and estimating the relative magnitude of sets (Feigenson et al., 2004; Geary, 2013; Geary et al., 2008, 2009, 2012; Halberda et al., 2008; Mazzocco et al., 2011; Rouder & Geary, 2014). **Number comparison:** Several studies have indicated that math difficulties are associated

(continued)

TABLE 37.1. *(continued)*

Subskill	Etiology	Associated impairments/cognitive correlates
Number sense *(continued)*	2008; Mussolin, De Volder, et al., 2010; Price & Ansari, 2013).	with deficient basic number-processing abilities, such as number comparison (Price & Ansari, 2013). These weaknesses are characterized by increased reaction times and error rates on tasks that involve comparing numbers, with particular difficulty when numbers are closer together (Mussolin, Mejias, & Noel, 2010).
Memorization of arithmetic facts	A left-hemisphere network that includes the precentral gryus, inferior parietal cortex, and intraparietal sulcus is often implicated in math fact retrieval (Dehaene, 1992; Dehaene & Cohen, 1997; Dehaene et al., 1999). Further, some researchers believe that rote math facts are retrieved from verbal memory, thereby requiring activation of the angular gyrus and other regions associated with linguistic processes (Dehaene, 1992; Dehaene & Cohen, 1995; Dehaene et al., 1999).	**Long-term retrieval:** Weak or impaired long-term retrieval of facts results in increased error rates in recall (Geary, 1993; Mazzocco et al., 2008). Because fact retrieval mechanisms fail to develop adequately, fluency is impaired, and those with dyscalculia continue to utilize procedural strategies rather than memory-based strategies (Geary et al., 1992, 2000; Hanich et al., 2001; Jordan & Hanich, 2003; Landerl et al., 2004).
Accurate or fluent calculation	Regions of the left fronto-parietal cortex, including the intraparietal sulcus, angular gyrus, and supramarginal gyrus, have been consistently associated with math calculation (Ansari, 2008; De Smedt et al., 2011; Dehaene et al., 2004). However, there is evidence to suggest that math fluency, while related to other skills, may be genetically distinct and may reflect variance above and beyond untimed calculation abilities (Hart et al., 2010; Petrill et al., 2012). The dorsolateral prefrontal cortex has also been found to show increased activation during calculation, implying that executive functioning and working memory may be playing roles in the process (Davis et al., 2009).	**Long-term retrieval:** See above. **Rapid naming:** The rate of access to information in long-term storage is believed to affect calculation fluency (D'Amico & Passolunghi, 2009). Some studies have found that math disorders are associated with deficits in rate of access of numerical information alone (e.g., D'Amico & Guarnera, 2005), while others have demonstrated that rate of access to both numerical and non-numerical information is impaired (e.g., Temple & Sherwood, 2002). **Processing speed:** There is a body of evidence to support the contribution of processing speed to math calculation fluency; however, the relationship remains unclear, as processing speed is often highly related to working memory and general intelligence (Berg, 2008; Bull & Johnston, 1997; Geary, 2011; Mazzocco & Rasanen, 2013; Willcutt et al., 2013).
Accurate math reasoning	As mentioned above, the intraparietal sulcus is often identified as a neural correlate of math disorders. However, it is likely that an entire network of brain regions is implicated, as the intraparietal sulcus plays a role in a variety of cognitive processes involved in math achievement (Szücs & Goswami, 2013). It has been suggested that the parietal network is involved in manipulating numerical quantities (Lemer et al., 2003). Some studies have also found that individuals with dyscalculia have structural abnormalities in the parietal cortex (Rotzer et al., 2008; Rykhlevskaia et al., 2009).	**Working memory:** Because mathematical reasoning relies on concurrently retaining multiple pieces of information while performing one or more procedures or mental operations, working memory is often implicated. Those with math difficulties tend to struggle with holding information in working memory, updating or revising the information, and tracking or monitoring the process, resulting in difficulties in sequencing, increased errors in counting, and other procedural errors (Geary, 2003; Lukowski et al., 2014; Pelegrina et al., 2014; Peng & Fuchs,

(continued)

TABLE 37.1. *(continued)*

Subskill	Etiology	Associated impairments/cognitive correlates
Accurate math reasoning *(continued)*	Prevalence of math disabilities is about 10 times higher in those with family members who have/had math disabilities (Shalev et al., 2001). Twin studies suggest a moderate genetic influence, with some studies finding additive genetic influences shared between math calculation and problem solving and several working memory components (Kovas et al., 2007; Lukowski et al., 2014). Environmental factors, including motivation, emotional functioning (e.g., math anxiety), and suboptimal or inadequate teaching, may also contribute to math difficulties (Szücs & Goswami, 2013; Vukovic et al., 2013). Furthermore, math achievement in particular may be associated with cultural or gender-based attitudes that may be transmitted in the family environment (e.g., Chiu & Klassen, 2010; Gunderson et al., 2011).	2016; Raghubar et al., 2010; Swanson & Jerman, 2006; Willcutt et al., 2013). **Visual–spatial ability:** Visual–spatial skills, such as visual perception, spatial reasoning, and mental rotation, have been found to influence math performance (Gunderson et al., 2012). Weaknesses in these may present as difficulties with representing numbers and aligning numerals, and problems in areas such as geometry or fractions (Geary, 2004; Swanson & Jerman, 2006). **Attention and executive functioning:** Math difficulties often reflect weaknesses in executive functioning skills, such as set shifting and cognitive inhibition (D'Amico & Passolunghi, 2009; van der Sluis et al., 2004; Willcutt et al., 2013). Poor attentional control (i.e., difficulty ignoring irrelevant information and focusing on goal-relevant information) is often observed as well (Geary, 2013).
Spelling accuracy	SLD with impairment in written expression Functional neuroimaging studies have provided substantial evidence for the role of the ventral temporal inferior frontal gyrus and the posterior inferior frontal gyrus in spelling (Rapp et al., 2015; van Hoorn et al., 2013). Other areas that have been identified include the left ventral cortex, bilateral lingual gyrus, and bilateral fusiform gyrus (Planton et al., 2013; Purcell et al., 2014; Richards et al., 2005, 2006). However, many of these regions have also been associated with reading and are not distinct to spelling/writing disorders. There is evidence that links spelling to a region of chromosome 15 (Schulte-Korne, 2001), although this locus has also been reported in dyslexia (Grigorenko, 2005).	**Phonological processing:** Phonological awareness is a significant predictor of spelling achievement (Caravolas et al., 2001; Cornwall, 1992; Holm et al., 2008; Skeide et al., 2015; Yeong et al., 2014). Weaknesses in this area may be manifested as poor segmentation of words into phonemes, poor sequencing of sounds, and omission or addition of sounds (Berninger, 1999). **Orthographic processing/orthographic coding:** Effective spelling involves storing and retrieving commonly occurring letter patterns in visual and motor memory; these skills are often impaired in poor spellers (Caravolas et al., 2001; Ehri, 2014; Yeong et al., 2014). **Motor skills:** Poor spelling is often accompanied by underlying skill deficits in areas such as fine motor control, motor planning, orthographic motor coordination, and visual–motor integration (Christensen, 2004; Daly et al., 2003; Feder & Majnemer, 2007).
Grammar and punctuation	With regard to English grammar, some researchers distinguish between the *mental lexicon* (i.e., memorized associations) and *mental grammar* (i.e., language rules and structure), and posit that each has distinct neural correlates (Pinker, 1994). There is some evidence to support this view, with data indicating that the mental lexicon involves left temporal and temporo-parietal regions, whiles the mental grammar recruits a system that includes left frontal regions (Ullman et al., 2005).	**Long-term memory:** It has been suggested that some components of long-term storage, in particular procedural and declarative memory, may be involved in grammar; however, much of this research has focused on children with language impairments (Conti-Ramsden et al., 2015; Hedenius et al., 2011).

(continued)

TABLE 37.1. *(continued)*

Subskill	Etiology	Associated impairments/cognitive correlates
Clarity of written expression	Neural correlates of writing are less understood, but some studies have suggested that the cerebellum and parietal cortex, particularly the left superior parietal lobe, may be involved (Katanoda et al., 2001; Magrassi et al., 2010). In addition, the frontal lobes have also been implicated and are considered crucial in planning, brainstorming, organizing, and goal setting (Shah et al., 2013). While there is a significant genetic component involved in the development of writing skills, this etiology is often shared with a broad variety of reading and language skills (Olson et al., 2013).	**Working memory:** A substantial body of research has highlighted the role of working memory in written expression, as text generation requires the coordination of multiple processes, such as synthesizing multiple ideas, retrieving grammar rules from long-term storage, and ongoing self-monitoring (Berninger, 1999; Bourke et al., 2013; Hooper et al., 2002; McCutchen, 1996). **Attention and executive functioning:** Various executive functions, including attention, planning, and self-monitoring, have been implicated in written expression (Altemeier et al., 2006; Graham et al., 2013; Graham & Harris, 2005; Hooper et al., 2002; Mason et al., 2011; Reiter et al., 2005; Rosenblum et al., 2009; Troia & Graham, 2002). **Language:** Levels of knowledge of syntax, morphology, semantics, and vocabulary have a significant impact on text generation ability (Dockrell et al., 2009; Fey et al., 2004; Olinghouse & Wilson, 2013). Language impairments are associated with higher rates of grammatical errors, less lexical diversity, and poorer overall content (Fey et al., 2004; Mackie & Dockrell, 2004).

skills require teaching and explicit learning. In the case of SLD, the normal pattern of acquiring academic skills is disrupted. Difficulties mastering basic skills such as reading, math, and writing can impair academic performance in other areas, such as science and social studies. In addition, the learning difficulties must persist for a period of 6 months or longer without evidence of "catching up" to same-grade peers, despite provision of extra support. A review of educational history including school reports, work samples, curriculum-based measures, and/or clinical interview can establish the persistence of learning difficulties.

Another critical component of the DSM-5 diagnosis of SLD is performance in an academic domain that is "well below average" (APA, 2013, p. 69) for the individual's age, as set forth in Criterion B. Clinical indicators are below-average scores in school or average performance with extraordinarily high levels of support; avoidance of activities requiring the impaired academic skill; and psychometric evidence from individually administered, psychometrically sound, norm-referenced, and culturally appropriate academic achievement measures. The authors of the DSM-5 description of SLD note that academic skills are distributed along a continuum; therefore, there is no natural cutoff score to differentiate those who have SLD from those who do not. Attempts to establish cutoff points are arbitrary, but the recommended 1.5 standard deviations below the mean is "needed for the greatest diagnostic certainty" (APA, 2013, p. 69). The authors provide a more "lenient threshold" of 1–2.5 standard deviations below the mean (i.e., standard scores from 85 to 63–85) when learning difficulties are supported by other sources of evidence.

According to DSM-5, the third core feature detailed in Criterion C is that the learning difficulties become observable during the early school years in most individuals. However, the authors note that some individuals may not fully manifest symptoms of the disorder until learning demands surpass the individuals' ability to compensate for "limited capacities." Thus, for example, an adult manifesting low academic achievement in college may be diagnosed with SLD for the first time.

Finally, Criterion D excludes learning difficulties attributable to other more general disorders such as intellectual disability (or intellectual developmental disorder, as it is also termed in DSM-5). DSM-5 considers "normal levels of intellectual functioning" to be an IQ estimate above 70, give or take 5 points to account for measurement error, and such cognitive functioning is considered to differentiate SLD from more general learning problems (APA, 2013, p. 73). In order to be considered to have SLD, an individual must demonstrate "unexpected academic underachievement," which is cited as the defining characteristic of SLD. An individual may be able to maintain adequate academic functioning with intense external supports, extraordinary effort, or compensatory strategies. Individuals who are intellectually gifted may also demonstrate symptoms warranting an SLD diagnosis. Criterion D further excludes general learning difficulties secondary to economic disadvantage, chronic absences, or lack of adequate education, and to neurological, motor, vision, or hearing disorders. The learning difficulties are also "specific" in that they may be restricted to one academic skill or domain. DSM-5 requires a comprehensive assessment involving professionals with expertise in SLD and psychological/cognitive assessment. Diagnosis can only be made after formal schooling has begun, but can be made for an individual at any point during the lifespan, provided that evidence of difficulties during formal schooling is available. The clinical diagnosis must be made as a result of synthesizing medical, developmental, educational, and family history; the history of the academic problem; the impact of the problem on academic, occupational, or social functioning; previous and/or current school reports; work samples; curriculum-based assessments; and previous or current scores from individualized standardized tests of academic achievement (APA, 2013).

Associated Impairments and Comorbidities

Delays in language, attention, or motor skills often, but not always, precede the manifestation of SLD. In addition, individuals with SLD often demonstrate uneven profiles of abilities and perform poorly on psychological tests of cognitive processing. According to DSM-5, "it remains unclear whether these cognitive abnormalities are the cause, correlate, or consequence of the learning difficulties" (APA, 2013, p. 70). While cognitive deficits associated with reading (i.e., dyslexia) are well known, those deficits associated with mathematics disorders or written expression disorders are less well understood. DSM-5 further notes that processing deficits observed in individuals with SLD are seen in individuals with other disorders as well, including attention-deficit/hyperactivity disorder (ADHD) and autism spectrum disorder (ASD).

In fact, the diagnosis of SLD is often comorbid with other types of neurodevelopmental disorders or other mental disorders. For example, children with ADHD are three times more likely than peers without ADHD to have a learning disability, but estimates vary widely, depending on the type of disorder and the criteria used for diagnosing learning disabilities (DuPaul, Gormley, & Laracy, 2013). While diagnosis of other disorders does not preclude the additional diagnosis of SLD, differential diagnosis under those conditions may be more difficult, as other disabilities may account for learning problems. Clinical judgment is needed to determine whether academic skills deficits set forth in Criterion A may be attributable to other disorders. For more information on impairments associated with SLD, see Table 37.1.

Course and Developmental Changes

As stated earlier, symptoms of SLD typically emerge within the developmental period during formal schooling, despite the fact that language or fine motor delays may be evident earlier. The disorder is lifelong, but symptom expression may vary depending on environmental demands on deficient skills, severity of the deficiency, comorbidity, and the supports and interventions provided to the individual. Typically, problems persist into adulthood (APA, 2013).

Age-related manifestations of symptoms of SLD vary. Preschool children may have difficulty speaking clearly, learning letters or numbers, or recognizing their names. Similarly, kindergarten children may have difficulty learning and/or writing the alphabet, writing their names, and so forth. Phonetic analysis may also be challenging for kindergarten students with SLD, and they may have trouble breaking words down into syllables, as well as difficulty with rhyming. As these children progress through the early elementary school years, they may have difficulty with sound–symbol correspondence, sounding out words, recognizing irregular words, or learning math facts. Children with SLD often perform academic tasks with significant effort or inefficiency (e.g., Geary, Hamson, & Hoard, 2000).

As children with SLD enter the late elementary and early middle school years, they may omit syllables in multisyllabic words and may have difficulty remembering information learned in class. In addition, they may demonstrate difficulty with comprehension, spelling, or writing assignments (Feifer, 2011; Mather & Wendling, 2011; Santangelo & Graham, 2014). Adolescents may have mastered basic reading skills such as decoding, but their reading may remain slow and dysfluent. They may demonstrate poor understanding of written text and may have difficulty with math problem solving. Adolescents with poor reading skills may also demonstrate increasing difficulty in content areas such as science and social studies. Adolescents and adults may continue to demonstrate poor spelling and difficulty pronouncing multisyllabic words. Rereading in order to understand the text may often be necessary for older individuals with SLD. Adults may have difficulty with drawing inferences from written text or from numerical information. As a result, they may avoid tasks involving these skills; symptoms of anxiety may also accompany the expression of learning difficulties (APA, 2013).

Prognosis

The risk of SLD is increased by several environmental factors, including prematurity, low birth weight, and prenatal exposure to nicotine. More students with SLDs come from households living in poverty as compared to students from the general population. Students with SLDs are also more likely to be in foster care or homeless. Genetic and physiological factors increase the risk of SLD as well. For example, the risk of SLD in reading and mathematics is 4–8 and 5–10 times higher, respectively, in first-degree relatives of individuals with these disorders compared to individuals without these disorders. Children whose parents have dyslexia or a history of reading difficulties are more likely to experience learning difficulties, literacy problems, or SLD (Cortiella & Horowitz, 2014).

Several factors in the preschool years are predictive of later learning difficulties or SLD. For example, inattention is predictive of later difficulties in reading and math, including failure to respond to effective academic interventions (e.g., Bental & Tirosh, 2007). Also, speech or language impairments, or deficits in specific cognitive processes (such as phonological processing, working memory capacity, and naming facility), in the preschool years predict later SLD (e.g., Scarborough, 2005). Furthermore, comorbidity with other disorders, such as ADHD, is predictive of worse mental health as compared to SLD without comorbidity (e.g., Smith & Adams, 2006).

Outcomes

Outcomes for individuals with SLD depend on many variables, such as type of treatment, severity of the disorder, intensity of intervention, sustainability of treatment, nature and extent of comorbidities, effort and motivation of the individuals, and availability of resources (e.g., parental involvement, home–school collaboration, accommodations). Table 37.2 provides a summary of outcomes for students with specific learning disabilities. It is important to note that poor outcomes may be circumvented by evidence-based interventions that are systematic, intensive, and individualized.

TABLE 37.2. Summary of Academic Performance and School Outcomes for Students with Specific Learning Disabilities

- From 12 to 26% of secondary students with learning disabilities received average to above-average scores on math and reading assessments, compared to 50% of students in the general population.
- From 7 to 23% of secondary students with learning disabilities receive well below-average scores on academic performance, compared to 2% of students in the general population.
- Students with learning disabilities earn lower grades and experience higher rates of course failure in high school than students without learning disabilities.
- About one-third of students with learning disabilities have been retained in a grade at least once.
- One in every two students with a learning disability faced a school disciplinary action such as suspension or expulsion in 2011.
- Sixty-eight percent of students with learning disabilities leave high school with a regular diploma, while 19% drop out and 12% receive a certificate of completion.
- Sixty-nine percent of students with learning disabilities have failed one or more graded courses in secondary school, compared to 47% of students in the general population.
- Black and Hispanic students with disabilities experience much higher rates of school disciplinary actions, higher rates of dropout, and lower rates of graduation.

Interventions

The primary purpose of intervention for individuals with SLD is *remediation* of skill deficits. Many interventions, particularly for reading, have been subjected to rigorous evaluation and found to be effective, meaning that when implemented with fidelity, they lead to positive outcomes (for reviews, see Cooney, Huser, Small, & O'Connor, 2007; Feifer, 2011, 2014; Flanagan & Alfonso, 2011; Kilpatrick, 2014; Mascolo, Alfonso, & Flanagan, 2014). Information about any of these interventions can be found at the What Works Clearinghouse (*https://ies.ed.gov/ncee/wwc*).

Not surprisingly, then, evidence-based interventions (as compared to interventions and techniques without such support) are often the ones that are used first in either general or specialized instructional settings. In general, it is incumbent upon practitioners to use evidence-based interventions with students who struggle academically. It is also prudent to use comprehensive interventions that can meet students' multiple manifest academic difficulties (e.g., remedial reading programs that contain the five essential components of reading; Feifer, 2011). However, it is clear from the literature that despite their overt relevance, not all comprehensive, evidence-based interventions address the academic needs of every student effectively (e.g., Della Tofallo, 2010; Hale, Wycoff, & Fiorello, 2011).

In a tiered service delivery model, interventions are selected on the basis of universal screening data. For example, students who are at risk for reading difficulties may receive Wilson if their reading difficulties are related primarily to decoding difficulties, or Read 180 if their reading difficulties are related primarily to comprehension difficulties (e.g., Feifer, 2011). When a student does not respond as expected to evidence-based interventions, a comprehensive evaluation is often recommended to gain a better understanding of the nature of and basis for the student's learning difficulties. Our opinion, based on our knowledge of and expertise in evaluation of specific learning disabilities, is that only through a comprehensive and focused evaluation of cognitive abilities/processes and specific academic skills can the intervention process move from *selecting an intervention program* to *tailoring an intervention* to meet the needs of students who do not respond as expected to evidence-based instruction (Mascolo, Flanagan, & Alfonso, 2014).

Selecting Interventions versus Tailoring Interventions

Selecting interventions involves identifying evidence-based interventions that are most often used in standard service delivery models to address manifest academic difficulties that are revealed via progress monitoring (e.g., a particular reading program is selected by a district as a tier 2 intervention for students with reading fluency difficulties). On the other hand, a primary focus on *tailoring* interventions involves understanding a student's pattern of cognitive and academic strengths and weaknesses and how this pattern interacts with the instructional materials used by the student, as well as with classroom instructional factors, environmental factors, and other individual/situational factors that may facilitate or inhibit learning. The goals for tailoring intervention, therefore, are (1) to use information about a variety of factors that are intrinsic and extrinsic to the student to design specific interventions; and (2) to ensure that a student has appropriate access to the curriculum by minimizing or bypassing the adverse effects that cognitive and other weaknesses have on the student's learning. Tailoring interventions may include modification (e.g., instructional, curricular), accommodation, remediation, and compensation. Definitions and examples of these interventions are provided in Table 37.3. For additional information about these interventions and the evidence in support of them, see Mascolo, Alfonso, and Flanagan (2014).

Vagaries in the DSM-5 Criteria for SLD

Historically, clinicians overrelied on IQ scores when making decisions about specific learning disorders and disabilities. A large body of research has shown that the IQ–achievement discrepancy method, when used as a primary or sole criterion for diagnosis of SLD, is invalid (see Stanovich, 2005, for a review). Therefore, the developers of the DSM-5 criteria for SLD should be commended for dropping this criterion. However, it seems clear from existing research that assessment of specific cognitive abilities and processes is an invaluable component in the evaluation of suspected learning disorders and disabilities (see Hale et al., 2010). As such, DSM-5 criteria for the diagnosis of SLD are limited, and when applied in isolation they may obscure information that is necessary to understand the nature of learning problems and

TABLE 37.3. Methods of Tailoring Intervention for Students with Specific Learning Disabilities

Tailoring method	Brief description	Examples
Modification	Changes content of material to be taught or measured; typically involves changing or reducing learning or measurement expectations; may change the depth, breadth, and complexity of learning and measurement goals.	• Reducing the amount of material that a student is required to learn • Simplifying material to be learned • Requiring only literal (as opposed to critical/inferential) questions from an end-of-chapter comprehension check • Simplifying test instructions and content
Accommodation	Changes conditions under which learning occurs or is measured, but does not change or reduce learning or assessment expectations. Accommodations may include timing, flexible scheduling, presentation, setting, and response accommodations.	• Extending time on exams • Assigning a project in advance or allowing more time to complete a project • Aligning math problems vertically, as opposed to horizontally • Providing a separate room to work • Having a student dictate responses to a scribe
Remediation	Techniques or programs used to ameliorate cognitive and academic deficits. Academic interventions typically focus on developing a skill, increasing automaticity of skills, or improving the application of skills. Cognitive interventions typically focus on improving cognitive processes such as working memory capacity and phonological processing. There are many techniques, published programs, and software designed for the purpose of remediation.	• Evidence-based programs listed at What Works Clearinghouse (*https://ies.ed.gov/ncee/wwc*) • Reading programs appearing on the Florida Center for Reading Research website (*www.fcrr.org*) • Techniques and materials from the Reading Rockets website (*www.readingrockets.org*) • CogMed (Pearson) • Spotlight on Listening Comprehension (LinguiSystems)
Compensation	Procedures, techniques, and strategies that are intended to bypass or minimize the impact of a cognitive or academic deficit.	• Teaching the use of mnemonic devices • Teaching the use of organizational aids or techniques • Teaching a student to outline or use graphic organizers

thus may lead to overdiagnosis. Following are a few of the most salient vagaries in DSM-5 criteria for SLD.

First, the DSM-5 definition of SLD relies on below-average achievement, without reference to underlying cognitive processing weaknesses that are known to interfere with basic academic skill acquisition and development. Below-average achievement can be caused by a variety of factors (e.g., attention problems, depression, poor motivation, behavior problems, low IQ), and the failure to include specific cognitive processes as part of the diagnostic criteria makes it difficult to determine the basis for academic underachievement. Essentially, the current definition reflects a "low-achievement" model for defining and diagnosing SLD, with an added caveat regarding poor response to intervention. Data show that states relying on low achievement and poor response to intervention only (e.g., Iowa), as the DSM-5 criteria do, have the highest percentage of students in special education under the category of specific learning disability. For example, while the national average of students with specific learning disabilities in special education is 41.5%, over 60% of the total special education enrollments in Iowa are students with specific learning disabilities (IDEAdata.org; cited in Cortiella & Horowitz, 2014).

Second, a number of terms and phrases in the DSM-5 criteria and diagnostic features are not defined sufficiently. For example, DSM-5 criteria allow for diagnosis of SLD with average achievement scores if those scores are only attainable by "extraordinary effort." Because extraordinary effort is not defined objectively, its meaning is left up to the varied, unstandardized judgments of clinicians relying largely on subjective data. Also, it is not clear what is meant by "exceed the individual's limited capacities," despite the examples given in Criterion C, including "reading or writing lengthy complex reports" and "excessively heavy academic loads." One problem with this criterion is that individuals with *average* cognitive and academic abilities often have difficulties with these tasks and often fail to meet the demands of an excessively heavy academic load. This fact, coupled with the fact that the DSM-5 criteria allow for diagnosis of SLD in adulthood based on self-report or report by others, could potentially allow just about anyone to be diagnosed with SLD—particularly older individuals who struggle in postsecondary educational programs.

Third, and perhaps most alarming, is the definition of "normal levels of intellectual functioning." It is important to know an individual's level of intellectual functioning because SLD is "specific" and therefore not attributable to intellectual disability (intellectual developmental disorder) or global developmental delay, for example. According to the DSM-5 criteria for SLD, normal intellectual functioning is generally estimated by an IQ score of greater than about 70 ± 5 points (or standard scores of 65–75 on standardized tests having a mean of 100 and standard deviation of 15). This score range, which corresponds to the 1st–5th percentiles, can in no way be conceived of as reflecting "normal levels of intellectual functioning." In fact, this score range is associated with cognitive impairment and intellectual disability. This score range is also identical to the range used to define intellectual developmental disorder in DSM-5 (APA, 2013, p. 37).

Interestingly, the DSM-5 SLD criterion for academic skills that are "substantially and quantifiably below those expected for the individual's chronological age" (APA, 2013, p. 67) is "low achievement scores on one or more standardized tests or subtests within an academic domain (i.e., at least 1.5 standard deviations . . . below the population mean for age, which translates to a standard score of 78 or less, which is below the 7th percentile)." Moreover, standard scores in this range are "needed for the greatest diagnostic certainty" (APA, 2013, p. 69). Given the properties of the normal probability curve, this criterion is certainly in line with what can be considered substantially below-expected levels of performance. Therefore, it is neither logical nor accurate to interpret scores that are lower than 78 (i.e., scores of 70 ± 5) as representing "normal" intellectual functioning.

Because the same standard score range is used to define normal intellectual functioning for SLD and impaired intellectual functioning for intellectual developmental disorder, the defining characteristic of SLD—*unexpected underachievement*—is not evident in the DSM-5 criteria, despite mention of this hallmark characteristic in the "Diagnostic Features" section (APA, 2013, p. 69). For example, individuals with IQs in the 70s and commensurate academic achievement scores meet DSM-5 criteria for SLD. However, this type of profile does not reflect unexpected underachievement, but rather *expected underachievement,* which historically has never been a defining characteristic of SLD. Expected underachievement is more consistent with general learning difficulties that are perhaps due to suspected but undiagnosed conditions, such as fetal alcohol spectrum disorders (e.g., Kodituwakku, 2007). Because the DSM-5 criterion for normal intellectual functioning is inaccurate, the definition of SLD is overly sensitive but not sufficiently specific, which will undoubtedly lead to a substantial increase in the number of individuals diagnosed with SLD.

It is beyond the scope of this chapter to discuss all of the potential issues related to diagnosis of SLD brought on by the revised SLD criteria included in DSM-5. It is our contention that failure to include criteria related to cognitive processes obscures the very nature of SLD. There is an abundance of evidence in the cognitive and neuropsychological literature demonstrating how cognition affects achievement (see Fiorello, Hale, & Wycoff, 2012; Fletcher-Janzen & Reynolds, 2008). Most academic learning tasks require general cognitive processes such as attention, language, and memory, and specific processes contribute uniquely to specific academic skills (see Geary, 2011; Shaywitz et al., 2004). Even the authors of the DSM-5 definition of SLD found in their review of predictive validators "quite strong support for the inclusion of cognitive processing deficits in the diagnostic criteria for SLD," especially in reading (Tannock, 2013, p. 18). Academic tasks require numerous cognitive processes. Administering specific, narrowly defined cognitive tasks helps to systematically isolate the underlying learning problems and to differentiate SLD from other conditions that affect learning and achievement (see Decker et al., 2013, for a discussion). The purpose of administering cognitive tests is not necessarily to obtain an IQ score, but to assist in understanding learning problems (Flanagan et al., 2013) and to develop effective interventions (Fuchs et al., 2011).

In short, we believe that approaches to SLD diagnosis that do not consider cognitive processing strengths and weaknesses are not supported by research (see Reynolds & Shaywitz, 2009). We support alternative research-based approaches to SLD diagnosis "because they emanate from the marriage of a collective body of knowledge that has been acquired through research in the fields of neuroscience, pedagogy, assessment, and intervention" (Della Tofallo, 2010, pp. 180–181). These approaches deemphasize IQ in favor of theory-based flexible batteries, which include measures of cognitive abilities and processes that are predictive of specific academic skills and that yield information relevant for instructional planning (see Flanagan & Alfonso, 2011, for a review).

CONCLUSION

This chapter has provided a brief history of the definition of specific learning disability, with emphasis on the criteria included in the five editions of the DSM. The DSM-5 criteria for SLD have been reviewed in detail. Also reviewed is the etiology of SLD, as well as associated impairments and comorbidities, course and developmental changes, prognosis, outcomes, and treatment. This chapter has also highlighted some salient, unexpected changes in the DSM-5 criteria—changes that appear to obscure the true nature of SLD as a disorder in one or more basic psychological processes.

CHAPTER 38

Should Our Future Include the Integration of Evidence-Based Neuropsychological Services into School Settings?

Elizabeth M. Power
Rik Carl D'Amato

CLINICAL NEUROPSYCHOLOGY IN THE SCHOOLS

The purpose of this chapter is to introduce the uninitiated reader to a neuropsychologically driven, brain-based approach to serving comprehensive medical and neurological disorders in the public schools. This chapter first highlights the growing medical and educational needs of children in the educational enterprise, and discusses why school neuropsychologists are uniquely qualified to become the largest group providing rehabilitation services in the world. The chapter then discusses how school psychologists can use a neuropsychologically driven approach to develop evidence-based interventions (EBIs) within a multi-tiered system of supports (MTSS) model. All brain-based areas are discussed in light of appropriate measures and progress-monitoring tools for MTSS. The chapter suggests types of data that can be collected by multiple levels of service providers, such as teachers, interventionists, and school psychologists.

One of the commitments that U.S. society has made has been to educate all children and to help them live and play successfully in the world. Despite our efforts to help children develop successfully in a complex world, various toxic influences affect them in many ways. Thus many children are in need of unique psychological interventions. All children are unique and respond differently to interventions (Merry, McDowell, Hetrick, Bir, & Muller, 2004). In order to find individualized supports, it is beneficial for children with disadvantages/disabilities to undergo neuropsychological evaluations (D'Amato, 1990). Neuropsychologists conduct comprehensive evaluations in order to determine appropriate supports for individuals who may have difficulty learning or functioning in daily life. School psychologists are also instrumental in choosing interventions for children with disabilities (Witmer, 1896). However, many school psychologists lack appropriate training in neuropsychology (D'Amato, Fletcher-Janzen, & Reynolds, 2005). With a neuropsychological background, school psychologists are well equipped to choose, implement, and monitor the progress of EBIs (Davis, 2011; Fletcher-Janzen, 2005).

We have liberally adapted material from 10 previous articles and book chapters to make this chapter possible. These include D'Amato (1990); D'Amato, Crepeau-Hobson, Huang, and Geil (2005); D'Amato, Rothlisberg, and Leu Work (1999); D'Amato and Wang (2015a, 2015b); Rhodes, D'Amato, and Rothlisberg (2008); Root, D'Amato, and Reynolds (2005); Traughber and D'Amato (2005); Witsken, D'Amato, and Hartlage (2008); and Witsken, Stoeckel, and D'Amato (2008).

Through public education, all children, no matter their backgrounds or socioeconomic classes, are given the chance to learn literacy, mathematics, and other related skills. However, it was not until the passing of Public Law 94-142 in 1975 (see U.S. Department of Education, 2016, for a fuller account) that students with disabilities were granted the right to have free and appropriate public education. When students with disabilities started to attend school, special education classes were created so that these students could have rights similar to those of their peers who were considered typically developing. The U.S. education system has made great strides since the 1970s in offering appropriate public education to students who have disabilities. There are now laws that enforce parents' and students' rights regarding education (again, see U.S. Department of Education, 2016). School staff members work hard to ensure that these students are taught in the least restrictive environments, and that they are educated as much as possible with their typically developing peers in general education classrooms. Despite the improvements in the education system, many problems continue to exist for students with disabilities (D'Amato, Fletcher-Janzen, & Reynolds, 2005). A significant problem that many schools have is finding EBIs for all students with similar difficulties (Witsken, Stoeckel, & D'Amato, 2008). This is the focus of the current chapter.

There is a growing need for a neuropsychological approach within school systems. As society continues to change, the need for services within schools has also grown. Due to changes in society, especially advances in modern medicine, the demand on schools to provide appropriate services for students with a wider, more complex array of difficulties (e.g., prematurity, spina bifida, sickle cell disease) has increased. School psychologists may not be well equipped to deal with the growing number of psychological and behavioral problems within classrooms (D'Amato & Hartlage, 2008). It may be that school psychologists are no longer able to master *all* areas of knowledge in order to operate as effective professionals (D'Amato, Fletcher-Janzen, & Reynolds, 2005). For example, school psychologists are expected to know more about the biological bases of neurodevelopmental disorders. There are an increasing number of medical diagnoses, such as low birth weight (Davis, 2011), that contribute to learning deficits in children of which school psychologists need to be aware. Moreover, new disorders seem to emerge each year (e.g., the Zika virus; Power, D'Amato, & Eusebio, 2017).

What Is School Neuropsychology?

According to the National Academy of Neuropsychology (2001), *clinical neuropsychology* is the applied science of brain–behavior relationships. Clinical neuropsychologists must apply a working understanding of psychology, physiology, and neurology to assess, diagnose, and treat patients with neurological, medical, neurodevelopmental, psychiatric, and cognitive disorders (D'Amato, Fletcher-Janzen, & Reynolds, 2005; Witsken, D'Amato, & Hartlage, 2008). In addition to using assessments of neurocognitive, behavioral, and emotional functioning to form hypotheses regarding a client's central nervous system functioning, neuropsychologists must carefully consider how these factors interact with the individual's psychosocial environment (National Academy of Neuropsychology, 2001; Teeter & Semrud-Clikeman, 2007). Viewed from this perspective, neuropsychological assessment should serve a variety of purposes beyond an initial diagnosis. Assessments must be used to guide treatment decisions by identifying an individual's strengths, weaknesses, and needs; to design individual treatment programs tailored to these findings; to evaluate changing treatment needs; and to monitor treatment effectiveness (Davis, 2011; Kazdin, 2011; Root, D'Amato, & Reynolds, 2005). In sum, an understanding of evidence-based neuropsychological functioning must drive our practice of all types and forms of neuropsychology, including counseling, consulting, assessment, and intervention. This claim should not be surprising, since the brain is the origin of human behavior (D'Amato & Wang, 2015a, 2015b).

The field of *school neuropsychology* is relatively new (D'Amato, Fletcher-Janzen, & Reynolds, 2005). In fact, many neuropsychological assessments have roots in adult neuropsychology (Koziol & Budding, 2011). However, as we have grown to understand pediatric brain functioning, more innovative assessments and interventions have been developed specifically for children. Pediatric neuropsychologists have training in applied psychology, clinical psychology, neurology, development, and educational systems (D'Amato & Dean, 1989). The emphasis within pediatric neuropsychology is often on comprehensive evaluations and the interpretation of results from a neurodevelopmental perspective. Clinical neuropsychologists working in schools should also have knowledge of EBIs and can adapt these specific tools to meet needs of individuals (Traughber & D'Amato, 2005). This expertise may be the most important weapon in these psychologists' arsenal.

A comprehensive neuropsychological evaluation typically involves the collection of an individual's detailed history. This history provides a professional with information, such as medical/health history, developmental milestones, and social functioning (see D'Amato, Fletcher-Janzen, & Reynolds, 2005, Appendix A, p. 859, for an example). The history is also essential for gathering information about an individual's culture. Cultural factors, such as age, gender, education, income, and other related factors, should always be taken into consideration during a neuropsychological evaluation. Such implications assist the clinician in determining outcomes.

Training in Clinical Neuropsychology

A neuropsychological interpretation requires specialized training in brain–behavior relationships (D'Amato, Hammons, Terminie, & Dean, 1992). All individuals in this field fall near one end of the neuropsychology training continuum. At one end, individuals have limited training in clinical neuropsychology, and at the other end they are comprehensively trained in it. An individual who is comprehensively trained in clinical neuropsychology will have completed clinical neuropsychology predoctoral coursework, a predoctoral clinical neuropsychology practicum, and an internship and dissertation in this specialization area (Witsken, D'Amato, & Hartlage, 2008). This individual will go on to complete advanced postdoctoral study for up to 2 years, thus allowing him or her to claim expertise in clinical neuropsychology. Individuals who fall at the other end of the continuum, with limited training, usually have completed a single course as required by the American Psychological Association (Witsken, D'Amato, & Hartlage, 2008).

Although many neuropsychologists are also trained as clinical or school psychologists, the reverse is less common. The use of some clinical neuropsychology assessment procedures in practice does not qualify one as a clinical neuropsychologist. By analogy, although a cardiologist uses a stethoscope, anyone who learns how to use a stethoscope does not automatically become a cardiologist (Hartlage, 1987). The fact that clinical and school psychologists and neuropsychologists frequently use similar tools has led to considerable debate about neuropsychologists' training and licensure requirements. Several professional organizations have arisen to represent clinicians and researchers in neuropsychology. These organizations have contributed to establishing training standards and regulating credentialing in neuropsychology. Among these are the International Neuropsychology Association; Division 40 (Clinical Neuropsychology) of the American Psychological Association; and the National Academy of Neuropsychology. Two major national professional credentialing boards in neuropsychology have emerged to specify and regulate practitioner qualifications. These include the American Board of Professional Psychology, which recognizes clinical neuropsychology as a specialty area of practice within psychology, and the American Board of Professional Neuropsychology, which exclusively recognizes specialists in neuropsychology. Currently, most clinical neuropsychologists have obtained a doctoral degree in psychology with coursework, research, and practicum experiences in neuropsychology, followed by postdoctoral training with a neuropsychology emphasis. In addition to core coursework in general psychology, clinical psychology, neurosciences, and clinical neuropsychology, the International Neuropsychology Association internship guidelines requires at least a minimum number of internship hours under supervision of a board-certified clinical neuropsychologist, with at least 50% of the time devoted to clinical neuropsychology. Practicing neuropsychologists are generally expected to obtain licensure from their respective state psychology licensure boards prior to seeking board certification in clinical neuropsychology. Some school psychology programs offer a major or specialization in clinical neuropsychology (e.g., Chicago School of Professional Psychology, University of Utah, Ball State University), which have allowed a variety of school psychologists to specialize in clinical neuropsychology. However, these specializations do not take the place of advanced postdoctoral training. In fact, comprehensive training in school psychology and clinical neuropsychology is advised (D'Amato, Fletcher-Janzen, & Reynolds, 2005).

Multicultural Considerations

Culture is evident in each portion of a neuropsychological evaluation, such as the gathering of background history, choice of assessments, and interpretation of results. Differences in gender, chronological age, nationality, race, and family have significant implications for clinical assessment (Manly, Jacobs, Touradji, Small, & Stern, 2002). All children come from different families, with different backgrounds, morals, and traditions. No parents/guardians raise their children the same way. Although this diversity may make it difficult to compare the results of an intervention's utility even among similar cultural groups, it necessitates that researchers and clinicians tailor programs for specific individuals. An individual's culture is essential in the design of an intervention plan. Our suggested approach highlights the importance of interactions between an individual and his or her interconnected settings (D'Amato, Fletcher-Janzen, & Reynolds, 2005). A professional must consider the social and cultural context in relation to each individual's neuropsychologically driven presentation (Bronfenbrenner & Morris, 1998).

Using Neuropsychology as an EBI in Schools

Numerous authors have argued that neuropsychological principles and practices can be used to improve instructional models and learner outcomes (Gaddes, 1980; Sousa, 2005). Advocates for the training of school psychologists to be able to integrate clinical neuropsychological perspectives into their practices have cited the following potential applications of neuropsychology within the schools (D'Amato, Fletcher-Janzen, & Reynolds, 2005; D'Amato & Wang, 2015a; Hale & Fiorello, 2004; Root, D'Amato, & Reynolds, 2005; Whitten, D'Amato, & Chittooran, 1992). School practitioners should:

1. Interpret the results of neuropsychological assessments to facilitate intervention planning.
2. Propose recommendations for remediation and compensation-based interventions integrating knowledge of developmental and neuropsychological principles, as well as scientifically validated interventions.
3. Integrate a working understanding of neuropsychological development in consultation efforts with teachers, to promote instructional practices that are aligned with knowledge of neurodevelopment.
4. Act as liaisons with the medical community, to better coordinate and evaluate intervention efforts.
5. Educate school staff and parents about the neuropsychological bases of development, behavior, and learning.
6. Conduct research regarding the efficacy of neuropsychologically based interventions and consultation in schools.
7. Serve as rehabilitation specialists in the schools, helping children return from medical or psychological treatment centers.

The literature documenting the potentially invaluable role that could be assumed by school psychologists trained in neuropsychology has been developing (D'Amato, Fletcher-Janzen, & Reynolds, 2005). Particular attention has been paid to the need for practitioners familiar with educational systems, learning, and brain–behavior relationships to serve as liaisons between medical and school teams (D'Amato, Fletcher-Janzen, & Reynolds, 2005; Sousa, 2005, 2006). Pelletier, Hiemenz, and Shapiro (2004) have advocated for the need for school psychologists to capably interpret and translate data from reports by medical professionals and clinical neuropsychologists into practical, empirically based school interventions. Many clinical neuropsychologists and medical practitioners trained in the medical model may be more accustomed to doling out prescriptive interventions, with little feedback from recipients regarding practical considerations unique to the school environment that may be necessary to facilitate successful outcomes. School psychologists are in a unique position to bridge this gap.

Grounded in the biological bases of behavior, a neuropsychological perspective can give practitioners added breadth and depth to their understanding of the thinking processes underlying behavior; such a viewpoint can be held without compromising the value of other perspectives in explaining observed behavior (Gaddes & Edgell, 1994). A neuropsychological approach also integrates the traditional views of looking for the internal causes of behavior (e.g., psychoanalysis) with the external antecedents and consequences of observable behavior (e.g., behaviorism) to gain a full understanding of each learner (Whitten et al., 1992). For more than a century, research has consistently shown that environmental factors explain approximately 40–60% of behavior, while biogenetic factors also explain approximately 40–60% of behavior (Hartlage & D'Amato, 2008).

School psychologists trained in neuropsychology may be the only professionals within the school system who are equipped to address teachers' concerns and questions about each child's unique neurological needs and expected outcomes (Root et al., 2005). School neuropsychologists may be able to provide inservice training to all school staff members who will be working with a child, to facilitate intervention fidelity. School neuropsychologists may also provide valuable services to children's families by answering their questions and providing them with ongoing information. Furthermore, some families may be coping with additional stress, financial problems, guilt, grief, sadness, or anger related to their children's medical conditions (Root et al., 2005). School neuropsychologists recognize the importance of family systems in facilitating successful outcomes for children and may be in a unique position to assist these families (Gaddes, 1980). Consultation between the school neuropsychologist and medical service providers may also be useful in limiting the costs of assessment and intervention by reducing the likelihood of duplicating services (Root et al., 2005). Increased collaboration can also reduce the likelihood of contradictory information and/or recommendations, which in turn will potentially reduce parents' and school staff members' frustration.

NEUROANATOMY AND THE BRAIN

It is important to understand that the brain is composed of four major lobes: the (1) frontal lobe, (2) parietal lobe, (3) occipital lobe, and (4) temporal lobe (see Figure 38.1). It is important to understand the location and function of these structures because such an understanding should inform interventions for children. While the distinct lobes work in concert with one another, each lobe has a specialized function. Due to advances in technology, such as functional magnetic resonance imaging, it is now apparent that EBIs are successful at changing the brain (Shaywitz, 2003). For example, the brain of a child who cannot read can be scanned. The child then can be taught to read by using an evidence-based reading intervention, as specified by the Individuals with Disabilities Education Improvement Act of 2004 (IDEA 2004). Next, a brain scan can be performed to show which part of the brain has changed as a result of the intervention (D'Amato, Fletcher-Janzen, & Reynolds, 2005).

Much has been learned about the structure and function of the brain in the last century. Although the cerebral hemispheres act in concert, the right hemisphere seems to be specialized for holistic, spatial, and/or nonverbal reasoning, whereas the left is more involved in verbal, serial, and/or analytic-type tasks (Reynolds, 1981; Walsh, 1978). Similarly, models of cognitive processing have been proposed that demonstrate the specialization of brain structure.

Luria and His Functional Integrative Systems

Alexander Luria was a neuroscientist from Russia who helped to pave the way for pediatric neuropsychology (Reynolds & French, 2005). Some areas of Luria's research interests included genetic psychology, aphasia, and neurology. However, it was Luria's neuroscientific approach to the study of human mental processes that contributed the most information to the field of neuropsychology viewed *systemically*. According to Luria, groups of brain areas, working in concert, each make unique contributions to an overall functional system (Kostanaya & Rossouw, 2013). Luria (1973) believed that the basic functions of brain are represented by three functional systems. The first system is responsible for arousal and attention. The second block involves the ability to analyze, code, and store knowledge. The third block is for the application of executive functions for the use of programming behavior. Each block is based on the function of another, and these units cannot carry out one activity completely independently. Luria used his *integrative functional systems* approach to diagnose and find the locations of brain injuries.

Using this innovative, integrative approach, Luria advocated for clinicians' administering a variety of assessments in order to evaluate the sensory, integrative, and generative structures of the brain. Based on the results of these evaluations, clinicians could determine approximate locations of brain injuries, as well as the structures that were affected by the injuries (Luria, 1973). A model such as Luria's hierarchal model of cortical functioning allows neuropsychologists to accurately identify children as having neurodevelopmental disorders (Davis, 2011). Not only can neuropsychologists utilize this model; other professionals, such as school psychologists, can benefit as well. The influence of Luria's model has led to significant development in popular intelligence tests. Both editions of the Kaufman Assessment Battery for Children (K-ABC and KABC-II; Kaufman & Kaufman, 1983, 2004), and both editions of the Cognitive Assessment System (CAS and CAS2; Naglieri & Das, 1997; Naglieri, Das, & Goldstein, 2014), stand firm on a Lurian foundation.

Luria has offered a model of brain organization that has attempted to explain the diversity and complexity of behavior (Luria, 1970, 1973; Reynolds & French, 2005). The elegance of Luria's system lies in its capacity to characterize the brain as an interconnected system of attention, information processing, and action, allowing researchers to visualize the integrated and reciprocal nature of the brain's organization. What is observed after damage or as a result of dysfunction is not the deficit per se, but how the remaining intact areas and subsystems deal with the task or information presented (Morris, 1989). Basic knowledge of how behaviors seem to be interrelated, and of which areas of the brain are purportedly involved in the behavior–behavior associations, gives practitioners an additional way of investigating learning.

Hemispheric Specialization and Learning

One of the simplest ways to understand the brain is to consider how the hemispheres process information in a specialized fashion (see Table 38.1). For example, *simultaneous processing* ability has been affiliated with the right hemisphere because of its holistic nature; it deals with the synthesis of parts into wholes and is often implicitly spatial (Das, Kirby, & Jarman, 1975; see also Naglieri & Otero, Chapter 6, this volume). In contrast, the left hemisphere processes information by using a more *successive/sequential processing* method—considering the serial or temporal order of input (Dean & Anderson, 1997).

Many learners display a preference for either sequential/successive or simultaneous styles of teaching and learning (Luria, 1973). These two modes of cognitive processing are complementary rather than hierarchical. That is, they work together to create an efficient and effective manner of learning. Reynolds and French (2005) also have advocated that the examination of these two styles of processing should be a principal component of understanding how an individual best learns (D'Amato, Crepeau-Hobson, Huang, & Geil, 2005).

Sequential processing involves breaking the stimuli into separate parts, in order to understand what the learner is experiencing. This also involves the serial or temporal order of the stimuli. Input often is organized in a defined order (Davis, 2011). The *Encyclopedia of Clinical Neuropsychology* (Kreutzer, DeLuca, & Caplan, 2011) has defined sequential (successive) processing as follows:

> The perception of stimuli in sequence and the subsequent production of information in a specific arrangement fall under successive processing. . . . Thus,

TABLE 38.1. Description of the Different Styles of Brain Processing by Cerebral Hemisphere

Function	Reference
	Right hemisphere
Processing modes	
Simultaneous	Sperry (1974)
Holistic	Dimond and Beaumont (1974); Sperry (1969)

> information can only be comprehended in a temporal, sequential manner, with each piece being dependent on the preceding element. (p. 2262)

For example, when one is teaching reading, the word *cat* can be broken into three segments, with *c* listed on one card, *a* listed on the second card, and *t* listed on the final card. This style of processing is similar to phonetic approaches to reading instruction (Sousa, 2006). Some have used the term *serial* to describe this approach, often seen as residing in the left hemisphere.

The *simultaneous processing* method, in contrast, is holistic and synchronized. Information is considered together, in its entirety, or as a whole. This approach involves integrating the stimuli spatially, organizing them simultaneously, and then integrating them into a whole (Davis, 2011). These functions are seen as residing in the right hemisphere. Kreutzer and colleagues (2011, p. 2301) have defined simultaneous processing as "the process of combining discrete and unconnected stimuli into a single group or whole to assist in comprehension and interpretation. It involves the comprehension of the relationships of and between separate entities and its relation or position to the whole." An example of simultaneous processing is teaching reading by emphasizing the shape of the word *cat*. In this approach, it is important to emphasize how the three letters are linked and shaped. Consequently, people who use this processing style may be able to look at the shape of a word and tell that it is spelled incorrectly, or they may remember where the idea they are searching for can be found on a text page.

It is essential to know that simultaneous and successive processes are neither modality- nor stimulus-specific. That is, although certain functions are processed more efficiently through one process than through the other, any type of information can be processed through either simultaneous or successive means (Reynolds & French, 2005). In terms of teaching and learning, it is important to find out which type of processing is most suitable to assist each student to learn. Some authors have suggested that informal tests and/or observations be used to determine which type of processing is most appropriate. Sousa (2006) has provided an informal hemispheric preference measure and mentions that similar tests are available, although no psychometric data are presented to support any measure. In addition, task demand, genetic predisposition, neurocultural traditions, an individual's level of attention to the task, and the individual's preferred means of completing the task are all factors that can change, depending on the cognitive processing style the individual applies (Luria, 1970, 1973).

NEUROPSYCHOLOGICALLY INFORMED APPROACHES TO ASSESSMENT

Recognizing Biogenetic and Ecological Differences in Disorders

Table 38.2 presents an abbreviated list of the many neuropsychological disorders that have been found to have biogenetic underpinnings (Witsken, D'Amato, & Hartlage, 2008). While clearly related to environmental support systems, the biogenetic bases of these disorders have been recently illuminated (Hartlage & D'Amato, 2008). All school personnel, parents, and teachers who are working to offer school support for biogenetic disorders need to realize that these categories are not unrelated. For instance, while a child with a traumatic brain injury may be supported through cognitive rehabilitation from the school psychologist, it is just as critical to educate those in the child's classroom (including both school personnel and peers) about their role in supporting the child's emotional, academic, and intellectual changes.

Lurian/Eastern versus Actuarial/Western Approaches

Beginning almost a century ago, two distinct approaches were advocated as suitable models to follow in assessing for intervention with children and youth: the *quantitative* approach and the *qualitative* approach. The basic differences between these two approaches relate to how data are collected, organized or aggregated, and linked to interventions related to student performance outcomes. Table 38.3 compares and contrasts these unique approaches to serving children, youth, and families. The quantitative approach, used primarily in the Western world, has focused on the acquisition of formal test data followed by a comparison of scores to normative samples. This approach compares the student's performance on standardized tests, in a variety of brain-related domains, to the performances of same-age peers. This comparison enables the evaluator to determine whether student functioning is below average, average, or

TABLE 38.2. Disorders Found to Have Biogenetic Underpinnings

- Alcoholism
- Alzheimer disease
- Asthma
- Aphasia
- Attention deficit disorder (ADD) and attention-deficit/hyperactivity disorder (ADHD)
- Behavioral/personality disorders
- Cancer
- Dementia not otherwise specified
- Diabetes
- Eating disorders
- Epilepsy
- Fetal alcohol syndrome
- Genetic and chromosomal disorders: phenylketonuria (PKU), Down syndrome
- Hearing/auditory disorders
- HIV/AIDS
- Huntington disease
- Hypertension
- Infants' exposure to prenatal toxins
- Language disorders
- Learning disorders: reading, mathematics, written expression
- Malnutrition
- Migraines/headaches
- Motor skill disorders
- Multiple sclerosis
- Muscular dystrophy
- Parkinson disease
- Perceptual disorders
- Pervasive developmental disorders
- Pick disease
- Prematurity
- Seizure disorders

- Zika virus

TABLE 38.3. Lurian/Eastern versus Actuarial/Western Approach

Lurian/Eastern approach	North American/Western approach
Theory-driven	No overall a priori theory; data-driven
Attempts to support or confirm a theory	Attempts to disconfirm specific hypotheses
Synthetic	Analytical
Observation-oriented	Evaluation-oriented
Single-case-oriented	Group-comparison-oriented
Describes behaviors	Evaluates behaviors
Subjective	Objective
Looks for patterns of functioning	Looks for differential diagnosis
Qualitative in nature	Quantitative in nature
Flexible	Fixed
Process-oriented	Product-oriented
Focuses on individualized activities	Focuses on multiple tests/procedures
Links behavioral data to functioning	Links psychometric data to diagnosis
Considers the functional system	Considers discrete brain-related areas
Clinical–theoretical	Actuarial–standardized

above average in a number of areas. Standardized tests can offer the practitioner a helpful set of tasks to evaluate important neuropsychological abilities. If an appropriately selected, comprehensive, wide-band neuropsychology battery is administered, most essential areas are likely to be evaluated (Johnson & D'Amato, 2011). For many practitioners who use uniform assessments, such tests are selected because they measure core neuropsychological abilities that should be evaluated within a traditional assessment. From a quantitative view, student data are generated and used primarily for four comparisons: (1) How does the student's performance compare to that of others in the class, in the community, or in the state/nation? (2) What are the student's unique patterns of performance, including strengths and weaknesses? (3) When right-hemispheric abilities (i.e., including sensory–motor processes) are compared to left-hemispheric abilities, do unique patterns emerge that reveal significant processing styles? (4) Does an analysis of displayed signs and symptoms suggest problems related to a specific disorder (e.g., a nonverbal learning disorder) or the potential course of a disorder? A quantitative approach is often used for complex cases in which multiple interventions have not helped students learn. For example, quantitative approaches are often used in an MTSS tier 3 evaluation.

On the other hand, the qualitative approach focuses on the uniqueness of the individual under study and seeks to match the procedures used with the individual's distinctive profile. Glozman (1999) indicated that "Luria's neuropsychological assessment is recognized today by the world's scientific community to be the most comprehensive and flexible method of neuropsychological evaluation available, which is also based on an understanding of the factors underlying complex psychological activities" (p. 23). A few seasoned neuropsychological practitioners have offered models of assessment that examine curriculum-related processing skills to evaluate student difficulties (D'Amato, Rothlisberg, & Leu Work, 1999; Glozman, 1999; Sousa, 2005). Sample tasks that could be used in a neuropsychologically based MTSS (NB-MTSS) model have been offered by Gaddes and Edgell (1994) and Luria (1970). Gaddes and Edgell offer tasks to evaluate auditory processes and aphasic signs in oral speech (17 questions; p. 411), visual processes (13 questions; pp. 411–412), tactile processes (6 questions; p. 412), and motor–expressive processes (6 questions; pp. 412–413). To evaluate auditory processes/abilities, here are six sample questions from Gaddes and Edgell's list (p. 411):

1. Can he recite all the letters of the alphabet?
2. Can he associate all the phonetic sounds of all the letters? . . .
3. Can he name common objects without hesitation?
4. Can he describe the use of common objects?
5. Word fluency: How many nouns can the child produce in one minute?
6. Can he construct a meaningful sentence if given three words?

It is obvious that an analysis such as this can provide a wealth of data that can be used to inform the choice of intervention(s). It is important to use the child's strengths to support his or her needs.

Similarly, Luria (1970) provided a list of evaluation activities to assess the neuropsychological processes that underlie arithmetic (Gaddes & Edgell, 1994). His steps included asking the student (1) to count aloud (to check memory of number in the correct sequence), (2) to recognize quantities, (3) to read and write single digits, (4) to read and write multidigit numbers (to show an understanding of the decimal system), (5) to recognize relative values, (6) to show competence in the basic arithmetic skills, and (7) to attempt more complex calculations (Luria, 1970, as cited in Gaddes & Edgell, 1994, p. 419). If integrated within an NB-MTSS framework, this type of approach is useful at tier 1, when interventions are developed from the curriculum or when informal techniques are used. When used at tier 2 or 3, this approach offers the ability to select or develop a battery based on the needs of the student under study.

Fixed- versus Flexible-Battery Approaches

The use of fixed or flexible batteries in neuropsychology has been described extensively elsewhere (Gaddes & Edgell, 1994; Rhodes, D'Amato, & Rothlisberg, 2008; Riccio & Wolfe, 2003; Teeter & Semrud-Clikeman, 2007). In general, practitioners appear to be divided between those who advocate a fixed-battery approach (i.e., administering a consistent, standardized battery to all students, regardless of their referral questions) and those who advocate a flexible-battery approach (i.e., using a case study analysis focusing on the dynamic clinical interactions and "the process" to better understand each individual). Integrative models of assessment incorporating elements of each approach have become increasingly popular (D'Amato, Fletcher-Janzen, & Reynolds, 2005; Davis, 2011). Selecting aspects of both approaches allows the clinician to emphasize the person being assessed, as well as the individual's fit with his or her environment. Because this approach allows examiners to select instruments unique to each child's needs in response to specific referral questions, it appears particularly useful in school-based practice, where large caseloads and legal requirements governing timely completion of evaluations make it necessary to efficiently select instruments that will be most likely to facilitate treatment planning. Our model advocates the composition of assessments based on both fixed and flexible ideas. For example, at tier screening, all students are evaluated using a fixed number of tasks, but tasks are selected from both quantitative and qualitative areas.

Integrating Comprehensive Ecological Neuropsychological Assessments with Interventions

The primary aim of neuropsychological approaches to assessment and later to intervention is to systematically integrate information collected about the individual's brain integrity with information obtained from a comprehensive review of the environmental systems that are influencing the child. The argument that neuropsychological models look only at the intrinsic aspects of an individual's performance misrepresents the true nature of practice (Gaddes, 1985; Gaddes & Edgell, I994). The practitioner who is using a neuropsychological model of inquiry is much more likely to conduct a more complete assessment than one who neglects the internal components of behavior. Far from ignoring environmental controls on performance, the practitioner with a neuropsychological background will also try to consolidate environmental and biological aspects that are contributing to the problem under study, with an emphasis on understanding *why* the difficulty exists (D'Amato, 1990; Taylor & Fletcher, 1990). Such an assessment allows the examiner to reduce the subjectivity in traditional neurological examinations by conducting assessments that lead to quantifiable standardized scores, thereby increasing the reliability of the assessment, as well as allowing for a more useful baseline for comparisons across time.

A comprehensive, ecologically driven, neuropsychologically based evaluation should include appraisal of all brain-based *systems* and individualized *contexts*, using a variety of *methods* covering various *sources* and *settings* (see Figure 38.2). Systems are brain-based and include communication/language, personality/behavior, sensory/perception, environmental fit, academic ability, motor functions, and cognitive ability. Information gathered should include data about when the problem or problems do and do not occur. Given these parameters, contemporary neuropsychological assessment should be designed to evaluate a variety of ecologies (Leu & D'Amato, 1994). Additionally, parents, teachers, and students should be consulted to determine for whom the behavior causes concern, what the desired changes are, and how individuals in the environment might facilitate change. Indeed, exploration of how the setting may have to change to accommodate students' needs should be considered. The most critical question we ask teachers is this: "What would you like the students to do that they are not currently doing?" (D'Amato, 1985).

WHAT AREAS SHOULD BE ASSESSED FROM A NEUROPSYCHOLOGICAL PERSPECTIVE?

D'Amato and colleagues (e.g., D'Amato et al., 1999) have long advocated for the importance of all ecologically sensitive neuropsychological evaluations to cover the nine major areas displayed in Table 38.4. These include the following areas: perceptual/sensory functions, motor functions, intelligence/cognitive abilities, executive functioning/attention, memory, communication/language skills, academic achievement, personality/behavior/family, and educational/classroom environment.

When an evaluation of the interaction between a child's characteristics and the instructional environment has been completed, an individualized education program based on the child's strengths as well as needs can be developed. Unlike the deficit model, the ecological neuropsychological approach to understanding how the brain processes information should focus on what the child can do, rather than what he or she cannot do (Hartlage & Telzrow, 1983). Such an approach to learning and educational intervention in general is strengths-based, keeping in mind the old adage "Dead tissue will not learn" (Hartlage & Telzrow, 1983; Riccio, Hynd, Cohen, & Gonzalez, 1993). All intervention should focus on the match between the child

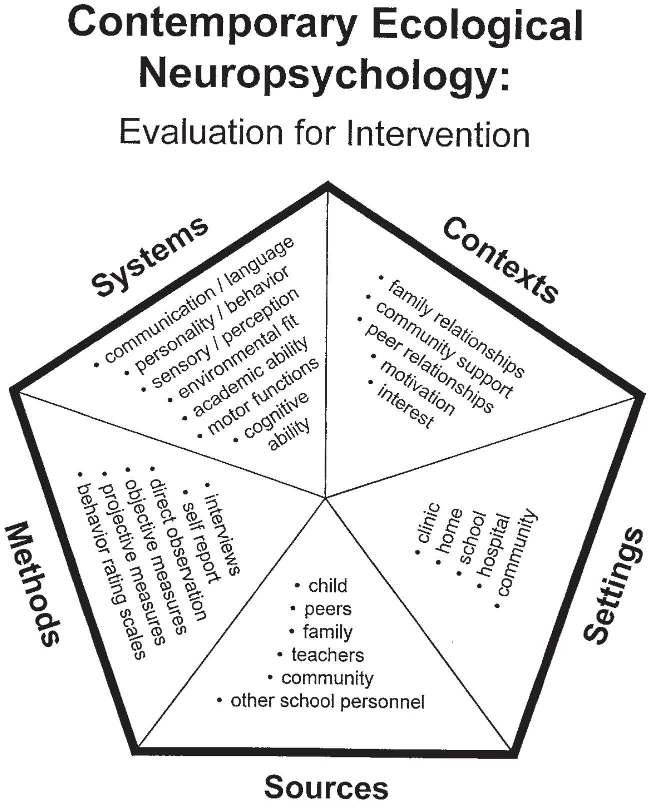

FIGURE 38.2. Components of an ecological neuropsychology evaluation. From D'Amato, Crepeau-Hobson, Huang, and Geil (2005). Copyright © Springer US. Reprinted by permission.

and his or her instructional environment, in addition to providing *remediation* and *compensation* skills for the child (D'Amato & Rothlisberg, 1996; Leu & D'Amato, 1994).

A Learner's Motivation and Neurodevelopment

The identification of a connection between the brain and learning creates the foundation for neuropsychological intervention in teaching and learning in educational settings. As D'Amato and colleagues (1999) have previously stated, offering an EBI should be the intended outcome of any evaluation for a school or university setting. Ornstein and Sobel (1987) have claimed that what a person can learn is also affected and organized by emotions and motivation; that is, the understanding of such aspects of the learner's motivation as attention, relevance, satisfaction, and confidence will determine future learning. Figure 38.3 shows how learner motivation must be understood within the context of attention (A), relevance (R), satisfaction (S), and confidence (C).

Evidence has shown that environmental factors contribute to the growth of the brain as a result of developmental plasticity through numerous activities such as cell death, dendritic branching, pruning, and selecting neuronal connections, just to name a few (Lezak, Howieson, Bigler, & Tranel, 2012; Witsken, D'Amato, & Hartlage, 2008). Furthermore, the neurodevelopment of the brain is influenced by environmental and inherited factors to a considerable degree (Beaumont, 2008; Davis, 2011). This fact also points to the importance of parental involvement during neurodevelopmental years (e.g., reading to toddlers).

Interventions for a student with emotional or learning issues may be directed toward any one area or a combination of the following areas: (1) changing the child (e.g., teaching compensatory or remedial skills); (2) changing the environment (e.g., altering the type of instruction and teaching to the student's strengths); (3) changing the per-

Problem Solving and EBIs in Neuropsychology

Neuropsychological assessment should be an approach to problem solving in which the goal is to provide both direct and indirect services to children to improve their rehabilitation, mental health, and educational development (D'Amato et al., 1999; Traughber & D'Amato, 2005). Therefore, the role of clinical neuropsychologists, school neuropsychologists, and special educators in the schools should be to make observations, formulate theories, generate and test hypotheses, evaluate data, and draw conclusions from empirical evidence about ways to intervene with children who are unsuccessful in their current educational system (Bray & Maykel, 2016a, 2016b; Rothlisberg, D'Amato, & Palencia, 2003; Stoner & Green, 1992). While special educators have been primarily responsible for remediating skills and developing compensatory strategies for students with learning difficulties (Hallahan & Kauffman, 1991), psychologists in the schools have generally been limited to their role as gatekeepers of special education (Ysseldyke, Reynolds, & Weinberg, 1984). As gatekeepers, school psychologists test, diagnose, and place children in special education programs. The focus has not been on individual differences, unique styles of processing, individual data, evidence-based practices, or providing services based on students' needs (Sattler & D'Amato, 2002a, 2002b). An NB-MTSS approach can be used to provide all of these previously discussed emotional and psychological interventions to help children, teachers, and schools find success. The traditional neuropsychological model has been criticized as a model that stressed pathology and labeling, as well as chronicity and permanence, while ignoring psychosocial factors and potential for change in children identified with specific learning difficulties (Gaddes & Edgell, 1994). As demonstrated throughout this chapter, this criticism is inaccurate and unwarranted.

At one of the most basic levels, all practitioners must understand the *content* and the *task* that present problems for the individual student under study. As Luria has stated, the next step should be a contextual analysis of the subject, as well as of how best to teach the content that has not been learned. This procedure should culminate in an understanding of how this student will best neuropsychologically process information for future learning.

BRIDGING THE GAP BETWEEN NEUROPSYCHOLOGY, SCHOOLING, AND SPECIAL EDUCATION

Clinical neuropsychology does pursue what Martens (1992) has referred to as "high-inference attributions" (i.e., "why" questions) about the relationship between atypical brain development and emotional or learning difficulties. These questions are referred to as high-inference because of the functional relationship between brain dysfunction and emotional or learning difficulties. A pediatric neuropsychologist should combine knowledge about brain–behavior relationships with knowledge gleaned from informal sources (i.e., the student, peers, teachers, and parents), in order to develop a complete picture of both biogenetic and psychosocial/environmental factors (D'Amato et al., 1999; Gaddes & Edgell, 1994).

In summary, ecological neuropsychology seeks to provide an *assessment-for-intervention link* rather than an *assessment-to-placement link*. In 2002, an international Future of School Psychology Conference was held in Indiana and resulted in the development of 54 goals grouped under five priority categories (Sheridan & D'Amato, 2003). Significantly, each priority area included an emphasis on *linking assessment to intervention,* as well as on ecological and systems theories in which students are viewed as part of family and school systems within the context of community and culture (Meyers, 2002). The ecological neuropsychology model is consistent with the mission of the conference and provides all psychologists with a framework to utilize in practice (Sheridan & D'Amato, 2003).

Historically, the educational system has sought to confirm diagnostic hypotheses about children, rather than to focus on the appropriate rehabilitation of children (Epps & Tindal, 1987; Traughber & D'Amato, 2005; Ysseldyke, 1987). Within this framework, an attempt to individualize education and seek effective treatment of children's learning problems has not been efficaciously pursued. To counter this movement, the MTSS framework has been instituted to intervene before students begin to fail. That is, this model does not wait for a student to fail before curriculum adaptations are made, and educators are able to offer interventions early, as needed. So, too, intervention outcomes are also documented and evaluated.

The school psychologist's role within MTSS has often been limited to providing small-group or classwide interventions. This circumstance continues to be surprising, since school neuropsychologists have again become one of the largest groups of providers of rehabilitation services for neuropsychologically impaired children and adolescents. Education has continued to change across the years, but what we know about how the brain processes information has not been integrated into the educational enterprise. IDEA is reauthorized from time to time, and it is only during the reauthorization review period that changes to the law can be made. In the review period for IDEA 2004, both the President's Commission on Excellence in Special Education and the Secretary of the U.S. Department of Education eliminated the learning disability discrepancy model from the federal regulations, which has reduced the demand for neuropsychological evaluations in the schools (Cortiella, 2003). While a discrepancy model may still be used, it is much more likely that alternative approaches like MTSS models will be employed. Yet, in more severe cases of students with learning disabilities, neuropsychological evaluations will still be needed. It would seem that we are not using our brain-based knowledge to guide our public education system.

INTEGRATING TRADITIONAL NEUROPSYCHOLOGICAL ASSESSMENT BATTERIES INTO EVALUATION

This section highlights some of the more widely used neuropsychological measures of cognitive, academic, and behavioral functioning. It is important to note that neuropsychology as conceptualized by most of the early pioneers includes an evaluation of each client's full range of human functioning. Hundreds of assessments exist that claim to be neuropsychological measures, and here we only describe some of the major batteries and tests (Davis, 2011). While many view neuropsychological assessments as a set of specific procedures for a clinical psychologist to administer, many commonly used school psychology measures can be interpreted as representing brain–behavior relationships (Rhodes et al., 2008). Some assessments can be used informally (i.e., they can be administered by general and special education teachers in a classroom setting).

A traditional example, and the most commonly used fixed battery, is the Halstead–Reitan Neuropsychological Battery (HRNB; Johnson & D'Amato, 2011). The HRNB was developed to address Halstead's insight that the then-current measures of intelligence did not account for a biogenetic basis of intelligence and failed to link assessments to brain functioning (Davis, Johnson, & D'Amato, 2005). Years later, research indicated that measures of neuropsychological functioning overlapped by a meager 10% with traditional IQ tests; this finding supported Halstead's early theories that these tests failed to capture the full range of human cognitive functioning (D'Amato, Dean, & Rhodes, 1998; D'Amato, Gray, & Dean, 1988; Sattler & D'Amato, 2002a, 2002b). The current HRNB was designed to differentiate patients with and without brain injuries through 10 subtests that are intended to be used as part of a complete battery, including the age-appropriate Wechsler scale and a comprehensive personality assessment measure. Historically, this was the first widely used, and for many years the most popular, neuropsychological battery in the world. Some have argued that the Luria–Nebraska Neuropsychological Battery (LNNB) is the second most commonly used neuropsychological test battery, although it has received quite mixed reviews (Davis et al., 2005).

Two contemporary, unique batteries have become popular recently and are marketed toward school psychologists. These additions include the NEPSY-II and the Dean–Woodcock Sensory–Motor Battery (DWSMB). Although these batteries may be classified as fixed quantitative approaches, they may also be used as part of a flexible battery. The original NEPSY: A Developmental Neuropsychological Assessment was the first to attempt to measure neuropsychological functioning specifically for children using a Lurian approach, rather than slightly modifying or renorming adult measures (Korkman, Kirk, & Kemp, 1998; Titley & D'Amato, 2008). The NEPSY-II, the second edition of the original NEPSY, was designed to assess neuropsychological development in children and adolescents ages 3–16 (Korkman, Kirk, & Kemp, 2007). To suit a variety of diagnostic needs, examiners may select from subtests organized to assess functioning across six domains: (1) Attention and Executive Functioning, (2) Language, (3) Visuospatial Processing, (4) Sensorimotor, (5) Memory and Learning, and (6) Social Perception. The NEPSY-II does not offer scores based on these six domains.

The DWSMB is an important part of the neuropsychological examination (Davis & D'Amato, 2005). This battery was developed to offer normative data related to the traditional neurological (behavioral) examination (Davis, 2011). This measure may be used alone or in conjunction with other psychological assessment tools. Used in this fashion, the DWSMB can provide useful data, including pathognomonic signs of cerebral dysfunction as well as neuropsychological functioning across sensory and motor domains (Davis & D'Amato, 2005).

The KABC-II (Kaufman & Kaufman, 2004) was among the first cognitive measures to be based on Luria's neuropsychological foundation. This measure includes the areas of learning, sequential and simultaneous processing, planning, and knowledge. No student can be understood without an assessment of his or her academic foundational knowledge, and the Kaufman Test of Educational Achievement, Third Edition (KTEA-3; Kaufman & Kaufman, 2014), allows such an analysis based on performance in reading, mathematics, written language, and oral language. Finally, it is critical not to disregard basic skills, which are the building blocks of how the brain processes information. Thus some component of the Dynamic Indicators of Basic Early Literacy Skills (DIBELS) should be included in all initial evaluations (Witsken, Stoeckel, & D'Amato, 2008).

EVIDENCE-BASED NEUROPSYCHOLOGICAL INTERVENTIONS

Given the current legal and educational context, school psychologists must have a working understanding of brain–behavior relationships as well as unique qualities of the educational environment to select EBIs that can be reasonably expected to produce desirable, measurable child outcomes (Traughber & D'Amato, 2005). Developments both within and outside the field of school psychology have encouraged practitioners to use treatment and intervention approaches that have been supported by credible research (Traughber & D'Amato, 2005). One ambitious effort was the creation of the APA Division 16 Task Force on Evidence-Based Interventions in School Psychology. The task force produced a procedural and coding manual containing a comprehensive and rigorous set of criteria for evaluating school-based interventions (Kratochwill & Stoiber, 2002).

However, numerous barriers to implementation of EBIs exist in the practice of school psychology. Kratochwill and Shernoff (2003) have discussed the challenge of promoting EBIs in professional practice. There are a number of groups participating in evaluating literature for EBIs whose various criteria may confound efforts. In addition, the adoption of EBIs into school psychology practice may be hampered by time constraints and limited resources, while some practitioners may follow clinical judgment rather than EBIs. Furthermore, lack of training among psychologists and teachers may prevent the implementation of EBIs in practice.

In addition to promoting EBIs in the field of school psychology, there is a need for shared responsibility, guidelines to support implementation and ensure efficacy, and professional development. Although understanding and applying EBIs to practice remains complex and challenging (especially when related to clinical neuropsychology), this chapter advocates for the use of neuropsychologically based EBIs by means of an MTSS approach (e.g., Traughber & D'Amato, 2005). At the same time, we believe that all practitioners must be reviewing traditional interventions in schools as potential EBIs. Each intervention they carry out should be viewed as a clinical study searching for additional evidence.

How to Measure EBIs

Within the MTSS framework, it is imperative that schools utilize EBIs to address the academic and behavioral needs of children. EBIs are practices that have been proven effective through outcome evaluations. As noted, there is no one encyclopedia or database that lists all EBIs; however, multiple sources, such as the What Works Clearinghouse (WWC; *https://ies.ed.gov/ncee/wwc*) and Kazdin (2011), provide critical features of EBIs that aide in determining effectiveness (Traughber & D'Amato, 2005). According to the WWC, the results of an intervention study can fall into one of three categories: (1) meets WWC standards without reservations, (2) meets WWC standards with reservations, or (3) does not meet WWC standards. In order for a study to meet WWC standards, the study must make clear that it had the following characteristics: groups randomly assigned, low sample attrition, and low/no confounding factors or concerns with outcomes.

The WWC standards have helped to identify many large-scale academic and behavioral interventions for children and youth ages 0–21, as well as school professionals with expertise in these interventions. However, due to the fact that the interventions listed on this website tend to be more expensive and require larger commitments for school districts, it may be more beneficial to refer to criteria such as those listed by Kazdin (2011). According to Kazdin, seven criteria can be used to establish an intervention as evidence-based. Other treatment manuals/coding schemes are reviewed in Traughber and D'Amato (2005).

According to Kazdin (2011), a multitude of disciplines in different countries, organizations, and professional groups see the necessity of EBIs. However, given the fact that not all interventions will meet the standards, it is beneficial to consider the benefits of using a single-case research design.

Using Single-Case Research Designs to Evaluate Neuropsychological Treatment

Single-case research designs allow experimental investigation of one subject (Kazdin, 2011). Single-case designs are used heavily in applied research, such as in schools or physicians' offices; they are used to evaluate programs in settings where typical group designs are not feasible (Kazdin, 2011). Single-case study designs are easily adjusted and altered in response to the child's performance. According to Kennedy (2005), single-case study designs have brought a new source of experimental rigor to the educational setting, have resulted in new and effective strategies for educating children, and have facilitated continued growth into new areas of educational implementation. A single-subject design is ideal for working with children with disabilities through a neuropsychological lens, as well as studying student behavior within the educational setting (Hill, 2015). In addition to their utility within applied settings, single-case research designs have played a significant role in elaborating relationships between the brain and behavior (Kazdin, 2011).

Specifically, a single-case study design allows experimental investigation of one subject (Kazdin, 2011) and involves repeated, systematic variables before, during, and after the introduction of an independent variable (Kratochwill et al., 2010). Thus a single-case study design often develops hypotheses about human behavior, serves as a source for developing intervention techniques, permits the study of unique and rare phenomena, provides a counterinstance of ideas that are considered universal, and has persuasive and motivational value (Kazdin, 2011).

We strongly encourage all doctoral students to consider dissertations that review neuropsychologically driven single-case EBIs. Almost two dozen such dissertations are available from our institution, and three studies are highlighted here to show how unique school neuropsychological participants can be matched with EBIs to demonstrate important results. In our first example, Sands, Fischer, and D'Amato (2016) explored the neuropsychological functioning of a 14-year-old male with comorbid Tourette syndrome and a generalized anxiety disorder. Results of the participant's neuropsychological evaluation were utilized to adapt and implement EBIs, which included cognitive-behavioral therapy (CBT) and the Breathe2Relax application, a stress management tool used for diaphragmatic breathing developed by the National Center for Telehealth. Breathe2Relax can be used in isolation as a stress reduction tool, or in combination with treatment by a health care professional. Results indicated that the participant demonstrated a decrease in anxiety during treatment and posttreatment conditions, as evidenced by self-report ($r = -.90$, slope $= .1021$, $p \leq .001$) and one teacher's standardized rating. This study was based on a dissertation by Fischer (2015).

We (Power, Hill, D'Amato, & Losoff, 2016) used a neuropsychological approach to intervene with a 15-year-old Hispanic male who was receiving special education services through meeting IDEA 2004 eligibility criteria for autism and an intellectual disability. The purpose of this study was to determine the effectiveness of Social Stories™ in increasing the frequency of eye contact, the knowledge of eye contact, and the social-emotional reciprocity of the participant. The results indicated that Social Stories was significantly effective in increasing the frequency of eye contact and knowledge of eye contact, but did not improve underlying neuropsychological deficits such as social-emotional reciprocity. This work is based on a dissertation by Hill (2015).

Skierkiewicz and D'Amato (2017) analyzed data from a single case to evaluate the effectiveness of CBT in reducing anxiety symptoms in a male child who had experienced sexual trauma. This study incorporated manualized CBT principles with neuropsychological theory, which allowed for an analysis of the intersection between behavioral principles and brain–behavior relationships. This study evaluated the effectiveness of Coping CAT, an intervention designed to reduce anxiety in elementary-age children, over the course of 14 individual sessions. Findings were mixed, suggesting continuation of this line of research, but resulting in more than 14 individualized suggestions for future research. This study was based on a dissertation by Skierkiewicz (2016).

Using an NB-MTSS Model

It seems important to offer a multi-tiered approach to providing services and interventions to struggling students at increasing levels of intensity. NB-MTSS can provide academic and behavioral screening with valid assessment measures and ongoing monitoring if improvement has not been made (Semrud-Clikeman, 2005). An NB-MTSS model can be used to help students improve in most academic and behavioral areas. Although reading is a primary focus in this section, other academic areas that should also be evaluated as part of an NB-MTSS model are presented in Table 38.5.

Using an NB-MTSS model will provide a valid evaluation of a child's ability to learn. To understand and predict educational outcomes, a child's ability to process language, comprehend what is heard, and organize and use information will need to be assessed. Semrud-Clikeman (2005) has argued that it is typical for current MTSS models to neglect neuropsychological variables by focusing on the curriculum in isolation. Although both a traditional MTSS model and an NB-MTSS model focus on data from the regular education cur-

[a] Can be measured via classroom-focused, curriculum-related assessments or the DIBELS (usually tier 1).

[b] Can be measured via standardized academic assessments (usually tier 2).

[c] Can be evaluated via psychological or neuropsychological examinations (usually tier 3).

riculum, the NB-MTSS model analyzes *why* skill weaknesses exist and evaluates the specific brain-based abilities that are needed for those specific skills. In the usual MTSS model, most summaries of student data (e.g., words pronounced correctly) are couched in terms of skill deficits, whereas the neuropsychological approach focuses on processing both strengths and weaknesses. It is important to ask how a student may best learn by using appropriate processing strengths with a focus on working around the observed processing weakness. A standard curriculum analysis does not offer information on the student's ability to generalize learning or to complete more inferential or abstract tasks, a potential problem as children grow older. Thus an NB-MTSS evaluation should consist of an assessment of specific neuropsychological processes (e.g., attention/executive functions, short-/long-term memory), as well as standardized information from the curriculum. During the initial weeks of school, screening should be completed for all children using data collected from the regular education curriculum. Most tier 1 students who display problems in learning will most likely display no neurological impairment (Lyon, Fletcher, & Barnes, 2003).

At the completion of screening, children's strengths and needs should be identified so that they can be grouped according to neuropsychological abilities. Targeted interventions can then be offered in reading groups with instructional measures that are related to reading abilities. Progress monitoring should take place every 2 weeks. If students continue to display significant difficulties after monitoring, teachers are asked to make instructional modifications and to document these reading interventions. At the completion of 6 weeks of monitoring, children who have been identified within the program as not making adequate progress should be identified and recommended for an NB-MTSS tier 2 service evaluation. Decisions concerning the need for additional services should be based on students' responses to additional EBIs (Lyon et al., 2003; Traughber & D'Amato, 2005).

A slightly different approach to providing services to students in tiers 1 and 2 has been detailed by Semrud-Clikeman (2005). Her model indicates that it is important to evaluate the needs of students so that the services offered are sure to succeed. Thus she has suggested that students screened at tier 1 who display extremely significant discrepancies (e.g., more than one standard deviation but less than two standard deviations below expectations) should move directly into a tier 2 intervention. Table 38.6 presents measures that can be used at all levels, in all areas, by all school personnel.

Tier 1 Services

We are proposing a three-tiered NB-MTSS model. In this model, tier 1 offers specialized neuropsychological screening at the beginning of first grade for all children. The majority of tier 1 screening takes place using classroom-based or curriculum-focused qualitative measures (e.g., phonemic awareness, vocabulary, reading comprehension). These measures are usually administered to students by classroom teachers. Specifically, a screening at this level based on a neuropsychological approach includes measures tapping phonological access and retrieval (see Table 38.6 for sample tasks). Another area supported by research that may need to be screened at this level (and is typically absent from traditional MTSS screening measures) is that of oral language skills (e.g., oral vocabulary, listening comprehension).

We recognize that research has not yet delineated how to match students' unique learning needs with appropriate levels of intervention. Some researchers have advocated for moving students to a level based on the magnitude of the students' impairment (e.g., two standard deviations below the mean), whereas others support determining intervention intensity based on students' outcomes following intervention (e.g., failure to demonstrate improvement following two interventions). However, research indicates that students who present with severe learning challenges (e.g., a suspected traumatic brain injury or cognitive disability) may warrant immediate referral to tier 3, which is the completion of a comprehensive neuropsychological evaluation.

Tier 2 Services

Individuals who have been identified at tier 1 but have not benefited from targeted interventions from the regular education teacher should be referred for a tier 2 evaluation. Tier 2 evaluations are conducted by the special education teacher or school psychologist, who works in concert with the regular education teacher to collect information from the student and classroom. Typically, a mixture of qualitative and quantitative data is collect-

ed again, with a focus on classroom-linked, curriculum-related measures. Tier 2 evaluations build on the areas that have been evaluated in tier 1. At tier 2, more neuropsychological data (see Table 38.6) will be collected to help understand why the student has not demonstrated improvement following specialized instructional interventions. Semrud-Clikeman (2005) has called for the evaluation of neuropsychological constructs such as working memory, attention, executive functioning, processing speed, and auditory processing ability. Screening children on neuropsychological variables that predict instructional success will help to identify those children who are at risk of not responding to an intervention later in the school year.

Tier 2 interventions will incorporate small-group EBIs tailored to the student's individual needs. Students not responding to the prescribed interventions will be assessed using more comprehensive measures of various neuropsychological constructs to determine why they are not responding to appropriate interventions. Again, any child performing more than one standard deviation below expectations should be closely monitored, and children scoring two standard deviations below expectations should be referred directly to tier 3 for a comprehensive neuropsychological evaluation.

Subsequent to the tier 3 evaluation, practitioners should be able to identify effective interventions for most students. Before this point, comprehensive neuropsychological assessment should generally be unnecessary. A neuropsychological evaluation does become appropriate, however, when school-related problems are not only resistant to intervention but also continue to defy standard analysis. When uncertainty regarding the nature of and solutions to individuals' problems persists, and little or no progress is made, a neuropsychological evaluation can generate unique hypotheses and help resolve the question of how best to intervene (D'Amato et al., 1999).

Tier 3 Services

Students can progress to a tier 3 evaluation in three different ways: (1) Students who have completed interventions in tiers 1 and 2 but have not made adequate progress are automatically referred to tier 3; (2) students displaying significant disabilities (e.g., cognitive problems, emotional problems, suspected autism) when assessed at tier 1 should be sent directly to tier 3; and (3) students who perform more than two standard deviations below expectations on the measures used to collect information about various neuropsychological constructs should also be referred to tier 3. At tier 3, students complete a wide-range neuropsychological evaluation as detailed in Table 38.6, as well as additional evaluations from other school team members (e.g., speech, physical, and/or occupational therapy) as needed. If a student qualifies for special education services, an individualized education program is developed, and services are provided to the student. If the student does not qualify for special education services after all evaluations are completed, the student moves back to tier 2 to receive additional evidence-based, curriculum-focused instructional interventions. The NB-MTSS model is unique in that neuropsychological knowledge, skills, and processes drive the special education service model and link neuropsychological processing to the classroom curriculum.

There is a serious, dramatic shortage of brain-driven EBIs that can be utilized in the schools. The global need for school psychologists to have additional training in neuropsychology has been repeatedly discussed within this chapter. This training will provide school psychologists with detailed knowledge of brain–learner–environment interactions, which will be instrumental in developing EBIs that are linked to the individual needs of students. School neuropsychology should no longer be viewed as a wave of the future. It is part of a new *Zeitgeist* in education and psychology that will only bring about positive changes in the educational enterprise and related fields that serve children, youth, teachers, and parents.

CHAPTER 39

Intellectual, Cognitive, and Neuropsychological Assessment in Three-Tiered Service Delivery Systems in Schools

George McCloskey
Jaime Slonim
Deanna Rumohr

From our perspective, intelligence test performance can be interpreted on multiple levels, with each successive level of interpretation representing a greater degree of aggregation and narrowing of the information available for interpretation. As illustrated in Figure 39.1, interpretive levels from bottom to top consist of the task-specific cognitive constructs involved in the performance of each item; the set of item scores of each subtest; the set of subtest scores; the set of specific composite scores; and the global composite score. Each aggregated level of interpretation within the framework masks clinical information that is potentially important to understanding a child's specific pattern of cognitive strengths and weaknesses. Additionally, we believe that two major conceptual perspectives influence contemporary intellectual assessment in the schools; we refer to these here as the *general abilities model* and the *cognitive neuropsychological model.* Each model emphasizes different levels of test interpretation. As shown in Figure 39.1, the general abilities model emphasizes interpretation of a global composite score and/or a set of specific composite scores (e.g., the Full Scale IQ [FSIQ] and the primary index scores of the Wechsler Intelligence Scale for Children—Fifth Edition [WISC-V]). In contrast, the cognitive neuropsychological model primarily emphasizes interpretation at the levels of subtests, items, and task-specific cognitive constructs, with attention to the specific composite level when such composites represent meaningful clinical clusters (Kamphaus, 2001; Reynolds & French, 2005). Meaningful clinical clusters may or may not be aligned with the composites that test developers identify through the use of factor-analytic techniques. In this chapter, the utility of these two models is discussed, with particular emphasis on the extent to which each model does or does not influence assessment at different service delivery tiers, and how each model can or cannot be integrated within the broader context of a three-tiered service delivery model.

The general abilities model is a traditional approach that has been in use since the inception of the intelligence test early in the 20th century (Jensen, 1998; Sarason, 1975). Proponents of the general abilities model often gravitate to the construct of *g* (Spearman, 1904) to explain the importance of assessing general ability (Deary, 2001; Gottfredson, 1997, 1998, 2008; Jensen, 1980, 1998; Kamphaus, Winsor, Rowe, & Kim, 2005; Kuncel, Hezlet, & Ones, 2004; McDermott & Glutting, 1997). Over time, *g* has come to be viewed as the quintessential indicator of overall intellectual ability. It is conceptualized as a stable trait that is

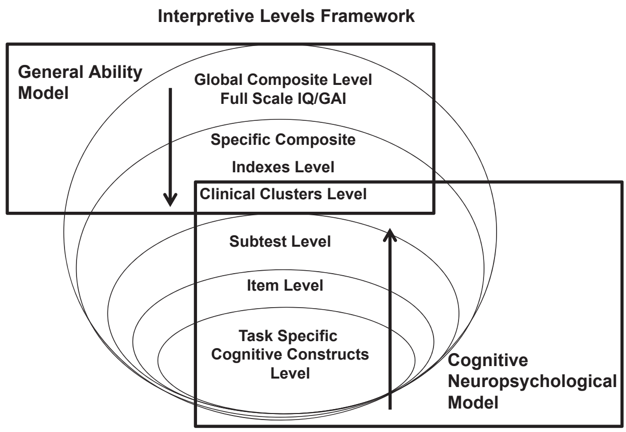

FIGURE 39.1. Interpretive levels coinciding with interpretive models.

not easily modified by educational or environmental interventions (Gottfredson, 1997, 1998, 2008; Jensen, 1998).

The general abilities model has guided the development of the intelligence tests currently available for use with school-age children, including the WISC-V (Wechsler, 2014), the Stanford–Binet Intelligence Scales, Fifth Edition (SB-5; Roid, 2003), the Differential Ability Scales—Second Edition (DAS-II; Elliott, 2007), the Kaufman Assessment Battery for Children—Second Edition (KABC-II; Kaufman & Kaufman, 2004), the Woodcock–Johnson IV Tests of Cognitive Abilities (WJ IV COG; Schrank, McGrew, & Mather, 2014), and several others. A general factor tends to emerge in analyses of subtest score data and is found in almost all intelligence tests that tap into a cognitively complex array of abilities (Saklofske, Prifitera, Weiss, Rolfhus, & Zhu, 2005). The conception of a learning disability as a condition wherein a student's intellectual capacity is significantly greater than the student's academic achievement (i.e., an ability–achievement discrepancy) stems directly from the rationale underlying the general abilities model (Bradley, Danielson, & Hallahan, 2002; Kavale, 2002; Sternberg, Grigorenko, & Bundy, 2001).

More recently, a cognitive neuropsychological perspective has emerged from the basic conceptions embodied in the fields of clinical neuropsychology and cognitive neuroscience. Cognitive neuroscience findings, including those gleaned from functional magnetic resonance imaging studies, have been applied to neuropsychology and have led to advances in the understanding of how children learn and produce academically (Berninger, 1994; Berninger & Richards, 2002; Posner & Rothbart, 2007). Several researchers and clinicians have applied this knowledge to reconceptualize the general methods used in assessment and intervention in educational settings, including approaches to intellectual assessment (Berninger, 1994; Berninger & Richards, 2002; Hale & Fiorello, 2004; Kaplan, Fein, Morris, Kramer, & Delis, 1999; Levine, 1998; Mapou & Spector, 1995; McCloskey, 2009a, 2009b; Miller, 2007; Pennington, 2009; Reynolds & Fletcher-Janzen, 1997; Sattler & D'Amato, 2002; Temple, 1997) and to generate specific cognitive neuropsychological models (Hale & Fiorello, 2004; Levine, 1998; McCloskey, 2009a; McCloskey & Perkins, 2012; McCloskey, Perkins, & VanDivner, 2009; McCloskey, Slonim, Whitaker, Kaufman, & Nagoshi, 2017).

The general abilities model has been articulated in this text and elsewhere (Gottfredson, 1997, 1998, 2008; Kamphaus et al., 2005) as a viable approach to conceptualizing intelligence and as a method of assessment with clinical utility within educational settings. The argument for the viability and clinical utility of a cognitive neuropsychological model has also been expressed in different sources (Allen, Hulac, & D'Amato, 2005; Berninger & Richards, 2002; Hale & Fiorello, 2004; Hale & Miller, 2008; Hale et al., 2008; Kaplan et al., 1999; McCloskey, 2009a, 2009b; McCloskey et al., 2017; Miller, 2007), but further refinements in the articulation of such a model are needed in order for the benefits of this approach to be fully recognized in educational settings. In this chapter, we outline and refine the cognitive neuropsychological model and contrast its use with the general abilities model within the context of the three-tier service delivery system currently used in U.S. schools.

A COGNITIVE NEUROPSYCHOLOGICAL MODEL OF ASSESSMENT

Within a neuropsychological model of cognition, brain function can be defined and assessed by using a set of psychological constructs. These cognitive constructs represent patterns of neural activation within various cortical and subcortical regions of the brain that are involved in the production of perception, thought, action, and the cognitive aspects of emotion (Berninger, 1994; Berninger & Richards, 2002; Dehaene, 2009, 2011; Levine, 1998; Mapou & Spector, 1995; McCloskey, 2009a; McCloskey et al., 2017; Willis, 2005). Assessment of cognition requires the understanding and use of the following specific cognitive constructs, the definitions of which are provided in Box 39.1: *processes*, *abilities*, *knowledge bases*, *skills*, *executive functions*, *strategies*, and *memory time frames of reference* (*initial registration*, *working memory*, and *long-term storage*). Additional terms defined in Box 39.1 that are critical for understanding the interaction of cognitive constructs include *sensory processing*, *motor functioning*, *processing speed*, *learning*, and *achievement*.

BOX 39.1. Operational Definitions within a Cognitive Neuropsychological Model of Assessment

Processes

Processes are narrow-band cognitive constructs responsible for the organization of input leading to the creation of basic mental representations. Processes thereby provide the basic elements of conscious thought used for academic learning and production, and serve as the springboard for academic skill development. Process deficits can impede learning and production, but often can be bypassed or compensated for (at least to some degree) because of their relatively restricted range of operation. For example, students who have difficulty perceiving and discriminating subword sound units can learn how to decode words and read, despite the phoneme discrimination difficulties that result from this highly specific auditory process deficit (Torgesen et al., 1999). In some instances, the effects of process deficits can be significantly reduced if the deficits are addressed during early developmental stages with a good intervention program (e.g., phonemic awareness training for difficulties with subword sound unit discrimination). In these cases, the process deficit may have been due more to underutilization or lack of maturation of intact neural networks than to the presence of damaged neural interconnections. In such cases, early instruction increases the frequency and effectiveness of the use of the process (McCloskey, 2009b). It is possible that basic process deficits resulting from damage to neural networks can be remediated through early childhood intervention as well (McCloskey, 2009b).

Severe basic process deficits can result in learning disabilities involving slowed and/or inconsistent learning and production. Basic processes underlying skill development in one or more academic domains include the following:

- Auditory perception
- Auditory discrimination
- Auditory attention
- Visual perception
- Visual discrimination
- Visual attention
- Kinesthetic perception
- Kinesthetic discrimination
- Kinesthetic attention

Processing

The term *processing* refers to neural activity that involves the coordinated use of one or more processes, almost always in conjunction with the accessing of one or more knowledge bases (described below) and typically under the direction of one or more executive functions (described below). Because of the manner in which processes are involved in creating mental representations, it is not possible to isolate and measure processes without some involvement from other cognitive constructs. *Processing* therefore refers not only to the integrated process of creating mental representations, but also to the tasks used to assess the effectiveness of processes during the act of creating mental representations.

(continued)

Basic Motor Functions

Basic motor functions are the fine motor capacities used in the performance of cognitive assessment tasks. All intellectual and cognitive assessment tasks require some form of motor output in order for the adequacy of task performance to be judged. Variations in the adequacy of motor functioning are important to observe and quantify, in order to understand how strengths or weaknesses in motor functioning may be enhancing or impeding learning of academic skills and production with academic tasks.

Processing Speed and Basic Motor Functioning Speed

The term *processing speed* refers to the speed with which one or more processes can be coordinated and applied in the formation of mental representations, often in conjunction with the accessing of knowledge bases and typically under the direction of one or more executive functions. For all processing speed assessment tasks, processing speed is combined with some form of basic motor function, in order to have an output that can be judged for adequacy of task performance. As a result, all measures of processing speed are also measures of basic motor functioning speed.

Abilities

Abilities are broad-band cognitive capacities that operate on the mental representations initially formed through cognitive processing. Abilities enable extended formulation and use of mental representations during learning and production. They include such integral constructs of thought as receptive and expressive language, complex visual–spatial representation and visualization, reasoning with language, reasoning with visual–spatial representations, reasoning with quantity, and idea generation.

Unlike process deficits, which can be bypassed or compensated for, ability deficits constrain learning and production. In other words, the degree of ability deficit places an upper limit on the quality (i.e., depth and complexity) of learning and production. Given the broad-based effects of ability deficits, compensatory or bypass strategies are typically not very effective in countering ability deficits within relatively short periods of time (McCloskey, 2009b). Severe ability deficits therefore result in cognitive impairments that greatly constrain learning and production, possibly throughout an individual's lifetime (e.g., severe language impairment, severe visual–spatial impairment, severe reasoning impairment, intellectual disability).

It should be noted that the word *ability* also often is used to denote the adequacy of a person's use of any or all cognitive constructs, as in "He has the ability to process phonemes," "She demonstrated the ability to retrieve information from long-term storage," or "He demonstrated the ability to decode words." As is clear from these examples, the use of the word in this sense indicates the individual's facility with the use of the specific cognitive constructs mentioned, rather than indicating the use of a specific cognitive construct that has been operationally defined as an ability. Use of the word *ability* as a term that can be applied to all cognitive constructs results in redundancy when one is discussing specific abilities, as in "He demonstrated the ability to use reasoning abilities."

Knowledge Bases

Knowledge bases are built up gradually through the storage of information during learning and skill acquisition. Once established, a knowledge base can be accessed for retrieval of information that can be used in conjunction with processes to form mental representations and to inform new learning or production. Knowledge bases can range from very basic, narrow forms of knowledge (e.g., the separate phonemes of the English language; how light strikes objects and creates shadows) to very complex forms of knowledge that vary greatly in depth and breadth (e.g., how to factor a polynomial; how to put a car engine [specific make and model] together; the influences of 18th-century classical composers on the early development of rock and roll).

Skills (Basic, Complex, Domain-Specific)

Skills are "knowledge bases under construction" that are acquired through formal or informal educational experiences. The term *skill* can be used in a temporal sense to represent what is being learned in the present

(continued)

moment, to represent what was learned in the past, or to represent what will be learned in the future. The set of skills to be taught often determines the content of instructional lessons. Skills can be further delineated by content as *basic*, *complex*, or *domain-specific*.

Basic Skills

Basic skills are the skills that form the foundation for all additional skill acquisition. The four broad basic skill domains are oral communication (listening and speaking), reading, writing, and mathematics. Each of these basic skill domains consists of many subdomains or subskills:

- Basic oral communication skills include reflective listening, diction and projection of voice, prosody, and rapid speech production.
- Basic reading skills include sight word recognition, phonological awareness, word decoding, and rapid word recognition.
- Basic writing skills include graphomotor letter, number and word formation and copying; word spelling; written sentence structure and formation; and rapid text production.
- Basic mathematics skills include computation procedures, basic quantity problem solutions, and rapid application of computation procedures.

Basic skills are the foci of instruction and learning in early elementary school. Basic skill learning represents the building of a set of general knowledge bases that will enable the application of oral communication, reading, writing, and mathematics to a wide range of subject content areas and to the learning of more complex skills. Skill building is an intermediate state between the immediate experiencing of new information and the retrieval of information from an established knowledge base. Skills that have been mastered form distinct knowledge bases. *Automaticity* refers to the speed with which basic skill knowledge bases can be accessed, and the ease with which information can be retrieved from the knowledge base and then applied.

Basic skill learning and use relies heavily on effective processing of auditory, visual, and kinesthetic stimuli taken in from the educational environment. Process deficits, therefore, can have a significant negative impact on skill acquisition and use.

Basic skill learning and acquisition also rely heavily on the use of multiple executive functions to cue and direct new learning and the construction of a new knowledge base. Basic skill learning, therefore, is likely to be disrupted when executive function deficits are present.

Complex Skills

Complex skills are oral communication, reading, writing, and mathematics skills that enable a person to take the mental representations formed through the use of basic skills, add new layers of representation, and manipulate all the information to produce relatively complex levels of meaning. Complex skills include extended listening and/or speaking for meaning, reading comprehension, extended written text generation, and applied mathematics problem solving.

Complex skill development and use involves the application of one or more basic skills integrated with the use of one or more abilities and the accessing of one or more knowledge bases, all under the direction of multiple executive functions. For example, the skill of complex reading comprehension requires the application of the basic skills of word recognition and/or decoding and reading rate to formulate an accurate basic mental representation of the information on the page. The more complex the grammatical structure of the material that was read, the greater the need for involvement of specific language abilities to enable meaningful representation at a deeper level. If the material being read relates to a specific topic, knowledge bases representing that person's knowledge of the topic will need to be accessed, along with language ability to provide a context for what was read. If the ideas represented by the words are complex, reasoning abilities will need to be engaged to obtain the highest level of meaning possible from the material. The application of these skills, knowledge bases, and abilities requires extensive use of executive functions to coordinate the multitasking that must take place during such complex reading comprehension. In addition to the use of multiple basic skills, knowledge bases, and abilities, application of complex skills very often requires the direction and use of working memory capacities (described below).

Complex skills are the foci of instruction and learning in the upper elementary grades.

(continued)

The development and use of complex skills can be disrupted by inadequate development of, or inadequate use of, basic skills (resulting from the effects of process deficits or lack of direct instruction); by insufficient storage of information in knowledge bases; by constraints imposed by inadequate or underdeveloped abilities; by constraints imposed by inadequate or underutilized working memory capacity; and/or by constraints imposed by inadequate or underutilized executive functions.

Domain-Specific Skills

Domain-specific skills are skills that are developed in specific subject domains and subdomains (e.g., the domain of science and the subdomains of biology, chemistry, and physics). Although basic and complex skills may be involved in learning in these content domains, the skills that are the foci of learning involve the building of knowledge bases related to the specific area of knowledge. The link between learning and knowledge base building in these content areas is apparent in the language used to denote course and learning objectives. Educators speak of increasing a student's knowledge of biology, rather than of increasing or building a student's biology skills. Despite the emphasis on specific content knowledge storage and retrieval, other knowledge bases are acquired (e.g., how to use biology or chemistry laboratory equipment) that are more readily perceived as skills.

Strategies

Strategies are learned and stored or newly generated routines that can be applied to increase an individual's efficiency of learning and/or production. Strategies are ways to chain together in a specific order a combination of processes, abilities, skills, and knowledge retrieved from knowledge bases to enhance learning and production. Strategies also involve the use of executive functions to sequentially or simultaneously cue and direct the use of the cognitive constructs involved in the strategy. Like skills, strategies can be taught and learned in formal or informal educational settings, or can be self-taught. Strategy development, storage, and use are all cued internally by executive functions or by an external mediating source, such as a teacher or a parent.

Executive Functions

Executive functions are a unique category of cognitive constructs defined by their directive role. Executive functions cue and direct the use of other cognitive constructs and coordinate multitasking efforts. They can be used to guide all cognitive constructs in all aspects of mental activity. They are not the processes, abilities, knowledge bases, skills, strategies, or memory states, but rather the cognitive constructs that orchestrate the use of all of these other cognitive constructs—cueing, directing, and coordinating all other elements of thought to produce coherent learning and production. Although executive functions are intricately involved in learning, the teaching process can mediate or substitute for students' inadequate use of executive functions. Executive function deficits are most noticeable in situations requiring independent or unsupervised production.

Memory: Time-Referenced States of Cognitive Functioning

Memory is very different from the other cognitive constructs discussed because different forms of memory actually represent different temporal states of mind in which a person may be using any number of processes, abilities, knowledge bases, skills, or strategies. Memory states are the mind's manifestations of time and space, providing the temporal and spatial contexts—a time signature—for all perception, emotion, cognition, and action.

The three major time-related memory states are these:

- Initial registration of information in the immediate moment: The experience of "now."
- Retrieval from long-term storage: Going back in time to recall previous "immediate" moments.
- Holding and manipulating information in mind: Extending the immediate moment into the future, projecting possible immediate moments into the future, or creating scenarios for future immediate moments.

These memory states enable a person to have a psychological sense of now (immediate

(continued)

memory or initial registration of stimuli), the past (retrieval from long-term storage), and the future (holding and manipulating mental representations beyond the immediate moment, or projecting mental activity various distances beyond the immediate moment).

Memory cannot be experienced or assessed outside the context of one or more processes, abilities, knowledge bases, skills, or strategies. What defines a memory state is what a person is doing at any given point in time.

A *memory deficit* is inadequate use of one or more cognitive constructs within a specific time frame. A person with poor immediate memory has difficulty effectively using processes and knowledge bases to initially register and briefly hold stimuli in mind. A person with long-term retrieval problems has difficulty accessing information stored in knowledge bases. A person with working memory problems has difficulty effectively applying abilities, knowledge bases, skills, or strategies to manipulate information being held in mind.

Although memory deficits are similar to ability deficits, in that both types can have a broad-based impact on learning and production, they are also similar to process deficits, in that memory state deficiencies often can be bypassed or compensated for (at least to some degree).

Lack of memory capacity can greatly obstruct learning and production:

- Poor initial registration constrains how much information can be represented in mind at one time.
- Poor retrieval capacity limits access to knowledge bases.
- Poor working memory capacity constrains how much information can be held in mind, how long that information can be held, and the extent to which the information being held in mind can be manipulated to enable extended states of learning, problem solving, and production.

Learning

Learning is the building of new knowledge bases. Whereas simple learning involves building a knowledge base through basic skill acquisition, complex learning occurs through the use of processes, skills, and strategies along with the accessing of knowledge bases and the application of abilities to create a new knowledge base or to link multiple knowledge bases for greater ease of strategy use. Learning can occur on a continuum from being mediated extensively by others to being self-mediated. The greater the self-mediation, the greater the demand for executive function involvement in the learning process.

Production

Production is the observable motor output or the unobservable mental output resulting from attempts to use processes, skills, and strategies; access knowledge bases; and apply abilities and executive functions to perform a task.

Achievement

Like production, *achievement* is the end result (the product) of the use of processes, skills and strategies; accessing of knowledge bases; and the application of abilities to perform a task. Assessment of achievement, therefore, often is not simply a matter of assessing skill development (basic, complex, or domain-specific). *Production* is typically referred to as *achievement* in formal educational settings, where production is directed at meeting specific academic goals related in some way to skill development.

Category Boundaries

It is important to note that the boundaries of these categories are somewhat amorphous and changeable. At least theoretically, processes, abilities, and executive functions can be taught and learned, thereby becoming skills. Skills can be stored, retrieved, and applied in the immediate moment, making them knowledge bases. The interrelated and overlapping nature of the category definitions, however, should not deter clinicians from making the important distinctions represented by each of these categories.

The cognitive neuropsychological model described in this chapter necessitates a more careful use of many terms that are frequently associated with intellectual assessment. Intellectual capacities have often been described in terms of *abilities*, *processes*, and *skills*, but these terms are typically used interchangeably in discussions of intelligence and in psychological reports describing the results of an intellectual assessment. In the model described herein, the terms ability, process, and skill have distinct, noninterchangeable definitions, and each represents a critical component of cognition. In addition to these three core terms, the role of the more recently introduced concept of *executive functions* is defined, and the more traditional but highly ambiguous constructs of *memory*, *achievement*, *learning*, and *strategy* (and the more generalized meaning of the term *ability*) are clarified. As explained in Box 39.1, effective application of tests of cognition requires not just an understanding of the distinctions among the various categories of cognitive constructs, but also an understanding of how the components of cognition interrelate during the occurrence of learning and production (Floyd, 2005; Saklofske et al., 2005). Figures 39.2–39.5 are conceptual diagrams applying the cognitive neuropsychological model to the primary academic domains of oral language, reading, writing, and math, respectively. These diagrams offer static representations of the cognitive constructs involved in listening/speaking, reading, writing and solving math problems. The brief narrative in Box 39.2 offers a description of the dynamic flow of information and the interplay of the cognitive constructs in Figure 39.3 as they are used in reading.

COMPARING THE TWO MODELS IN SCHOOL-BASED ASSESSMENT

In educational settings, the general abilities model is used to interpret intelligence test performance from the perspective of predicting later academic success (Gottfredson, 1997, 1998, 2008; Sternberg et al., 2001; Weinberg, 1989). From this model's perspective, intellectual assessments are conducted because the results can effectively predict academic achievement, and can therefore be used to identify learning disabilities by distinguishing a child who has the capacity to achieve academically from a child who does not have this capacity (Kavale, 2002; Mather & Wendling, 2005; Sternberg et al., 2001). We have been able to apply the general abilities model of interpretation to individ-

ual case results to help convince parents, teachers, and administrators that particular students have more academic potential than previously thought, as indicated by the relatively high general ability scores obtained by these students. We also have been able to apply this model to convince parents, teachers, and administrators of the substantial educational challenges faced by children with limited cognitive resources, as indicated by these students' extremely low general ability scores.

The limitations of the traditional general abilities model become apparent, however, when professionals who administer intelligence tests are considerably more interested in actively helping a child improve his or her academic achievement than in passively reporting current levels of ability in order to predict future levels of academic achievement. When the purpose of assessment is reconceptualized in an effort to characterize a student's pattern of cognitive strengths and weaknesses, to understand how these strengths and weaknesses will affect learning and production, and to understand how instruction can be modified to improve learning and production, the general abilities model falls short. This model also falls short in light of research suggesting that children with learning disabilities are more likely to demonstrate varied than consistent cognitive capacity profiles at the subtest level (Fiorello, Hale, McGrath, Ryan, & Quinn, 2001; Fiorello et al., 2007; Flanagan, Alfonso, Ortiz, & Dynda, 2010; Fletcher-Jansen, 2005; Hale & Fiorello, 2004; Miller, 2007). In cases such as this, global composite level interpretation can mask clinically meaningful information and lead to inaccurate characterizations of cognitive constructs (Hale & Miller, 2008; Hale et al., 2008; Kaplan, 1988; Kaplan et al, 1999; McCloskey, 2009a, 2009b; McCloskey & Maerlender, 2005).

One thing that should be clear from Figures 39.2–39.5 and the discussion of the cognitive neuropsychological model applied to the various academic domains is that listening, speaking, reading, writing, and mathematical thinking are extremely complex in nature. Given the multifaceted nature of all these domains, it is not surprising that diagnostic assessment is a complicated endeavor that requires the use of specialized assessment instrumentation rather than the use of a single intelligence test (even one with multiple subtests) in order to identify the potential cognitive deficits underlying problems in each domain. In cases

BOX 39.2. The Dynamic Interplay of Cognitive Constructs during Reading

Reading does not start with the words on the page. Rather, reading starts in the brain with the accessing of knowledge bases containing what we already know about how to read—that is, our knowledge of how words sound when they are said and what they look like in print. In young children new to reading, these knowledge bases are built up through prereading instruction in phonemic awareness, orthographic awareness, and language experience activities (Berninger & Richards, 2002; Dehaene, 2009; Posner & Rothbart, 2007; Shaywitz, 2003; Uhry & Clark, 2005). Once we are engaged with words in print, these knowledge bases must be accessed and used in conjunction with sensory processes that enable us to see the words on the page (visual processes involved in perceiving and discriminating the shapes on the page in order to create visual mental representations of words) and to hear ourselves say the words (auditory processes involved in perceiving and discriminating the phonemes and syllables in order to create the pronunciations of the words on the page), as well as with basic motor routines that enable us to orally or subvocally say the words. If the orthographic and phonological awareness knowledge bases have been constructed, and the basic processes and motor capacities are in place, these can be used during the instructional process to learn and store new words (sight recognition skills), to analyze and sound out unfamiliar words (decoding skills), and to learn to perform both of these tasks quickly and efficiently (fluency skills). It is important to note that the goal of learning these skills is to enable readers to build part- and whole-word pronunciation knowledge bases, so that they can apply them independently to read any word they encounter in a text.

Quick and efficient recognition of the words in print, however, is only the first stage of reading. Additional cognitive constructs must be used to link the words being read with their individual meaning, and to link the meaning of each word with every other word in a sentence to grasp the meaning of each sentence (Berninger, 1994, 1998; Berninger & Richards, 2002). Turning words in print into meaning requires the use of language abilities, as well as the accessing of knowledge bases that store knowledge of the meanings of words and phrases, and knowledge bases that store knowledge about the topic that the sentence is addressing. Depending on what the words are attempting to communicate, extracting meaning from what is being read also may require the use of reasoning to understand more fully what is being read and/or visual–spatial abilities to “see” what is being read (Dehaene, 2009). Reading also involves the three time frames of reference in varying degrees. The words on the page must be initially registered in the immediate moment; knowledge of words in print and their meanings must be retrieved from long-term storage; and the longer the passage being read, the greater the need to hold and manipulate what is being read in working memory. Finally, all of this mental activity must be cued, directed, and integrated through the use of multiple executive functions working in a coordinated manner (Berninger & Richards, 2002; McCloskey & Perkins, 2012; McCloskey, Perkins, & Van Divner, 2009).

where production is poor within a particular academic domain, the assessment process must determine the extent to which each cognitive construct is capable of performing its role during functioning within that domain.

When contemporary intelligence tests are considered in light of the conceptual model presented in Box 39.1 and the context of diagnostic assessment, it is apparent that such tests consist of multiple tasks, each of which represents a complex amalgam of many of the constructs described in the cognitive neuropsychological model. At the same time, however, the ways in which the tasks are combined are not consistent with the cognitive models depicted in Figures 39.2–39.5. This lack of alignment with the academic domain models greatly reduces or completely nullifies their usefulness in the diagnostic process (Alfonso, Flanagan, & Radwan, 2005). The primary reason for this state of affairs is the fact that the development of contemporary intelligence tests has been dictated primarily by the general abilities model rather than by the cognitive neuropsychological model.

The statistical techniques (predominantly factor analysis) used to organize intelligence test tasks into composites for interpretation based on a general abilities model often obscure the distinctions necessary for effective understanding and interpretation of the cognitive constructs that an individual may use to complete these tasks (Flanagan & Kaufman, 2009; Hale & Miller, 2008; Hale et al., 2008; McCloskey, 2009a, 2009b; McCloskey & Maerlender, 2005; McCloskey et al., 2017). Table 39.1 illustrates the obfuscation created by the general abilities model: It examines the cognitive constructs required to perform tasks that have been aggregated to form a general ability composite. The inadequacy of the general abilities model for diagnostic purposes becomes even clearer when the general ability composites are disaggregated into their component subtests and the additional subtests within each composite domain (Watkins, Glutting, & Youngstrom, 2005). Table 39.2 aligns the subtests of multiple intelligence tests with the

cognitive construct components of the cognitive neuropsychological model as applied to each of the basic academic domains. As reflected in Table 39.2, the most frequently used intelligence tests in school settings involve very few of the cognitive constructs related to performance in all four academic domains. Because the intelligence tests in use today have been based on a general abilities model rather than a cognitive neuropsychological model, they are not well suited to the diagnostic process at the heart of psychoeducational assessment in the schools, especially as it occurs at tier 3 (Mather & Wendling, 2005).

INTELLECTUAL ASSESSMENT IN THE CONTEXT OF THREE-TIERED SERVICE DELIVERY SYSTEMS

Three-tiered service delivery systems emphasize the need for appropriate instruction, assessment, and intervention at varying levels of intensity. Assessment at tier 1 typically involves the administration of brief progress-monitoring instruments at regular benchmark intervals to all students in general education. These brief assessments may be administered more frequently to students who do not make progress at the expected levels and/or rates. Students who continue to lag behind despite efforts to alter instruction are referred for tier 2 services. At tier 2, progress-monitoring assessment efforts continue, typically on a more frequent basis than at tier 1. In some instances, diagnostic assessments of some processes and skills are conducted to try to pinpoint a student's academic difficulties more specifically, and to identify interventions that might be more likely to enable the student to succeed. Students who continue to struggle at tier 2 for a prolonged period of time despite multiple efforts to alter instructional approaches are referred for a comprehensive assessment before either their assignment to instruction at tier 3 or their return to tier 2 services with a more specific plan for intervention efforts (Berninger, 1998; Berninger, O'Donnell, & Holdnack, 2008).

Although the results of the assessment may not lead to special education placement, a tier 3 assessment is accompanied by a host of requirements and stipulations associated with federal laws governing consideration of a student for special education placement (including receipt of written permission from the parents allowing an intellectual assessment to be conducted, and a specific time frame within which the assessment must be completed after permission has been received). The nature of a tier 3 referral makes it imperative that the student's specific cognitive strengths and weaknesses, and their impact on learning and production, be clearly specified. As noted previously, although an intellectual assessment guided by the general abilities model may be helpful in identifying overall intellectual capacity, the use of global and specific composites does not enable the level of specificity of cognitive strengths and weaknesses required in a tier 3 assessment.

The need for more specific information about a child's pattern of cognitive construct strengths and weaknesses associated with one or more specific academic domains makes the cognitive neuropsychological model a better fit for selection and interpretation of assessments at tier 3. As mentioned previously, however, contemporary intelligence tests are not well suited to the needs of a tier 3 assessment within the context of a cognitive neuropsychological model. This is because modern-day intelligence tests do not sufficiently assess many of the cognitive constructs involved in academic learning and production. Psychologists conducting assessments at tier 3 need to incorporate tasks from a broader array of cognitive test batteries in order to effectively assess all of the cognitive constructs associated with one or more academic domains (Berninger, Dunn, & Alper, 2005; Decker, 2008; Hale, Kaufman, Naglieri, & Kavale, 2006; Volker, Lopata, & Cook-Cottone, 2006). Table 39.3 provides examples of the types of tasks from other cognitive tests that could be incorporated into diagnostic assessment work at tier 3.

The utility of an intellectual assessment has been questioned, even at tier 3 (Reschly & Grimes, 2002). If psychologists persist in relying solely on a general abilities model for interpretation of test results, criticisms of the use of intellectual assessments at tier 3 are likely to continue because of the lack of relevance of the findings to the diagnostic process necessitated at tier 3. Application of a cognitive neuropsychological model at tier 3, however, is likely to steer psychologists away from the use of traditional intellectual assessments in favor of tests that offer more specific information about the cognitive constructs involved in academic learning and production. This will create the potential for more meaningful assessments, which in turn can improve intervention selection (Decker, 2008).

The critical differences between the general abilities model and the cognitive neuropsychologi-

cal model are most apparent when they are applied to the concept of learning disabilities. As shown in Figure 39.6, current models of learning disabilities—such as those discussed by Hale and Fiorello (2004) and by McCloskey (2009a)—look significantly different, depending on the model applied in the interpretation of intellectual assessment results. In the general abilities model, the contrast between a global composite score obtained from an intellectual assessment and scores from academic skill measures is central to the identification of a learning disability. In contrast, the cognitive neuropsychological model incorporates at most only a few subtest level scores or clinically meaningful composite cluster scores from an intellectual assessment and supplements these with cognitive measures of processing, abilities, knowledge bases, executive functions, memory time frame use, and academic skills measures based on the constellation of academic difficulties exhibited by the student (Berninger et al., 2005).

Applying the General Abilities Model in a Three-Tiered System

When the general abilities perspective is applied across all three levels of a three-tiered system, the focus is on predicting which students are likely to succeed and which are likely to fail. At tiers 1 and 2, the progress-monitoring devices serve as the predictors of the students' later competencies in the academic domains. The need for intellectual assessment at these tiers is typically not even considered, since the progress-monitoring devices are serving as the predictors during the early stages of service delivery. Even at tier 3, the need for an intellectual assessment is questioned when the purpose of such an assessment is the prediction of later academic success. At best, such an assessment at tier 3 offers an indicator of potential for later success from a longer, more reliable intellectual assessment source. In school systems where instruction at tiers 1 and 2 is not particularly strong, many students are referred for what is per-

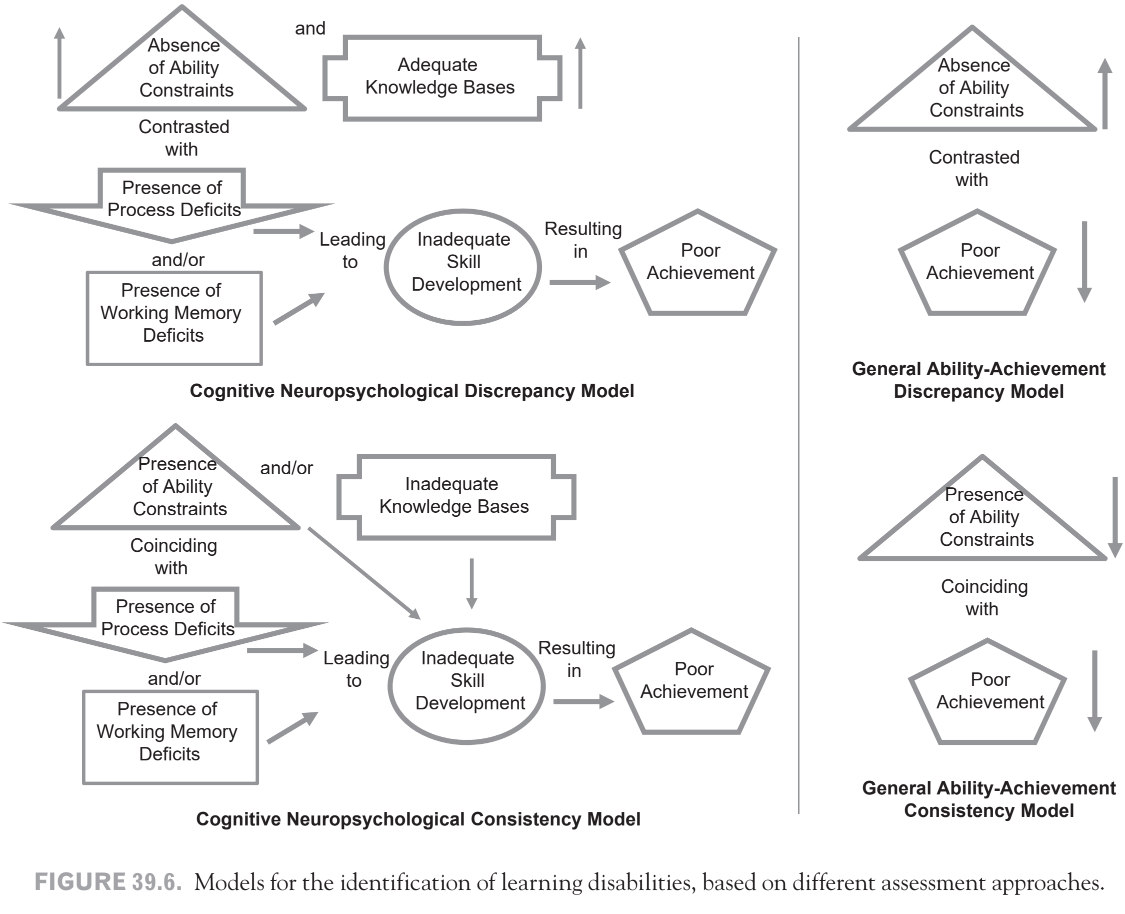

FIGURE 39.6. Models for the identification of learning disabilities, based on different assessment approaches.

ceived as a meaningless intellectual assessment at tier 3, simply because it is mandated as part of the process for consideration for placement in special education and for access to some types of tier 3 services. Whether those services are any better than the supports being provided at tiers 1 and 2 seems irrelevant, as the assessment process merely seems to function as a catalyst for moving a student out of the instructional environments at these tiers and into a tier 3 instructional environment. It should not be surprising that psychologists balk at being involved in such a process and bemoan their role as that of "gatekeepers for special education," with little or no relevance to the educational process other than to specify an arbitrary numerical cutoff for discrepancy between actual achievement and predicted achievement, on the basis of which it will be determined whether the student is or is not placed in a tier 3 special education program (Reschly & Grimes, 2002).

Applying the Cognitive Neuropsychological Model in a Three-Tier System

When a cognitive neuropsychological model is applied, the focus is on characterizing students' cognitive strengths and weaknesses, appreciating how these strengths and weaknesses affect learning and production, and understanding how instruction can be modified to improve learning and production. The need for this type of information is apparent at all three tiers. When assessments directly address these needs, parents, teachers, and administrators grasp the value of a comprehensive assessment for students who are struggling academically—not simply for placement in a tier 3 program, but for identifying instructional practices that are most likely to improve learning and production. Although the services of psychologists who competently use a cognitive neuropsychological model may be desired at all three tiers, it is neither possible nor practical to provide every struggling student with a comprehensive assessment. It may, however, be possible to administer to additional students at tier 2 a brief diagnostic battery that addresses most of the cognitive constructs in the cognitive neuropsychological models associated with the specific academic area of concern. This type of assessment would, at times, necessitate the involvement of psychologists in general education assessment below tier 3. The reason for this involvement rests with the need to administer some tasks, such as those involving reasoning with verbal information, that have traditionally been administered only by a psychologist in the context of a comprehensive intellectual assessment. Such diagnostic assessment activity could open the door for academic consultation services that would have an impact on a larger number of students, providing that the psychologist is well trained in diagnostic assessment and research-based instructional programs (Berninger et al., 2005).

The Contrast between the Two Models

With the emphasis on prediction of academic skill levels based on global intellectual assessment results, the general abilities model has little to offer school-based professionals who must identify a student's specific pattern of cognitive strengths and weaknesses and recommend interventions most likely to increase academic skill proficiency. Conversely, the cognitive neuropsychological model can offer a wealth of information about the extent to which a student can effectively process information during initial registration and create adequate mental representations; apply abilities and access knowledge bases; hold, manipulate, store, and/or retrieve mental representations; and use academic skills—all cued, directed, and coordinated by executive functions in order to demonstrate adequate academic production. How knowledge of these cognitive constructs can affect educational programming for students is illustrated by the six case profiles presented in Table 39.4. All of these elementary-school-age students were referred for evaluations by teachers or parents because of suspected reading difficulties. Comparing and contrasting the six cases provides some important insights related to assessment and intervention for reading problems and their relationship to what has traditionally been defined as intellectual ability:

1. The greater the number of process, ability, knowledge base, executive function, and memory time frame weaknesses identified, the greater the number of reading skill weaknesses, and the poorer the overall level of reading achievement.
2. Although students may be diagnosed with the same type of reading problem, their specific patterns of cognitive strengths and weaknesses may vary greatly, thereby necessitating different intervention plans.
3. The amount of time and energy invested, and the diversity of intervention techniques that

must be employed will vary in proportion to the number of cognitive construct weaknesses identified.

To illustrate these points, consider the first three cases provided in Table 39.4, all of which display the cognitive construct characteristics of *developmental phonological dyslexia* (DPD) (Berninger & Richards, 2002; Dehaene, 2009; Shaywitz, 2003; Temple, 1997; Uhry & Clark, 2005). Although the processing profiles of these students look similar, the case 1 student exhibits fewer reading skill and reading achievement weaknesses because she is able to effectively employ her well-developed executive functions, reasoning and language abilities, strategies, knowledge bases, and working memory time frame—all of which enable her to compensate for (but not completely eradicate) her word-level reading disability.

The case 2 student exhibits difficulties with more reading skills and inconsistent performance with reading achievement, stemming from the presence of additional weaknesses in the use of executive functions to consistently cue the use of strategies and skills. Note, for example, the additional weaknesses in word recognition fluency and silent reading/comprehension fluency that reflect an inability to balance speed and accuracy, resulting in a quick work pace that is countered by excessive word-reading error rates. Note also that the weakness in use of strategies is not due to an overall lack of knowledge of word- or sentence-level reading strategies, but rather to a failure to cue the use of these learned strategies when reading individual words and sentences (McCloskey et al., 2009; Meltzer, 2010; Swanson, 1993).

The case 3 student exhibits basic reading skill and executive function weaknesses similar to those of the case 2 student, but the additional weaknesses in the use of the working memory time frame experienced by this student are creating difficulties with the more complex skill of reading comprehension, and subsequently are resulting in poorer performance on measures of reading achievement (Berninger & Richards, 2002; Swanson, 1999, 2008).

The critical importance of assessing abilities and knowledge bases that constrain the act of reading—constructs typically classified as intellectual abilities—becomes more evident when the first three cases (involving only DPD) are contrasted with the next three cases, in all of which the students exhibit weaknesses in reasoning with verbal information and poor stores of word knowledge and general knowledge. For this reason, these students are designated in Table 36.4 as exhibiting an *ability deficit (AD)*. The absence of any processing deficits in the case 4 student, combined with adequate use of executive functions to direct basic word reading and effective use of the working memory time frame, have enabled this student to develop basic reading skills at the word level. At the same time, however, the student's ability and knowledge base weaknesses are constraining the development of reading comprehension skills at the sentence and passage levels, and are resulting in poor performance on measures of reading achievement.

The case 5 student exhibits ability and knowledge base weaknesses similar to those of the case 4 student, but these are compounded by a phonological processing weakness that is impacting the development of decoding skills and performance on fluency measures due to poor use of decoding skills in a manner similar to that of the case 1 student. Unlike that student, however, this student is exhibiting weaknesses with reading comprehension and poor performance on reading achievement measures, due to weaknesses in reasoning ability and word knowledge. Note that although this student has not stored an adequate amount of knowledge about words and topics related to school, he can adequately recall information that actually has been stored.

The case 6 student exhibits reasoning ability and knowledge base weaknesses similar to those of the students in cases 4 and 5, but these are joined by weaknesses in receptive and expressive language abilities, phonological and orthographic processing, and oral–motor functioning, as well as weaknesses in executive functions and inadequate use of all three time frames of reference. The consequent effect on reading is evident in the display of weaknesses for all reading skills and extremely poor performance on measures of reading achievement.

In terms of classification, recommendations for intervention, and outlook for improvement, the advantages of the use of a cognitive neuropsychological model over a general abilities model are unequivocal and numerous. The general abilities model would merely specify that an ability–achievement discrepancy exists for the first three students (those with DPD only), and that an ability–achievement consistency exists for the other three students (those with AD or AD/DPD). The cognitive neuropsychological model offers a richer context for understanding the nature of the reading problems in each of these six cases by specifying levels of performance with tasks involving the full array of cognitive constructs involved in the act of reading. As a result, each child's specific pattern of cognitive strengths and weaknesses can effectively be used to specify the nature and number of interventions required, as well as the intensity of the intervention efforts needed to improve reading skills.

In terms of intervention, the case 1 student represents the least degree of difficulty, as supplemental instruction in decoding skills will most likely be sufficient to address the reading skills deficits of this third-grade student (National Reading Panel [NRP], 2000; Shaywitz, 2003; Uhry & Clark, 2005). The case 2 student will also require supplemental instruction in decoding skills, but in addition, the executive function difficulties and failure to use learned strategies for word reading and comprehension will need to be addressed through guided practice in their use when the student is reading sentences and paragraphs. Gradually (likely over the course of 1 or more years), instruction will need to move from guided practice to self-regulated practice in using executive functions to cue and direct word reading and comprehension skill use. Intervention efforts with this third-grade student will be more challenging and will require more time than those for the case 1 student, and progress is likely to be slower (McCloskey et al., 2009; Swanson, 1993).

The case 3 student will benefit from supplemental interventions similar to those provided for the case 2 student, but will require additional instructional strategies to compensate for poor use of the working memory time frame (Swanson, 1999, 2008). Note that the interventions outlined briefly here relate to supplemental instruction and are not intended to be complete replacements for all elements of a balanced literacy curriculum. All three of these students will need to receive instruction focused on vocabulary, comprehension, and fluency development, but the cognitive strengths of these students should enable them to benefit from general education instruction related to these components of the reading curriculum (NRP, 2000). Because of the students' age, the phonological processing deficits they exhibit are not addressed directly. Instead, the decoding instruction provided reflects a compensation for weak phonological processing (Aylward et al., 2003).

The case 4 student (the one with AD only) represents a very different challenge in terms of intervention because the reading skill weaknesses demonstrated by this student do not stem from deficits in processing, executive functions, strategy use, or memory time frame use, but rather are results of the student's ability and knowledge base weaknesses. For the two students with AD/DPD (cases 5 and 6), interventions must take into account deficits in processing, executive functions, strategy use, and memory time frame use, and the associated specific reading skill deficits in a manner similar to that described for each of the three students with DPD (cases 1–3). Like case 4, cases 5 and 6 are much more challenging because these students exhibit concomitant deficits in reasoning ability, word knowledge, and general knowledge that are constraining reading comprehension (Berninger & Richards, 2002). Intervention efforts, therefore, will need to be greater in number and will require greater amounts of time devoted to remediation. Given the severity and number of deficits that each of these students exhibits, intensified intervention efforts are still likely to require long periods of time.

It is important to note that the cognitive construct deficits that distinguish the three students with AD or AD/DPD from the three students with DPD only are the cognitive constructs that have traditionally been associated with intellectual assessment (i.e., cognitive abilities and knowledge bases). The intervention challenges presented by the students in cases 4–6 are at the heart of a fundamental ideological debate about intelligence: Do intelligence test scores based on tasks involving reasoning with verbal information and descriptions of word meanings represent innate, immutable intellectual traits or acquired, malleable cognitive constructs? Some psychologists point out that such scores combine very different cognitive constructs that are better addressed individually (Hale & Fiorello, 2004; Hale & Miller, 2008; McCloskey, 2009a, 2009b; McCloskey et al., 2017). Others assert that vocabulary represents a crystallized knowledge base that can be increased through academic instruction or self-directed learning, but that reasoning with verbal information represents a more fluid ability and is much more difficult to alter through academic instruction (Flanagan & Kaufman, 2009; Lichtenberger & Kaufman, 2009; McGrew, 2000). Strict adherents of a general abilities model ignore the differences between the two tasks and espouse the view that the composite represented by the combination of these tasks represents a core of relatively innate immutable verbal ability, or *g* (Gottfredson, 1998; Jensen, 1973, 1998).

When the issue of intervention is raised, however, proponents of a general ability model and most adherents of a cognitive neuropsychological model tend to believe that tasks that involve reasoning with verbal information and describing the meaning of words are representative of innate, immutable traits. Regardless of which model guides the interpretation of intellectual assessments, reports we have reviewed typically do not provide specific recommendations for interventions focused on improving vocabulary knowledge and/or improving reasoning with verbal information. In other words, these constructs tend to be viewed as innate abilities rather than teachable skills. The tendency to view the tasks that are combined to form verbal ability composites as representative of unitary traits have led some to ignore or deny the role that reasoning with verbal information plays in the development of reading comprehension skills (Fletcher, Lyon, Fuchs, & Barnes, 2007).

Proponents of this viewpoint could correctly point out that no specific, well-researched intervention curriculum has been developed that enables educators to raise the reasoning ability of a student from two standard deviations below the mean to the mean within any reasonable amount of time. This fact fuels the argument that reasoning (whether innate or conditioned) should be discounted as an instructional variable, or even as a source of variability in skill performance, in teaching for acquisition of reading skills. Although no specific intervention program for quickly and dramatically improving reasoning deficits exists at this time, a number of instructional techniques and specific teaching exercises designed to increase reasoning with verbal information have been developed and have been used to improve the academic achievement of students in grades K–12 (Dean, Hubbell, Pitler, & Stone, 2013; Marzano, Pickering, & Pollock, 2001; Sternberg & Grigorenko, 2007). Likewise, teaching strategies and techniques have been developed and used with good results to improve students' vocabulary knowledge and subsequently to raise students' reading achievement levels (Dean et al., 2013; Marzano et al., 2001; NRP, 2000). What these instructional techniques are doing, in essence, is reinforcing the idea that a word knowledge lexicon can be built through academic instruction. Most importantly, such strategies serve to advance the idea that reasoning ability can be reframed as a teachable skill.

In order for improvement in reading comprehension skill acquisition and increased scores on reading achievement measures to occur, intervention efforts must attempt to address the reasoning and word knowledge deficits of the three students with AD (cases 4–6) depicted in Table 39.4, and of all other children with similar cognitive construct weaknesses who are currently enrolled in our K–12 schools. This discussion serves to highlight the most important distinction between the general abilities model and the cognitive neuropsychological model: The general abilities model locks the door of opportunity for further cognitive growth by perpetuating the belief that intelligence is an innate, immutable trait, whereas the cognitive neuropsychological model opens the door of opportunity for further cognitive growth by advancing the belief that intelligence represents a multifaceted set of cognitive constructs that are malleable and teachable given the appropriate investment of energy, time, and effort by all stakeholders—students, parents, and educators.

SUMMARY AND CONCLUSIONS

This chapter has described and contrasted two models that can be used to guide the use and interpretation of intellectual assessments. Although the general abilities model may be useful in specific situations where overall level of ability is a central factor in educational programming, the cognitive neuropsychological model holds much greater promise for fulfilling the important diagnostic role of identifying patterns of cognitive strengths and weaknesses and their relationships to intervention programming, especially for students with specific learning disabilities and AD. Additionally, the cognitive neuropsychological model appears much better equipped to address assessment needs in the context of the three-tiered service delivery systems that have become more prevalent in U.S. schools. The assessment demands in school settings necessitate a shift away from a narrow general abilities model focused on predicting achievement. Such a model avoids addressing or highlighting the specific cognitive constructs that may be constraining or impeding academic production; confines interpretation to one or a handful of composite scores; and limits perspectives on intervention by espousing a model that implies that intelligence is an innate, immutable trait.

Assessment practices in today's schools ought to encompass a much broader perspective. The cognitive neuropsychological model provides a means to accomplish this objective by enabling clinicians to assess a broad array of cognitive constructs, which can then be interpreted within the context of their role in learning and production in specific academic domains. Moreover, the model facilitates the linkage of assessment results to a broad array of intervention efforts. The need for a paradigm shift in assessment practices is reflected in the Learning Disabilities Association of America's white paper on learning disability identification (Hale et al., 2010), which advocates for the assessment and consideration of patterns of cognitive strengths and weaknesses in identification and treatment of learning disabilities.

Although contemporary intellectual assessments are not well suited to meeting these specific assessment needs in the schools, some of the requisite instrumentation is currently available through various specific cognitive tests of processing, abilities, knowledge bases, executive functions, memory time frames of reference, and academic skills. Ideally, the shift to a cognitive neuropsychological model would necessitate the development of new cognitive test batteries that directly address the broad array of cognitive constructs specifically involved in listening/speaking, reading, writing, and math.

Psychologists must make a choice about their role in the use of assessment instruments in the future. To effectively implement a cognitive neuropsychological model such as the one described in this chapter, psychologists working in the schools will need to have a thorough grasp of cutting-edge assessment instrumentation and intervention techniques in reading, writing, and math, in order to diagnose academic problems and to recommend interventions most likely to produce skill growth. Although the field of school psychology generally claims expertise in this academic skill domain (National Association of School Psychologists, 2006), many school psychologists acknowledge a lack of adequate knowledge in these areas, and some other professionals question whether psychologists really have the knowledge to be involved in such work (Kirby, 2009). If psychologists choose to continue emphasizing the use and interpretation of traditional intelligence tests through the lens of the general abilities model, and if they continue to approach AD and knowledge base deficits as immutable and irremediable traits, then they may find it increasingly difficult to break out of a meaningless test-and-place model of assessment. Indeed, they may find that their services are no longer needed, as they are being replaced by a cadre of other professionals competently trained in the use and interpretation of a host of processing, ability, and skill tests that are directly related to learning and production in academic domains but do not have the word *intelligence* in their titles.

Alternatively, psychologists can choose to expand their repertoire of assessment skills, incorporating cognitive measures of processing, skills, knowledge bases, abilities, executive functions, and memory time frames of reference with the occasional handful of intelligence test subtests to provide assessment results that can drive intervention efforts. They can become the leading proponents of a movement to change reasoning ability into a teachable skill, can develop expertise in academic intervention programs, and can attain mastery in linking assessment results with intervention practices. Concurrently, psychologists can encourage test publishers to increase their efforts to develop more germane cognitive neuropsychological test batteries—ones that directly relate to learning and production in the various academic domains.

Regardless of the choices made by psychologists working in the schools, we predict that the future of assessment belongs to cognitive assessment guided by a cognitive neuropsychological model, rather than to intellectual assessment guided by a general abilities model. If the next edition of this text is titled *Contemporary Cognitive Assessment*, then the accuracy of this prediction will be apparent.
